H1 and HSE FOUNDATION Fieldbus User Application Layer • H1 FOUNDATION Fieldbus • HSE FOUNDATION Fieldbus • Open Systems Implementation

41.4 Conclusions

Salvatore Cavalieri
University of Catania, Faculty of Engineering

41.1 Introduction

FOUNDATION Fieldbus is an all-digital, serial, two-way communication system. Its specification has been developed by the for-no-profit Fieldbus Foundation association [1]. Since its very beginning, FOUNDATION Fieldbus has shown two fundamental and unique (at that time, at least) features: an emphasis on the standardization of the description of the devices to be connected to the fieldbus, and the adoption of the main link access mechanisms (i.e., token-based and centralized ones), which the IEC/ISA fieldbus committee (IEC 61158 and ISA SP50) was trying to derive from the existing proposals within a new and complete solution [2–5].

One of the aims of this chapter is to emphasize the value of the choices made by Fieldbus Foundation association as well as their impact on current features of the FOUNDATION Fieldbus communication system. Furthermore, these features will be described in great detail, allowing the reader to clearly understand the key points of the system.

The chapter is organized into two parts: the first part (Section 2) gives an overview of the principles of FOUNDATION Fieldbus; the second part (Section 3) introduces the main features of this communication system.

41.2 Principles of FOUNDATION Fieldbus

Since the first fieldbus communication systems [6,7] have appeared on the market, the need to achieve just one Fieldbus standard was felt immediately. Over 15 years ago, the International Electro-technical Commission (IEC) and Instrument Society of America (ISA) embarked on a joint standardization effort identified by two codes: 61158 on the IEC side and SP50 on the ISA one. The main aim of the standard committee was the definition of a unique communication system able to merge the main features of the Fieldbuses available on the market: FIP [8] and Profibus [9].

Fieldbus Foundation (note that Fieldbus Foundation refers to the name of the association, while FOUNDATION Fieldbus is used for the relevant communication system [1]), established in 1994 as the result

© 2005 by CRC Press LLC

of a merger between ISP (Interoperable System Project) and WorldFIP North America, has defined a small set of basic principles.
These basic principles included two main cornerstones:

1. The adoption of both the main Medium Access Control (MAC) mechanisms that the IEC/ISA fieldbus committee was trying to derive from the existing proposals within a truly complete solution
2. Emphasis on the standard description of the devices to be connected on the fieldbus.

Cornerstone (1) made Fieldbus Foundation free from the persistent solution issue: "scheduled access vs. circulated token." IEC 61158 Type 1 DLL stated:

Both paradigms, circulated token and scheduled access were good, but insufficient at the same time; they were complementary, not alternative, and a complete fieldbus solution needs the two together [3].

FOUNDATION Fieldbus, since being established, fully adopted an approach to provide both the "predefined scheduling philosophy" of FIP and the "token rotation philosophy" of Profibus. Section3, provides more details about these two fundamental mechanisms.

Cornerstone (2) allowed Fieldbus Foundation to avoid a situation (which affected most of the previous fieldbus proposals) in which, after defining the communication stack, much more still needed to be done in order to make devices operational after being connected to a fieldbus.

In fact, the previous fieldbus proposals started their developments by focusing on the communication aspects (physical media, access mechanisms, addressing, connections, quality of services, etc.). That mostly motivated by the fact that, when switching from a dedicated low-frequency 4–20 mA signal to a multidata high-frequency serial link, the most evident change was relevant to the communication mechanism itself: Was that cable still good? What's the best encoding method? How can we guarantee noise recovery? Will too many data on the same medium affect their timeliness? And so on.

But once the communication aspects were defined and proven, the data, which such communication was able to transfer between two or more devices, did not make those devices able to interoperate.

FOUNDATION Fieldbus had this concept clear in sight since the beginning, and included the definition of data semantic plus their configuration and use within the first set of specifications.

The only aspect that initially Fieldbus Foundation left intentionally "behind" was the higher speed version H2 of Fieldbus. That was mostly because the market addressed by Fieldbus Foundation was relevant to the replacement of existing 4–20 mA devices with the ones compliant with FOUNDATION Fieldbus, trying to reduce as much as possible the relevant costs. This market strategy, chosen in order to make the adoption of the new fieldbus technology easier, could be realized if the already laid-down twisted-pair cables (connecting the old 4–20 mA devices), which support only the slow-speed H1 version, were maintained. This explains why such a strong effort was put in the development of the H1 technology as opposed to the higher speed H2 version of FOUNDATION Fieldbus.

For H2, Fieldbus Foundation initially planned to adopt the IEC/ISA high -speed standard [2], but ultimately decided to use the High-Speed Ethernet (HSE) instead, mainly due to the wide availability of components and the existence of networks in the plants (at least at backbone level).

41.3 Technical Description of FOUNDATION Fieldbus

FOUNDATION Fieldbus is an all-digital, serial, two-way communication system. Foundation Fieldbus specifications include two different configurations: H1 and HSE [1,10]. H1 (running at 31.25 kbit/sec) interconnects "field" equipment such as sensors, actuators, and Inputs/Outputs (I/Os). HSE (running at 100 Mbit/sec) provides integration of controllers (such as DCSs and PLCs), H1 subsystems (via a linking device), data servers, and workstations. HSE is based on standard Ethernet technology to perform its role. In detail:

- The H1 FOUNDATION Fieldbus communication system is mainly devoted to distributed continuous process control and to replacement of existing 4–20 mA devices. Its communication functionalities, specifically foreseen for time critical applications, are supported by services grouped within levels, as in all other OSI-RM open system architectures. The number of levels is minimal, in order

© 2005 by CRC Press LLC

to guarantee maximum speed in data handling. Below the Fieldbus Application Layer, H1 FOUNDATION Fieldbus directly presents the Data Link Layer (DLL) managing access to the communication channel. A Physical Layer deals with the problem of interfacing with the physical medium. A Network and System Management Layer is also present. Figure 41.1 compares the H1 FOUNDATION Fieldbus architecture against the ISO OSI reference model.

- HSE FOUNDATION Fieldbus defines an Application Layer and associated management functions, designed to operate over a standard TCP/UDP/IP stack, over twisted-pair or fiber-optic switched Ethernet. It is mainly foreseen for discrete manufacturing applications, but of course, it can also be used to interconnect H1 segments, as well as foreign protocols through IP/TCP gateways, in order to build complete plant networks. Figure 41.2 compares the HSE FOUNDATION Fieldbus architecture against the ISO OSI reference model.

Looking at Figures 41.1 and 41.2, it becomes evident that the Fieldbus Foundation has specified a User Application Layer, significantly differentiating the solution from the ISO OSI model, which does not define such a layer. The H1 and HSE FOUNDATION Fieldbus User Application Layer is mainly based on Function Blocks, providing a consistent definition of inputs and outputs that allow seamless distribution and integration of functionality from various vendors [11].

H1 and HSE FOUNDATION Fieldbus User Application Layer

As above mentioned, the Fieldbus Foundation has defined a standard User Application Layer based on "Blocks." Blocks are representations of different types of application functions. The types of blocks used

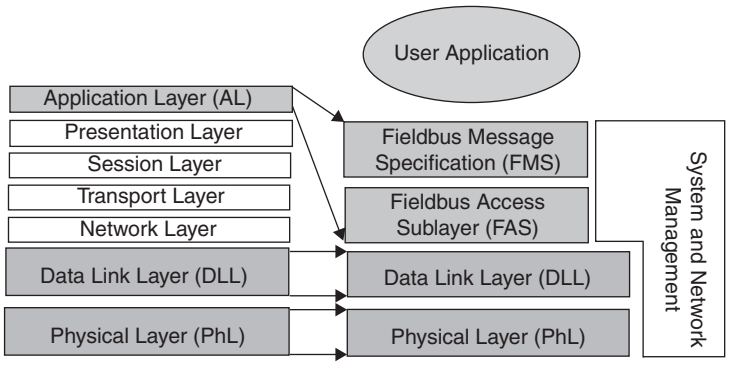

FIGURE 41.1 H1 FOUNDATION Fieldbus vs. ISO OSI Architecture.

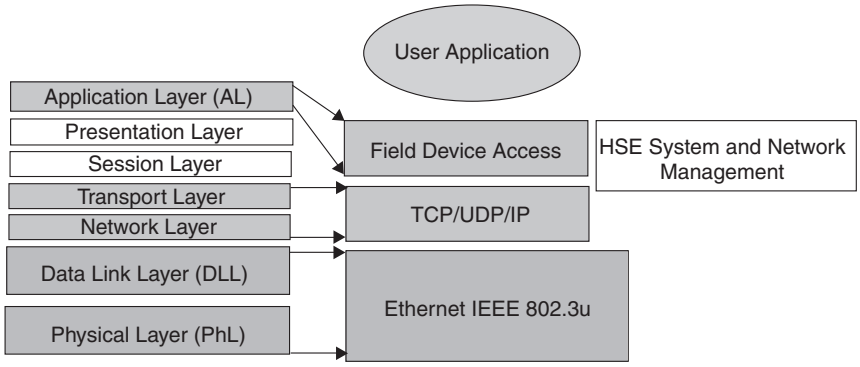

FIGURE 41.2 HSE FOUNDATION Fieldbus vs. ISO OSI Architecture.

© 2005 by CRC Press LLC

in a User Application are Resource, Transducer and Function. Devices are configured by using Resource Blocks and Transducer Blocks. The control strategy is built by using Function Blocks (FBs) [11] instead.

Resource Block

The Resource Block describes characteristics of the fieldbus device such as the device's name, manufacturer, and serial number. There is only one Resource Block in a device.

Function Block

FBs provide the control system behavior. The input and output parameters of FBs running in different devices can be linked over the fieldbus. The execution of each FBs is precisely scheduled. There can be many FBs in a single User Application. The Fieldbus Foundation has defined sets of standard FBs. Ten standard FBs for basic control are defined by the specification in [12]. These blocks are summarized in Table 41.1. Other, more complex, standard FBs are defined by [13, 14].

The Flexible Function Block (FFB) is defined by [15]. An FFB is a user-defined block. FFB allows a manufacturer or user to define block parameters and algorithms to suit an application that interoperates with standard FBs and host systems.

FBs can be built into fieldbus devices as required in order to achieve the desired device functionality. For example, a simple temperature transmitter may contain an AI FB. A control valve might contain a PID FB as well as the expected AO block. Thus, a Complete Control Loop can be built using only a simple transmitter and a control valve (Figure 41.3).

Transducer Blocks

Like the Resource Block, the Transducer Blocks are used to configure devices. Transducer Blocks decouple FBs from the local I/O functionalities required in order to read sensors or to command the actuator's output. They contain information such as calibration date and sensor type [16,17].

TABLE 41.1 Basic FBs

FB Name	Symbol Name
Analog Input	AI
Analog Output	AO
Bias/Gain	BG
Control Selector	CS

H1 Foundation Fieldbus

H1 FOUNDATION Fieldbus is made up of different layers (as shown in Figure 41.1), whose functionalities will be described in the following.

H1 FOUNDATION Fieldbus Physical Layer

The H1 FOUNDATION Fieldbus Physical Layer has been conceived to receive messages from the communication stack in order to convert them into physical signals on the fieldbus transmission medium and vice-versa [18]. Conversion tasks include the adding and removing of preambles, start delimiters, and end delimiters. The preamble is used by the receiver to synchronize its internal clock with the incoming fieldbus signal. The receiver uses the start delimiter to find the beginning of a fieldbus message. After finding the start delimiter, the receiver accepts data until the end delimiter is received.

The Physical Layer is defined by approved standards issued by the IEC and ISA. In particular, the FOUNDATION Fieldbus H1 Physical Layer is the 31.25Kbauds version of IEC(Type 1)/ISA Fieldbus [2,19]. Signals (± 10 mA on 50 Ω load) are encoded using the synchronous Manchester Biphase-L technique and can be conveyed on low-cost twisted-pair cables. The signal is called "synchronous serial" because the clock information is embedded in the serial data stream. Data are combined with the clock signal while creating the fieldbus signal. The receiver of the fieldbus signal interprets a positive transition in the middle of a bit time as a logical "0" and a negative transition as a logical "1." Special codes are defined for the preamble, start delimiter, and end delimiter. Special N+ and N − characters are used in the start delimiter and end delimiter. Note that the N+ and N − signals do not have a transition in the middle of a bit time.

Fieldbus Signalling.
The transmitting device delivers ±10 mA at 31.25 kbit/sec into a 50 Ω equivalent load to create a 1.0 V peak-to-peak voltage modulated on top of the direct current (DC) supply voltage. The DC supply voltage can range from 9 to 32 V. The 31.25 kbit/sec fieldbus also supports Intrinsically Safe (IS) fieldbuses for bus-powered devices. To accomplish this, an IS barrier is placed between the power supply in the safe area and the IS device in the hazardous area. In this case (IS applications), the allowed power supply voltage depends on the barrier rating.

Fieldbus Wiring.
H1 FOUNDATION Fieldbus wiring is based on trunk cables featuring terminators installed at each end. H1 FOUNDATION Fieldbus allows for stubs or "spurs" located anywhere along the trunk, and connected to the trunk by a junction box, as shown by Figure 41.4. A single device can be connected by each spur. Existence of spurs allows that a 31.25 kbit/sec device can operate on wiring previously used for 4–20 mA devices [20,21].

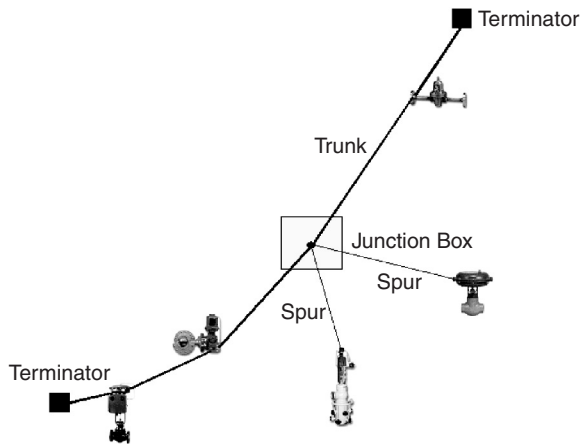

FIGURE 41.4 Trunk, junction box and spurs in H1 FOUNDATION Fieldbus.

© 2005 by CRC Press LLC

More trunks can be connected in a fieldbus link by means of repeaters. Up to five trunks (by means of four repeaters) can be interconnected.

The spur length varies from 1 up to 120 m depending on the number of devices connected to the fieldbus link.

The maximum number of devices on a fieldbus link is 32; the actual number depends on factors such as the power consumption of each device, the type of cable, the use of repeaters, etc. In particular, the maximum number of devices is usually six for IS applications and power delivered through the bus, 12 for non-IS applications but power still delivered through the bus, and 32 for non-IS applications without any power delivered through the bus [22].

The total trunk length (including spurs) is 1900 m and the number of network addresses available for each link is 240.

H1 FOUNDATION Fieldbus DLL

H1 FOUNDATION Fieldbus DLL controls the transmission of messages onto the fieldbus. As already mentioned, FOUNDATION Fieldbus fully adopted the IEC(Type 1)/ISA DLL statement: "Both paradigms, circulated token and scheduled access were good, but insufficient at the same time; they were complementary, not alternative, and a complete fieldbus solution needs the two together" [3,23,24].
Thus, fieldbus needs a good mix of circulated token and scheduled access: well balanced to avoid losing bandwidth for the scheduled access when it is not really needed, but always giving priority to scheduled access over circulated token when a conflict arises.
That is what the IEC(Type 1)/ISA DLL documents propose, and FOUNDATION Fieldbus made real: an overall schedule able to guarantee the needed data at the needed time but also allowing gaps within which a circulated token mechanism can take place while complying with a defined maximum rotation time.

Such a philosophy clearly needs an arbitrator that univocally imposes the transmission of defined data at a defined time by a defined entity, when so required, but also guarantees a defined minimum amount of free time to each entity. This arbitrator is called Link Active Scheduler (LAS) within IEC(Type 1)/ISA and H1 FOUNDATION Fieldbus DLL [3,23,24]. Essentially, LAS performs:

- access to the physical medium on a scheduled basis;
- circulation of the token only when no scheduled traffic is needed; token is passed for a limited amount of time that is always shorter than the interval left before the next scheduled traffic;
- a policy for the management of the token, according to which the token is returned to the LAS instead of passing it onto a new node so that the LAS, depending on the time left, can decide whether to actually pass the token once more or to resume link control to manage the scheduled traffic.

Specific needs of the token mechanism such as

- giving enough contiguous token time to each node and
- guarantee of the most regular, as possible, token rotation time among all the nodes

are granted by the token method of IEC(Type 1)/ISA and H1 FOUNDATION Fieldbus DLL.
Other needs such as

- keeping the token cycle short enough and
- satisfying the occurrence of high-priority events

are substituted by the scheduled access method of IEC(Type 1)/ISA and H1 FOUNDATION Fieldbus DLL.

Device Types.
Two types of devices are defined in the DLL specification: Basic Device and Link Master. Link Master devices are capable of becoming the LAS. Basic Devices do not have the capability to become the LAS.

Scheduled Communication.
The way in which the LAS manages the centralized government is based on the following mechanism. The LAS has a list of transmitting times for all data buffers in all devices that need to be periodically

© 2005 by CRC Press LLC

transmitted. When it is time for a device to send the contents of a buffer, the LAS issues a CD message to the device.

Upon receipt of the CD, the device broadcasts or "publishes" the Data Item (DT) in the buffer to all devices on the fieldbus. Any device configured to receive the data is called a "subscriber". Figure 41.5 shows this access mechanism.

Scheduled data transfers are typically used for the regular, periodic transfer of control loop data between devices on the fieldbus.

Unscheduled Communication.

The federal autonomy of each node is given by a bandwidth distribution mechanism based on the use of a circulating token. In unused portions of the bandwidth (i.e., not occupied by the transmission of CDs), the LAS sends a Pass Token (PT) to each node included in a particular list called "Live List" (described in the following). Each token is associated with a maximum utilization interval, during which the receiving node can use the available bandwidth to transmit what it needs. On the expiration of the time interval or when the node completes its transmissions, the token is returned to the LAS by using another frame called Return Token (RT). A Target Token Rotation Time (TTRT) defines the interval time desired for each token rotation. The value to be assigned to this parameter is linked to the maximum admissible delay in the transmission of the asynchronous flow. Figure 41.6 shows the token circulation managed by the LAS.

Live List Maintenance.

The list of all devices that properly respond to PT is called the "Live List."

New devices may be added to the fieldbus at any time. The LAS periodically sends Probe Node (PN) messages to all the addresses not yet present in the Live List. If a new device appears at an address and receives the PN, it immediately returns a Probe Response (PR) message.

When a device returns a PR, the LAS adds the device to the Live List and confirms its addition by sending the device a Node Activation message.

The LAS is required to probe at least one address after it has completed a cycle of sending PTs to all the devices in the Live List.

The device will remain in the Live List as long as it responds properly to the PTs sent from the LAS.

The LAS will remove a device from the Live List if the device does not reply to the relevant PT for three successive tries.

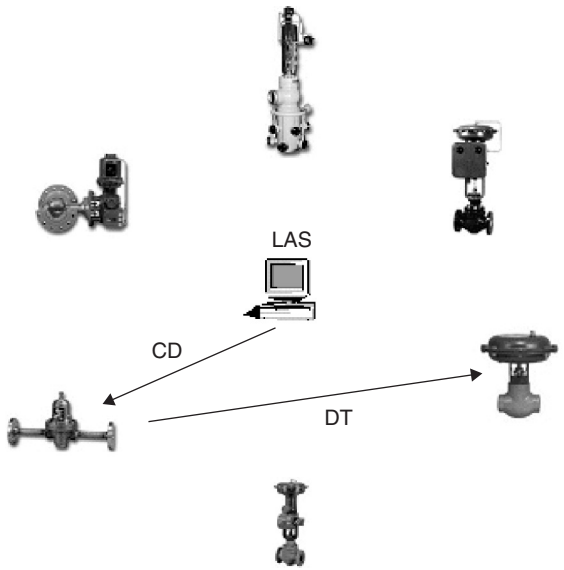

FIGURE 41.5 Centralized access mechanism.

© 2005 by CRC Press LLC

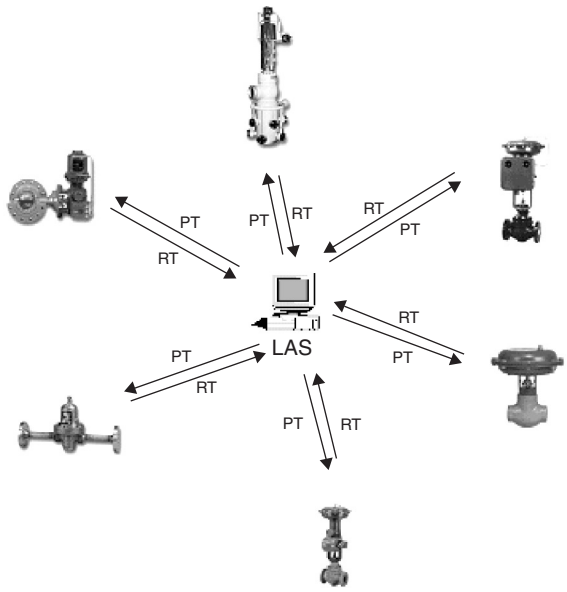

FIGURE 41.6 Token passing mechanism.

Whenever a device is added or removed from the Live List, the LAS broadcasts changes in the Live List to all devices; this allows each Link Master device to maintain a current copy of the Live List in order to be ready to become LAS if needed.

Data Link Time Synchronization.
A DLL time synchronization mechanism is provided so that any node can request the LAS for a scheduled action to be executed at a defined "time" that represents the same absolute instant for all the nodes.

The LAS periodically broadcasts a Time Distribution (TD) message on the fieldbus so that all devices have exactly the same data link time. This is important because scheduled communications on the fieldbus and scheduled FB executions in the User Application Layer are based on timing derived from these messages.

LAS Operation.
The algorithm used by the LAS is shown in Figure 41.7.

LAS Redundancy.
IEC(Type 1)/ISA and H1 FOUNDATION Fieldbus DDL provides the possibility to have more than one potential LAS on each link as well as back-up procedures that are essential for fieldbus availability. In particular, as a fieldbus may have multiple Link Masters, if the current LAS fails, one of the Link Masters will become the LAS and the operation of the fieldbus will continue.

H1 FOUNDATION Fieldbus Application Layer

The H1 FOUNDATION Fieldbus Application Layer includes two sublayers: FAS and FMS [25,26].

Fieldbus Access Sublayer (FAS)
FAS uses both the scheduled and unscheduled features of the DLL to provide services for the Fieldbus Message Specification (FMS) [25].

The type of each FAS service is described by Virtual Communication Relationships (VCR). VCR defines the kind of information (messages) exchanged between two applications. Possible features of the VCR may be the number of receivers (one or many) for each transmitter, memory organization (queue or buffer) used to store the messages to be sent/received, and the DLL mechanism used to send the message (PT or CD).

© 2005 by CRC Press LLC

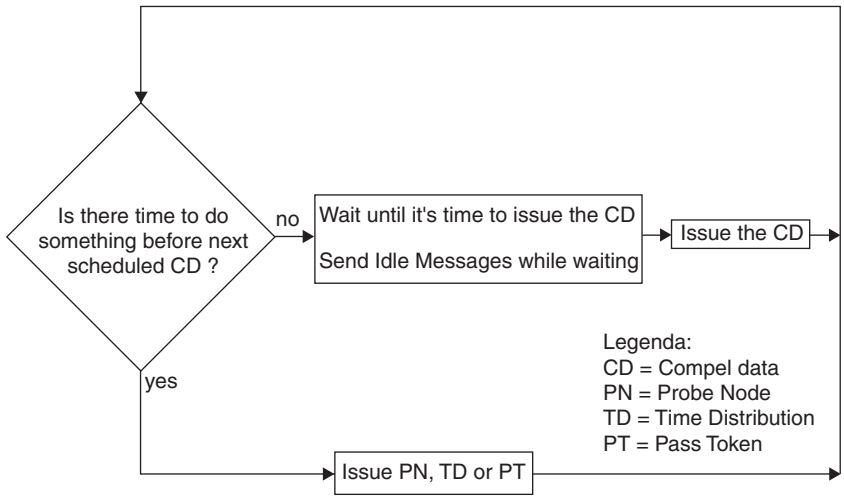

FIGURE 41.7 LAS Algorithm.

The types of VCR defined by Fieldbus Foundation are:

- *Client/Server VCR Type.* The Client/Server VCR Type is used for queued, unscheduled, user-initiated, one-to-one communication between devices on the fieldbus. Queued means that messages are sent and received in the order submitted for transmission, according to their priority, without overwriting previous messages. When a device receives a PT from the LAS, it may send a request message to another device on the Fieldbus. The requester is called the "Client" and the device that received the request is called the "Server." The Server sends the response when it receives a PT from the LAS. The Client/Server VCR Type is used for operator-initiated requests such as setpoint changes, access to and change of a tuning parameter, alarm acknowledgment, and device upload and download.
- *Report Distribution VCR Type.* The Report Distribution VCR Type is used for queued, unscheduled, user-initiated, one-to-many communications. When a device, holding an event or a trend report to send, receives a PT from the LAS, it sends its message to a "group address" defined by its VCR. Devices that are configured to listen for that VCR will receive the report. The Report Distribution VCR Type is normally used by fieldbus devices to send alarm notifications to the operator consoles.
- *Publisher/Subscriber VCR Type.* The Publisher/Subscriber VCR Type is used for buffered, one-to-many communications. Buffered means that only the latest version of the data is maintained within the network. New data completely overwrite previous data. When a device receives Compel Data (CD), the device will "Publish" (broadcast) its message to all devices on the fieldbus. Devices that wish to receive the Published message are called "Subscribers." CD may be scheduled in LAS, or it may be sent by Subscribers on an unscheduled basis. An attribute of the VCR indicates which method is used. The Publisher/Subscriber VCR Type is normally used by the field devices for scheduled publishing of User Application FB inputs and outputs.

Fieldbus Message Specification.

FMS services allow user applications to send messages to each other across the fieldbus by using a standard set of message formats. FMS describes the communication services, message formats, and protocol behavior needed to build messages for the User Application [26].

Data that are communicated over the fieldbus are described by an "object description." Object descriptions are collected together in a structure called an "Object Dictionary" (OD).

© 2005 by CRC Press LLC

The object description is identified by its "index" in OD. Index 0, called the object dictionary header, provides a description of the dictionary itself, and defines the first index for the object descriptions of the User Application. The User Application object descriptions can start at any index above 255. Index 255 and below define standard data types such as boolean, integer, float, bitstring, and data structures that are used to build all other object descriptions.

A "Virtual Field Device" (VFD) is used to remotely view local device data described in the object dictionary. A typical device will have at least two VFDs: the Network and System Management VFD and the User Application VFD. The Network and System Management VFD provides access to the Network Management Information Base (NMIB) and to the System Management Information Base (SMIB). NMIB data include VCR, dynamic variables, statistics, and LAS schedules (if the device is a Link Master). SMIB data include device tag and address information, and schedules for FB execution.

The User Application VFD is used to make the device functions (the function of a fieldbus device is defined by the selection and interconnection of blocks) visible to the fieldbus communication system. The header of the User Application OD points to a Directory which is always the first entry in the FB application. The Directory provides the starting indexes of all of the other entries used in the FB application. The VFD object descriptions and their associated data are accessed remotely over the fieldbus network using VCR.

FMS communication services provide a standard way for user applications, such as FBs, to communicate over the fieldbus. Specific FMS communication services are defined for each object type. Table 41.2 summarizes the communication services available. Detailed descriptions for each service are provided in [26]. All of the FMS services use the Client/Server VCR Type except as noted (see notes 1 and 2 in Table 41.2).

H1 FOUNDATION Fieldbus System Management

Inside H1 FOUNDATION Fieldbus specification, System Management handles important system features [27] such as:

- *Scheduling.* FB must often be executed at precisely defined intervals and in the proper sequence for correct control system operation. System Management synchronizes execution of the FBs to a common time clock shared by all devices. A "macrocycle" is a single iteration of a schedule within a device. According to the type of device, we can have a LAS macrocycle and a device macrocycle. According to the first one, System Management can synchronize execution of the FBs across the entire fieldbus link. On the basis of the device macrocycle, instead, System Management can synchronize execution of FBs inside each device.
- *Application clock distribution.* This function allows publication of the time of day to all devices, including automatic switchover to a redundant time publisher. FOUNDATION Fieldbus supports an application clock distribution function. The application clock is usually set equal to the local time of day or to Universal Coordinated Time. System Management has a time publisher that periodically sends an application clock synchronization message to all fieldbus devices. The data link scheduling time is sampled and sent with the application clock message so that the receiving devices can adjust their local application time. During the intervals between synchronization messages, application clock time is independently maintained within each device relying on its own internal clock.
- *Device address assignment.* Fieldbus devices do not use jumpers or switches to configure addresses. Instead, device addresses are set by configuration tools using System Management services. Every fieldbus device must have a unique network address and physical device tag for the fieldbus to operate properly. To avoid the need for address switches on the devices, assignment of network addresses can be performed by configuration tools using System Management services. The sequence for assigning a network address to a new device is as follows:
  - An unconfigured device will join the network at one of four special temporary default addresses.
  - A configuration tool will assign a physical device tag to the new device using System Management services.

Note:
(1) Service can only use the Publisher/Subscriber or the Report Distribution VCR.
(2) Service can only use the Report Distribution VCR.

  - A configuration tool will choose an unused permanent address and assign it to the device using System Management services.
  - The sequence is repeated for all devices that enter the network at a default address.
  - Devices store the physical device tag and node address in nonvolatile memory, so they will retain these settings also after a power failure.
- *Find Tag Service*. For the convenience of host systems and portable maintenance devices, System Management supports a service for finding devices or variables by a tag search. The "find tag query" message is broadcasted to all fieldbus devices. Upon receipt of the message, each device searches its VFD for the requested tag and returns complete path information (if the tag is found) including the network address, VFD number, VCR index, and OD index. Once the path is known, the host or maintenance device can access the data by its tag.

All of the configuration information needed by System Management such as the FB schedule is described by object descriptions in the Network and System Management VFD. This VFD provides access to the SMIB and also to the NMIB.

H1 FOUNDATION Fieldbus Network Management

H1 FOUNDATION Fieldbus Network Management mainly provides for the configuration of the communication stack [28].

HSE FOUNDATION Fieldbus

HSE FOUNDATION Fieldbus foresees the architecture depicted in Figure 41.2. As shown, its main feature is the use of Internet Architecture (full TCP/UDP/IP and IEEE 802.3u stack [29–31]) for high-speed discrete control and, more generally, for interconnecting several H1 segments in order to achieve a plant-wide fieldbus network [32].

Before describing the HSE FOUNDATION Fieldbus specifications, a brief overview of its general features will be given, with particular emphasis on the capability to interconnect different H1 FOUNDATION Fieldbus segments.

There are four basic HSE device categories (but several of them are typically combined into a single real device): linking device, Ethernet device, host device, and gateway device. A Linking Device (LD) connects H1 networks to the HSE network. An Ethernet Device (ED) may execute FBs and may have some conventional I/O. A Gateway Device (GD) interfaces other network protocols such as Modbus [33], DeviceNet [34], or Profibus [9]. A Host Device (HD) is a non-HSE device capable of communicating with HSE devices. Examples include configurators, operator workstations, and an OPC server.

The network in Figure 41.8 shows a Host System operating on an HSE bus segment labeled Segment A. Communications to H1 segments (B and C, as shown in the figure) are achieved by means of an Ethernet switch. The same switch is used to connect a second HSE segment (D) and a segment running a foreign protocol (segment E).

Any of the devices connected to the switch may attempt communication to any other device and it is the function of the switch to provide the correct routing and to negotiate transmission without collisions.

The connecting mechanism between HSE and H1 segments is performed by an LD. A typical LD will serve multiple H1 segments, although for simplicity only one segment per LD is shown in Figure 41.8. The connection between HSE and a foreign protocol is made through a GD. The capabilities of the interconnections shown in Figure 41.8 are as follows:

- *HSE Host/H1 segment*. The HSE Host interacts with a standard H1 device through an LD. In this situation, the HSE Host is able to configure, diagnose, and publish and subscribe data to or from the H1 device.
- *HSE Host/HSE segment.* The HSE Host interacts with an HSE device and is able to configure, diagnose, and publish and subscribe data to or from the HSE device.
- H1/H1 segment. In this situation, the interaction is between two H1 devices on two distinct H1 bus segments. The segments are connected to the Ethernet by LDs. Communications between devices on two H1 segments are functionally equivalent to communications between two H1 devices on the same bus segment. But it is clear that real-time communication between devices belonging to different H1 segments cannot be guaranteed due to the lack of a unique scheduler of the communication among different H1 segments.
- HSE Host/foreign protocol. This connection defines the relationship between a foreign device and the FOUNDATION Fieldbus application environment. The connection is made by GD. The foreign device is seen as a publisher to an HSE resident subscriber; the HSE host can handle the data stream from the I/O gateway in the same manner as it treats the data streams from devices on H1/HSE segments.

HSE FOUNDATION Fieldbus Physical, Data Link, Network and Transport Layer

As explained before, a higher speed physical layer specification was always intended for selected process applications and for factory (discrete parts) automation. The original high-speed solution, called H2, was based on H1 protocol and FB application running on different media at either 1 Mbit or 2.5 Mbit/ sec.

© 2005 by CRC Press LLC

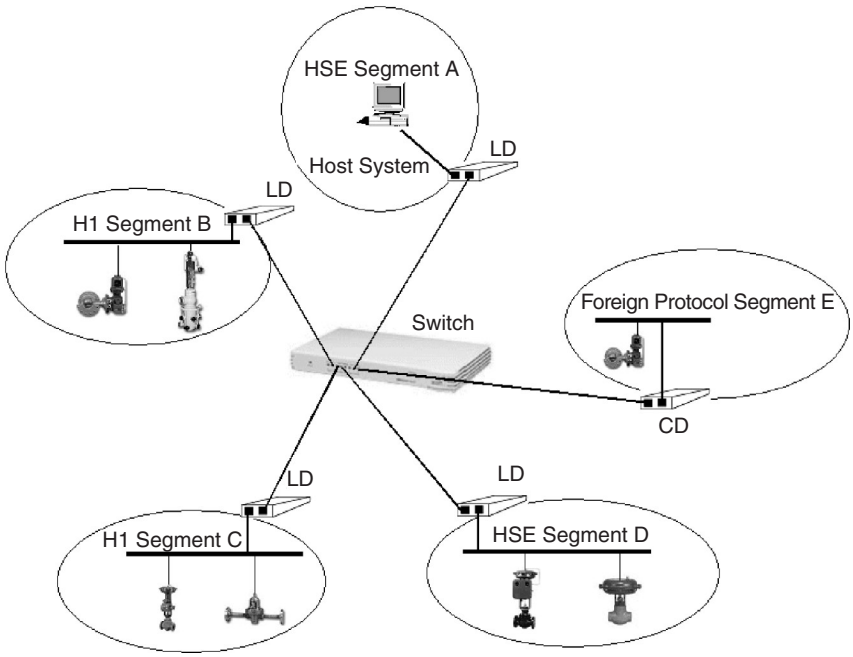

FIGURE 41.8 H1 and HSE FOUNDATION Fieldbus Interconnection.

In March 1998, the Foundation Board of Directors reconsidered the high-speed solution options, and terminated further work on H2. The new approach was based on Ethernet and was intended to make use, as much as possible, of commercially available, off-the-shelf technology (COTS) components and software.

The new solution, HSE, is designed to integrate multiple protocols, including multiple H1 FOUNDATION Fieldbus segments as well as foreign protocols, as described before.

For its high-speed Physical Layer version, Fieldbus Foundation has selected HSE at 100Mbaud. The specifications for the physical layer, as well as for the Ethernet DLL, are maintained by the Institute of Electrical and Electronic Engineers (IEEE) [30,31].

HSE also makes use of well-established internet protocols that are maintained by the Internet Architecture Board. These include Transport Control Protocol (TCP), Unit Datagram Protocol (UDP), and Internet Protocol (IP) [29].

Standard HSE stack components are Distributed Host Configuration Protocol (which assigns addresses), Simple Network Time Protocol (SNTP) and Simple Network Management Protocol (SNMP), which rely on TCP and UDP over IP and the IEEE 802.3 MAC and physical layers.

This has resulted in a practically unlimited number of nodes (IP-addressing) over a star topology network made up of as many links as required, the length of which can be up to 100 m for twisted pair and 2000 m on fiber.

Messages sent on Ethernet are bounded by a series of data fields called frames. The combination of a message and frame is called an Ethernet packet. Typically, a packet encoded according to the TCP/IP protocols will be inserted in the message field of the Ethernet packet.

FOUNDATION Fieldbus uses a similar data structure where messages are bounded by addressing and other data items. What corresponds to a packet in Ethernet is called a Protocol Data Unit (PDU) in FOUNDATION Fieldbus.

Let us consider a communication between two H1 devices over an interposed HSE segment, as illustrated in Figure 41.8. The easiest method for LD might be, upon receiving a communication from an H1 device, to simply insert the entire H1 PDU into the message part of the TCP/IP packet. Then LD on the

© 2005 by CRC Press LLC

destination H1 segment, upon receiving the Ethernet packet, would merely strip away the Ethernet frame and send the H1 PDU on to the receiving H1 bus segment. This technique is called tunneling, and is commonly used in mixed protocol networks.

The solution developed by HSE FOUNDATION Fieldbus is somewhat more complex, but more efficient than tunneling. HSE FOUNDATION Fieldbus PDU is inserted into the data field of a TCP/IP message field. However, the Fieldbus address is encoded as a unique TCP/IP address, so the Fieldbus PDU address is used to fill the address field of the TCP/IP packet. The entire TCP/IP packet is then inserted into the message field of the Ethernet packet. Because of the HSE encoding scheme, networks having multiple LDs can locate and transfer messages to the correct destination much more quickly, with far less extraneous bus traffic, as opposed to tunneling. Perhaps even more important, every H1 device (and every HSE device for that matter) has a unique TCP/IP address and can be directly accessed over standard IT and Internet networks.

HSE FOUNDATION Fieldbus Application Layer

Existing Fieldbus specifications, which have been widely tested in H1 applications and had already been maintained by the Fieldbus Foundation, have been used in the HSE standard too, where applicable. These include FMS and SM (System Management).

New specifications were developed and tested to provide complete high-speed communications and control solutions. The new technology is based on the FDA Agent (Field Device Access Agent) [35].

The FDA Agent allows SM and FMS services used by the H1 devices to be conveyed over the Ethernet using standard UDP and TCP. This allows HSE devices to communicate with H1 devices that are connected via an LD.

The FDA Agent is also used by the local FBs in an HSE device. Thus, the FDA Agent enables remote applications to access HSE devices and/or H1 devices through a common interface.

HSE FOUNDATION Fieldbus System Management

The following aspects of management are supported in the HSE System Management Layer [36]:

- Each device has a unique and permanent identity, and a system-specific configured name.
- Devices maintain version control information.
- Devices respond to requests aiming to locate objects, including the device itself.
- Time is distributed to all devices on the network.
- FB schedules are used to execute FBs.
- Devices are added and removed from the network without affecting other devices on the network.

HSE FOUNDATION Fieldbus Network Management

HSE Network Management allows HSE host systems to perform management operations over the HSE network [37]. The following capabilities are provided by the network management:

- Configuring the H1 Bridge, which performs data forwarding and republishing between H1 interfaces.
- Loading the HSE Session List, or single entries in this list. An HSE Session Endpoint represents a logical communication channel between two or more HSE devices.
- Loading the HSE VCR List, or single entries in this list. An HSE VCR is a communication relationship used for accessing VFDs across HSE.
- Performance Monitoring for Session Endpoints, HSE VCRs, and the H1 Bridge.
- Fault Detection Monitoring.

HSE FOUNDATION Fieldbus Redundancy

HSE FOUNDATION Fieldbus specification provides for the management of redundant network interfaces. This capability protects against single and multiple faults in the network. Each device monitors the

© 2005 by CRC Press LLC

network and selects the "best" route to destination for each message it has to send. HSE provides for various levels of redundancy up to and including complete device and media redundancy. HSE fault tolerance is achieved by operational transparency, that is, the redundancy operations are not visible to the HSE applications. This is necessary because HSE applications are required to coexist with standard Information Technology applications. The HSE LAN Redundancy Entity (LRE) coordinates the redundancy function. Each HSE device periodically transmits on both of its Ethernet interfaces a diagnostic message (representing its view of the network) to the other HSE devices. Each device uses the diagnostic messages to maintain a Network Status Table (NST), which is used for fault detection and transmission port selection. There is no central "Redundancy Manager." Instead, each device determines its behavior in response to the faults it detects [38].

Open Systems Implementation

One of the main features of FOUNDATION Fieldbus (in both H1 and HSE configurations) is the availability to build open communication systems. It is clear that this represents a key issue in a communication system as building up a perfect communication stack between two devices is completely useless if these two devices are not able to understand the meaning of each other's data, nor each other's behavior.

Implementation of open systems is achieved through the use of FBs and the adoption of a standard way to represent them (the Device Description Language [DDL]). FOUNDATION Fieldbus has defined a set of standard FBs Blocks that can be combined and parameterized to build up a device [11]. Due to the standard format, behavior, and connection of such FBs, their access and use through the bus is immediate, allowing to achieve interoperability and interchangeability.

Further, a manufacturer can improve and innovate on an existing FB, creating again a new standard FB.

The solution adopted inside FOUNDATION Fieldbus to realize this has been the DDL able to provide a formal Device Description (DD), which can then be interpreted by the DD Services Library available through FOUNDATION Fieldbus [39–41]. Such DD acts as a "driver" for each specific device and is supplied together with the device itself.

Within each DD, and for each FB included in the device, a hierarchy of definitions is followed: first, the "universal parameters" of the device itself; second, the common parameters of each FB; third, the common parameters of the Transducers Blocks; and fourth, the parameters specific of the manufacturer.

DD may also include small programs able to interoperate with the device (e.g., for its calibration) as well as download capability for managing manufacturer upgrading.

41.4 Conclusions

Fieldbus Foundation so far appears as the only multisupplier organization able to achieve concrete results in proposing a large-scale fieldbus solution merging the initial FIP/Profibus proposals.

This is mainly due to its features providing true device interoperability and a combination of guaranteed scheduling and token rotation.

42.1 Introduction

The history of Controller Area Network (CAN) started more than 20 years ago. At the beginning of the 1980s, a group of engineers at Bosch GmbH were looking for a serial bus system suitable for use in passenger cars. The most popular solutions adopted at that time were considered to be inadequate for the needs of most automotive applications. The bus system, in fact, had to provide a number of new features that could hardly be found in the already existing fieldbus architectures. The design of the new proposal also involved several academics and had the support of Intel, as the potential main semiconductor producer.

The new fieldbus was presented officially in 1986 with the name of "*Automotive Serial Controller Area Network*" at the SAE congress held in Detroit. It was based on a multimaster access scheme to the shared medium that resembled the well-known carrier-sense-multiple-access (CSMA) approach. The peculiar aspect, however, was that CAN adopted a new distributed nondestructive arbitration mechanism to solve contentions on the bus by means of priorities implicitly assigned to the colliding messages. Moreover, the fieldbus specifications also included a number of error detection and management mechanisms to enhance the fault-tolerance of the whole system.

In the following years, both Intel and Philips started to produce controller chips for CAN following two different philosophies. The Intel solution (often referred to as FullCAN in the literature) required less host CPU power, since most of the communication and network management functions were carried out directly by the network controller. Instead, the Philips solution (BasicCAN) was simpler but imposed a higher load on the processor used to interface the CAN controller. Since the mid-1990s, more than 15 semiconductor vendors, including Siemens, Motorola, and NEC, have been producing and shipping millions of CAN chips mainly to car manufacturers such as Mercedes-Benz, Volvo, Saab, Volkswagen, BMW, Renault, and Fiat.

© 2005 by CRC Press LLC

The Bosch specification (CAN version 2.0) was submitted for international standardization at the beginning of the 1990s. The proposal was then approved and published as the ISO 11989 standard [IS898] at the end of 1993 and contained the description of the network access protocol and the physical layer architecture. In 1995, an addendum to ISO 11898 was approved to describe the extended format for the message identifiers also used in CAN. The CAN specification is currently in the process of being revised and reorganized, and has been split into four separate parts: [ISO1, ISO2, ISO3, TTC].

The standard documents provided satisfactory specifications for the lower communication layers but did not offer guidelines or recommendations for the upper part of the OSI protocol stack, in general, and for the application layer in particular. This is why the earlier applications of CAN outside the automotive scenario (i.e., textile machines, medical systems, and so on) adopted "*ad hoc*" monolithic solutions. The "CAN in Automation" (CiA) users' group, founded in 1992, was originally concerned with the specification of a "standard" CAN application layer. This effort led to the development of the general-purpose "CAN Application Layer" (CAL) specification. CAL was intended to fill the gap between the distributed application processes and the underlying communication support; but in practice it was not successful, the main reason being that, as CAL is actually application-independent, each user had to develop a suitable profile based on CAL for his specific application field.

Even though it was conceived for vehicle applications, CAN began to be adopted in different scenarios, too. For instance, at the beginning of the 1990s, Allen-Bradley and Honeywell started a joint distributed control project based on CAN. Although the project was abandoned a few years later, Allen Bradley and Honeywell continued their works separately and focused on the higher protocol layers. The results of these activities were the Allen-Bradley DeviceNet solution and the Honeywell Smart Distributed System (SDS). For a number of reasons, SDS remained, in practice, an internal solution to Honeywell Microswitch, while DeviceNet was soon switched to "Open DeviceNet Vendor Association" and was widely adopted in a number of U.S. factory automation areas, thus becoming a serious competitor to widespread solutions such as Profibus-DP and Interbus.

Besides DeviceNet and SDS, other significant initiatives were focused on CAN and its application scenarios. CANopen was conceived in the framework of the European Esprit project ASPIC by a consortium led once again by Bosch GmbH. The purpose of CANopen was to define a profile based on CAL, which could support communications inside production cells. The original CANopen specifications were further refined by CiA and were released in 1995. Later, both CANopen and DeviceNet became European standards and are now widely used, especially in two different areas, that is, factory automation and machine-distributed controls.

42.2 CAN protocol basics

The CAN protocol architecture is structured according to the layered approach of the ISO OSI model. However, as in most of the currently existing networks conceived for use at the field level in the automated manufacturing environments, only a few layers have been considered in its protocol stack. This is to make implementations more efficient and inexpensive. Few protocol layers, in fact, imply reduced processing delays when receiving and transmitting messages and simpler communication software.

The CAN specification [ISO1], in particular, includes only the *physical* and the *data link* layers, as depicted in Figure 42.1. The physical layer is aimed at managing the effective transmission of data over the communication support, and tackles the mechanical, electrical, and functional aspects. Bit timing and synchronization, in particular, belong to this layer.

The data link layer, instead, is split into two separate sublayers: the *medium access control* (MAC) and the *logical link control* (LLC). The purpose of the MAC entity is basically to manage the access to the shared transmission support by providing a mechanism aimed at coordinating the use of the bus, so as to avoid unmanageable collisions. The functions of the MAC sublayer include frame encoding and decoding, arbitration, error checking and signaling, and also fault confinement. The LLC sublayer, instead, offers the user (i.e. the application programs running in the upper layers) a proper interface, which is

© 2005 by CRC Press LLC

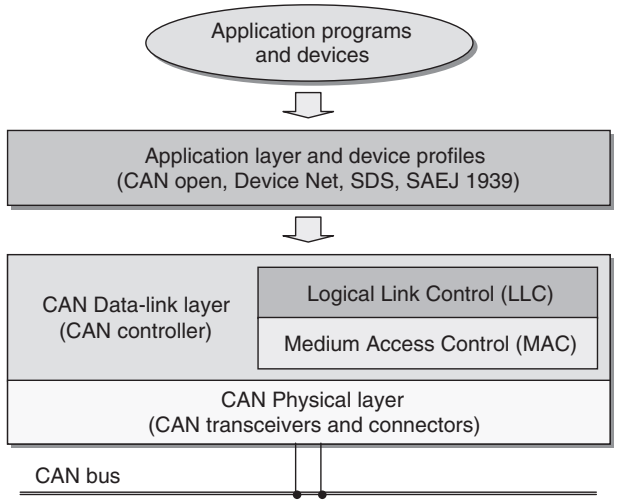

FIGURE 42.1 CAN protocol stack.

characterized by a well-defined set of communication services, in addition to the ability to decide whether an incoming message is relevant or not to the node.

It is worth noting that in CAN, there is considerable flexibility both in terms of the implementation of the LLC services and also in terms of the choice of the physical support, whereas there can be no modifications to the behavior of the MAC sublayer.

Unlike most fieldbus networks, the CAN specification does not include any native application layer. However, a number of such protocols exist that rely on CAN and ease the design and the implementation of complex CAN systems.

Physical layer

The features of the physical layer of CAN that are valid for any system, such as those related to the physical signaling, are described in the ISO 11898-1 document [ISO1]. Instead, the medium access units (i.e. the transceivers) are defined in two separate documents, namely ISO 11898-2 [ISO2] and ISO 11898-3 [ISO3] for high-speed and low-speed communications, respectively. The definition of the medium interface (i.e. the connectors) is usually covered in other documents.

Network topology

CAN networks are based on a shared bus topology. Buses have to be terminated at each end with resistors (the recommended nominal impedance is 120 Ω), so as to suppress signal reflections. For the same reason, the standard documents state that the topology of a CAN network should be as close as possible to a single line. Stubs are permitted for connecting devices to the bus, but their length should be as short as possible. For example, at 1 Mb/s the length of a stub must be shorter than 30 cm.

Several kinds of transmission media can be used:

- Two-wire bus, which enables differential signal transmissions and ensures reliable communications. In this case, a shielded twisted pair can be used to further enhance the immunity to electromagnetic interferences.
- Single-wire bus, a simpler and cheaper solution that features lower immunity to interferences and is mainly suitable for use in automotive applications.
- Optical transmission medium, which ensures complete immunity to electromagnetic noise and can be used in hazardous environments. Fiber optics are often adopted to interconnect (through repeaters) different CAN subnetworks. This is done to cover plants that are spread over a large area.

© 2005 by CRC Press LLC

Several bit rates are available for the network, the most adopted being in the range from 50 kb/s to 1 Mb/s (the latter value represents the maximum allowable bit rate according to the CAN specifications). The maximum length of the CAN bus depends directly on the bit rate. The exact relation between these two quantities also involves parameters such as the delays introduced by transceivers and opto-couplers. Generally speaking, the mathematical product between the length of the bus and the bit rate is approximately constant. For example, the maximum extension allowed for a 500 kb/s network is about 100 m, and it increases up to about 500 m when a bit rate of 125 kb/s is considered.

Repeaters can be used to increase the network extension, especially when large plants have to be covered and the bit rate is low to medium. However, they introduce additional delays on the communication paths; hence, the maximum bus length is effectively shortened at high bit rates. Using repeaters also achieves topologies different from the bus (trees or combs, e.g.). In this case, a good design may increase the effective area that is covered by the network.

It is worth noting that, unlike other field networks, such as, for example, Profibus-PA, there is in general no cost-effective way in CAN to use the same wire for both the signal and the power supply.

Curiously enough, connectors are not standardized by the CAN specification. Instead, several higher-level application standards define their own connectors and pin assignment. CiA DS102 [DS102], for example, foresees the use of a SUB-D9 connector, while DeviceNet and CANopen also suggest the use of either 5-pin mini-style, micro-style, or open-style connectors.

Bit encoding and synchronization

In CAN, the electrical interface of a node to the bus is based on an open-collector-like scheme. As a consequence, the level on the bus can assume two complementary values, which are denoted symbolically as *dominant* and *recessive*. Usually, the dominant level corresponds to the logical value 0, while the recessive level coincides with the logical value 1.

CAN relies on the *non-return to zero* (NRZ) bit encoding, which features very high efficiency in that synchronization information is not encoded separately from the data. Bit synchronization in each node is achieved by means of a *digital-phase locked loop* (DPLL), which extracts the timing information directly from the bit stream received from the bus. In particular, the edges of the signal are used for synchronizing the local clocks, so as to compensate tolerances and drifts of the oscillators.

To provide a satisfactory degree of synchronization among the nodes, the transmitted bit stream should include a sufficient number of edges. To do this, CAN relies on the so-called *bit stuffing* technique. In practice, whenever five consecutive bits at the same value (either dominant or recessive) appear in the transmitted bit stream, the transmitting node inserts one additional stuff bit at the complementary value, as depicted in Figure 42.2. These stuff bits can be easily and safely removed by the receiving nodes, so as to obtain the original stream of bits back.

From a theoretical point of view, the maximum number of stuff bits that may be added is one every 4 bits in the original frame; hence, the encoding efficiency can be as low as 80% (see e.g., the rightmost part of Figure 42.2, where the original bit stream alternates sequences of four consecutive bits at the dominant level followed by four bits at the recessive level). However, the influence of bit stuffing in real operating conditions is noticeably lower than the theoretical value computed above. Simulations show that, on average, only 2 to 4 stuff bits are effectively added to each frame, depending on the size of the identifier and data fields.

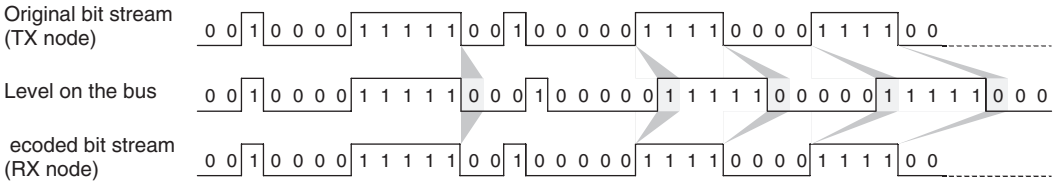

FIGURE 42.2 Bit stuffing technique.

© 2005 by CRC Press LLC

Not all the fields in a CAN frame are encoded according to the bit stuffing mechanism: in particular, it applies only to the parts of the frames from the SOF bit up to the CRC sequence. The remaining fields, instead, are of fixed form and are not stuffed.

Frame format

The CAN specification [ISO1] defines both a standard and an extended frame format. These formats mainly differ in terms of the size of the identifier field and in terms of some other bits in the arbitration field. In particular, the standard frame format (which is also known as CAN 2.0A format) defines an 11-bit identifier field, which means that up to 2048 different identifiers are available to the applications executing in the same network (several older CAN controllers, however, only support identifiers in the range from 0 to 2031). The extended frame format (identified as CAN 2.0B), instead, assigns 29 bits to the identifier, so that up to half a billion different objects could exist (in theory) in the same network. This is a fairly high value, which is virtually sufficient for any kind of application.

Using extended identifiers in a network that also includes 2.0A compliant CAN controllers usually leads to unmanageable transmission errors, which effectively make the network unstable. Thus, a third category of CAN controllers was developed, known as 2.0B passive: they manage in a correct way the transmission and the reception of CAN 2.0A frames, while CAN 2.0B frames are simply ignored.

It is worth noting that, in most practical cases, the number of different objects allowed by the standard frame format is more than adequate. Since standard CAN frames are shorter than the extended ones (because of the shorter arbitration field), they permit a higher communication efficiency (unless part of the payload is moved into the arbitration field). As a consequence, they are adopted in most of the existing CAN systems, and also most of the CAN-based higher layer protocols, such as CANopen and DeviceNet, basically rely on this format.

The CAN protocol foresees only four kinds of frames: *data*, *remote*, *error,* and *overload* frames. Their format is described in detail in the following text.

Data frame

Data frames are used to send information over the network. Each data frame in CAN begins with a *start of frame* (SOF) bit at the dominant level, as shown in Figure 42.3. Its role is to mark the beginning of the frame, as in serial transmissions carried out by means of conventional UARTs. The SOF bit is also used to synchronize the receiving nodes.

Immediately after the SOF bit, there is the arbitration field, which includes both the *identifier* and the *remote transmission request* (RTR) bit. As the name suggests, the identifier field identifies-uniquely on the whole network-the content of the frame that is being exchanged. The identifier is also used by the MAC sublayer to detect and manage the priority of the frame, which is used whenever a collision occurs (the lower the numerical value of the identifier, the higher the priority of the frame).

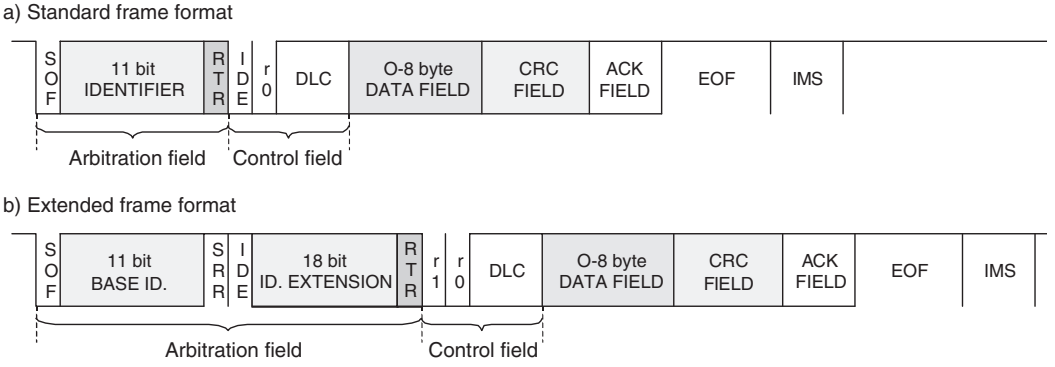

FIGURE 42.3 Format of data frames.

© 2005 by CRC Press LLC

The identifier is sent starting from the most up to the least significant bit. The size of the identifier is different for the standard and the extended frames. In the latter case, the identifier has been split into an 11-bit base identifier and an 18-bit extended identifier, so as to provide compatibility with the standard frame format.

The RTR bit is used to discriminate between data and remote frames. Since a dominant value of RTR denotes a data frame while a recessive value stands for a remote frame, the data frames have a higher priority than remote frames, if the same identifier is considered.

Next to the arbitration field comes the control field. In the case of standard frames, it includes the *identifier extension* (IDE) bit, which discriminates between standard and extended frames, followed by the reserved bit r0. Instead, in the extended frames the IDE bit effectively belongs to the arbitration field, as well as the *substitute remote request* (SRR) bit — a placeholder that is sent at recessive value to preserve the structure of the frames. In this case, the IDE bit is followed by the identifier extension and then by the two reserved bits r1 and r0. After the reserved bits, there is the *data length code* (DLC), which specifies — encoded on 4 bits — the length (in bytes) of the data field. Since the IDE bit is dominant in the standard frames while it is recessive in the extended ones, when the same base identifier is considered standard frames have precedence over extended frames.

Reserved bits r0 and r1 must be sent by the transmitting node at the dominant value. Receivers, however, will ignore the value of these bits. For the DLC field, values ranging from 0 to 8 are allowed. Higher values (from 9 to 15) can be used for application-specific purposes. In this case, however, the length of the data field is meant to be 8. The data field is used to store the effective payload of the frame. In order to ensure a high degree of responsiveness and minimize the priority inversion phenomenon, the size of the data field is limited to 8 bytes at most.

After the data field, there are the CRC and the acknowledgement fields. The former field is composed of a *cyclic redundancy check* sequence encoded on 15 bits, which is followed by a CRC delimiter at the recessive value. The kind of CRC adopted in CAN is particularly suitable to cover short frames (i.e. counting less than 127 bits). The acknowledgement field, instead, is composed of two bits, that is to say the ACK slot followed by the ACK delimiter. Both of them are sent at the recessive level by the transmitter. The ACK slot, however, is overwritten with a dominant value by each node that has received the frame correctly (i.e. no error was detected up to the ACK field). It is worth noting that, in this way, the ACK slot is actually surrounded by two bits at the recessive level, that is to say the CRC and ACK delimiters. By means of the ACK bit, the transmitting node is enabled to discover whether at least one node in the network has received its frame correctly.

At the end of the frame, there is the *end of frame* (EOF) field, composed of seven recessive bits, which notifies the end of an error-free transmission to the nodes. In particular, the transmitting node assumes that the frame has been exchanged correctly if no error is detected until the last bit of the EOF field, while in the case of receivers the frame is valid if there are no errors until the sixth bit of EOF.

Different frames are interleaved by the *intermission* (IMS), which consists of three recessive bits and effectively separates consecutive frames exchanged on the bus.

Remote frames

Remote frames are very similar to data frames. The only difference is that they carry no data (i.e. the data field is not present in this case). They are used to request that a given frame be sent on the network by a remote node. It is worth noting that the requesting node does not know who is the producer of the related information. It is up to the receivers to discover the one that has to reply.

The DLC field in remote frames is not used by the CAN protocol. However, it is set to the same value as the corresponding data frame, so as to cope with the situations where several nodes send remote requests with the same identifier at the same time (this is legal in a CAN network). In this case, it is necessary for the different requests to be perfectly identical, so that they will overlap in the case of a collision.

It should be noted that, because of the way the RTR bit is encoded, if a request is made for an object at the same time as the transmission of that object is started by the related producer, the contention is resolved in favor of the data frame.

Error frames

Error frames are used to notify the nodes in the network that an error has occurred. They consist of two fields: *error flag* and *error delimiter*. There are two kinds of error flag: the active error flag is composed of six dominant bits, while the passive error flag consists of six recessive bits. An active error flag violates the bit stuffing rules or the fixed-format parts of the frame that is currently being exchanged; hence, it enforces an error condition that is detected by all the other stations connected to the network. Each node that detects an error condition transmits an error flag on its own. In this way, following the transmission of an error flag, there can be from 6 to 12 dominant bits on the bus.

The error delimiter, instead, is composed of eight recessive bits. After the transmission of an error flag, each node starts sending recessive bits and, at the same time, it monitors the bus level until a recessive bit is detected. At this point, the node sends seven more recessive bits, thus completing the error delimiter.

Overload frames

Overload frames can be used by the slow receivers to slow down operations on the network. This is done by adding an extra delay between consecutive data and/or remote frames. Their format is very similar to the error frames. In particular, it is composed of an overload flag followed by an overload delimiter. It is worth noting that today's CAN controllers are very fast and so they make the overload frame almost useless.

Access technique

The medium access control mechanism on which CAN relies is basically the *carrier sense multiple access* (CSMA). When no frame is being exchanged, the network is idle and the level on the bus is recessive. Before transmitting a frame, the nodes have to observe the state of the network. If the network is idle, the frame transmission begins immediately; otherwise, the node must wait for the current frame transmission to end. Each frame starts with the SOF bit at the dominant level, which informs all the other nodes that the network has switched to the busy state.

Even though very unlikely, it may happen that two or more nodes start sending their frames exactly at the same time. This is actually possible, in that the propagation delays on the bus — even though very small — are anyway greater than zero. Thus, one node might start its transmission while the SOF bit of another frame is already traveling on the bus. In this case, a collision will occur. In CSMA networks that are based on collision detection, such as, for example, nonswitched Ethernet, this unavoidably leads to the corruption of all the frames involved, which means that they have to be retransmitted. The consequence is a waste of time and a net decrease of the available bandwidth. In high-load conditions, this may lead to congestion: when the number of collisions is so high that the net throughput on the Ethernet network falls below the arrival rate, the network becomes stalled.

Unlike Ethernet, CAN is able to resolve the contentions in a deterministic way, so that neither time nor bandwidth is wasted. Therefore, congestion conditions can no longer occur and the entire theoretical system bandwidth is effectively available for communications.

For the sake of truth, it should be stated that contentions in CAN occur more often than one may think. In fact, when a node that has a frame to transmit finds the bus busy or loses the contention, it waits for the end of the current frame exchange and, immediately after the intermission has elapsed, it starts transmitting. Here, the node may compete with other nodes for which, in the meanwhile, a transmission request has been issued. In this case, the different nodes synchronize on the falling edge of the first SOF bit that is sensed on the network.

This implies that the behavior of a CAN network is effectively that of a network-wide distributed transmission queue where messages are selected for transmission according to a priority order.

Bus arbitration

The most distinctive feature of the medium access technique of CAN is the ability to resolve in a deterministic way any collision that should occur on the bus. In turn, this is made possible by the arbitration mechanism, which effectively finds out the most urgent frame each time there is a contention for the bus.

© 2005 by CRC Press LLC

The CAN arbitration scheme allows the collisions to be resolved by stopping the transmissions of all the frames involved except the one that is characterized by the highest priority (i.e., the lowest identifier). The arbitration technique exploits the peculiarities of the physical layer of CAN, which conceptually provides a wired-and connection scheme among all the nodes. In particular, the level on the bus is dominant if at least one node is sending a dominant bit or, vice versa, the level on the bus is recessive if all the nodes are transmitting recessive bits.

By means of the so-called *binary countdown* technique, each node — immediately following the SOF bit — transmits the message identifier serially on the bus, starting from the most significant bit. When transmitting, each node checks the level observed on the bus against the value of the bit that is being written out. If the node is transmitting a recessive value whereas the level on the bus is dominant, the node understands that it has lost the contention and withdraws immediately. In particular, it ceases transmitting and sets its output port to the recessive level so as not to interfere with the other contending nodes. At the same time, it switches to the receiving state so as to read the incoming (winning) frame.

The binary countdown techniques ensure that, in the case of a collision, all the nodes that are sending lower priority frames will abort their transmissions by the end of the arbitration field, except for the one that is sending the frame characterized by the highest priority (it should be noted that the winning node does not even realize that a collision has occurred). This implies that no two nodes in a CAN network can be transmitting messages related to the same object (that is to say, characterized by the same identifier) at the same time. If this is not the case, in fact, unmanageable collisions could take place, which, in turn, cause transmission errors. Because of the automatic retransmission feature of the CAN controllers, this will lead almost certainly to a burst of errors on the bus, until the stations involved are disconnected by the fault confinement mechanism. This implies that, in general, only one node can be the producer of each object.

One exception to this rule is given by the frames without a data field, such as, for example, the remote frames. In this case, should a collision occur among frames with the same identifier, they overlap perfectly and hence no collision effectively occurs. The same is also true for data frames that have a nonempty data field, provided that the content of this field is the same for all the frames sharing the same identifier. However, it makes no sense in general to send frames with a fixed data field.

All the nodes that lose the contention have to retry the transmission as soon as the exchange of the current (winning) frame ends. They will all try to send their frames again immediately after the intermission is read on the bus. Here, a new collision could take place that also involves the frames sent by the nodes for which a transmission request was issued while the bus was busy.

An example that shows the detailed behavior of the arbitration phase in CAN is outlined in Figure 42.4. Here, three nodes (that have been indicated symbolically as A, B, and C) start transmitting a frame at the same time (maybe at the end of the intermission following the previous frame exchange over the bus). As soon as a node understands it has lost the contention, it switches its output level to the recessive value, so

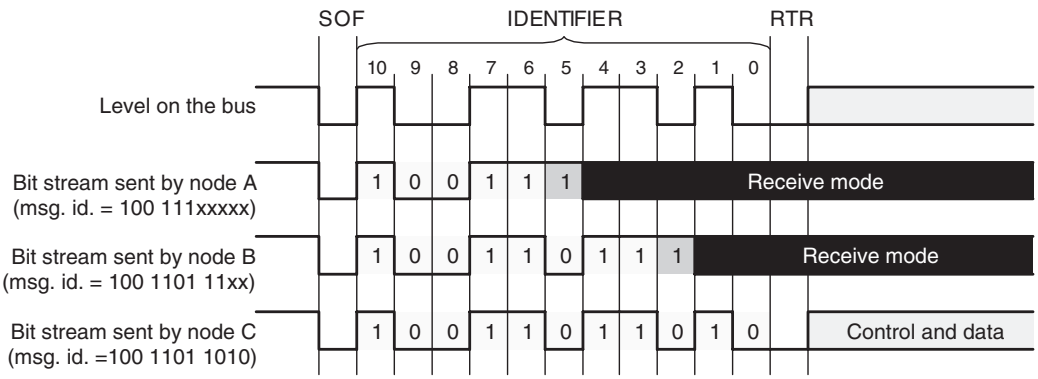

FIGURE 42.4 Arbitration phase in CAN.

© 2005 by CRC Press LLC

that it no longer interferes with the other transmitting nodes. This event takes place when bit ID_5 is being sent for node A, while for node B this happens at bit ID_2. Node C manages to send the entire identifier field, and then it can continue transmitting the remaining part of the frame.

Error management

One of the main requirements that was fundamental in the definition of the CAN protocol was the need to have a communication system characterized by high robustness, that is, a system that is able to detect most of the transmission errors. Hence, particular care has been taken in defining error management.

The CAN specification foresees five different mechanisms to detect transmission errors:

1. *Cyclic redundancy check*: When transmitting a frame, the originating node adds a 15-bit-wide CRC to the end of the frame itself. Receiving nodes reevaluate the CRC to check if it matches the transmitted one. Generally speaking, the CRC used in CAN is able to discover up to five erroneous bits distributed arbitrarily in the frame or errors bursts including up to 15 bits.
2. *Frame check*: The fixed-format fields in the received frames can be easily tested against their expected value. For example, the CRC and ACK delimiter as well as the EOF field have to be at the recessive level. If one or more illegal bits are detected, a form error is generated.
3. *Acknowledgement check*: The transmitting node checks whether the ACK bit has been set to the dominant value in the received frame. On the contrary, an acknowledgement error is issued.
4. *Bit monitoring*: Each transmitting node compares the level on the bus against the value of the bit that is being written. Should a mismatch occur, an error is generated. This does not hold for the arbitration field or the acknowledgement slot. Such an error check is very effective to detect local errors that may occur in the transmitting nodes.
5. *Bit stuffing*: Each node verifies whether the bit stuffing rules have been violated in the portion of the frames from the SOF bit up to the CRC sequence. In the case when 6 bits of identical value are read from the bus, an error is generated.

The residual probability that a corrupted message is not detected in a CAN network — under realistic operating conditions — has been evaluated and is found to be about 4.7×10^{-11} times the frame error rate or less.

Fault confinement

To avoid a node that is not operating properly sending repeatedly corrupted frames, thus blocking the entire network, a fault confinement mechanism has been included in the CAN specification. The fault confinement unit supervises the correct operation of the related MAC sublayer and, should the node become defective, it disconnects that node from the bus.

The fault confinement mechanism has been conceived to discriminate, as long as it is possible, permanent failures from short disturbances that may cause burst of errors on the bus. According to this mechanism, each node can be in one of the three following states:

- Error active
- Error passive
- Bus off

Error-active and error-passive nodes take part in the communication in the same way. However, they react to the error conditions differently. They send active error flags in the former case and passive error flags in the latter. This is because an error-passive node has already experienced several errors, and hence it should avoid interfering with the network operations (a passive error flag, in fact, does not corrupt the ongoing frame exchange).

The fault confinement unit uses two counters to track the behavior of the node with respect to the transmission errors, and they are known as *transmission error count* (TEC) and *receive error count* (REC).

© 2005 by CRC Press LLC

The rules by which TEC and REC are managed are actually quite complex. However, they can be summarized as follows: each time an error is detected, the counters are increased by a given amount, whereas successful exchanges decrease them by one. Furthermore, the amount of the increase for the nodes that first detected the error is higher than the nodes that simply replied to the error flag. In this way, it is very likely that the counters of the faulty nodes reach values higher than the nodes that are operating properly, even when sporadic errors due to electromagnetic noise are considered.

When counters exceed the first threshold (127), the node is switched to the error-passive state, so as to try not to affect the network. When a second threshold (255) is exceeded, instead, the node is switched to the bus-off state. At this point, it can no longer transmit any frame on the network, and it can be switched back to the error-active state only after it has been reset and reconfigured.

Communication services

According to the ISO specification [ISO1], the LLC sublayer of CAN provides two communication services only: L_DATA, which is used to broadcast the value of a specific object over the network, and L_REMOTE, which is used to ask for the value of a specific object to be broadcast by the related remote producer. From a practical point of view, these primitives are implemented directly in the H/W by all the currently available CAN controllers.

Model for information exchanges

Unlike most network protocols conceived for use in automated manufacturing environments (which rely on node addressing), CAN adopts object addressing. In other words, messages are not tagged with the address of the destination and/or originating nodes. Instead, each piece of information that is exchanged over the network (often referred to as an *object*) is assigned a unique identifier, which denotes unambiguously the meaning of the object itself in the whole system.

This fact has important consequences in the way communications are carried out in CAN. In fact, identifying the objects that are exchanged over the network according to their meaning rather than the node they are intended for implicitly allows multicasting and makes it very easy for the control applications to manage interactions among devices according to the producer/consumer paradigm.

The exchange of information in CAN takes place according to the three phases shown in Figure 42.5:

1. the producer of a given piece of information encodes and transmits the related frame on the bus (the arbitration technique will transparently resolve any contention that should occur);
2. because of the intrinsically broadcast nature of the bus, the frame is propagated all over the network, and every node reads its content in a local receive buffer;

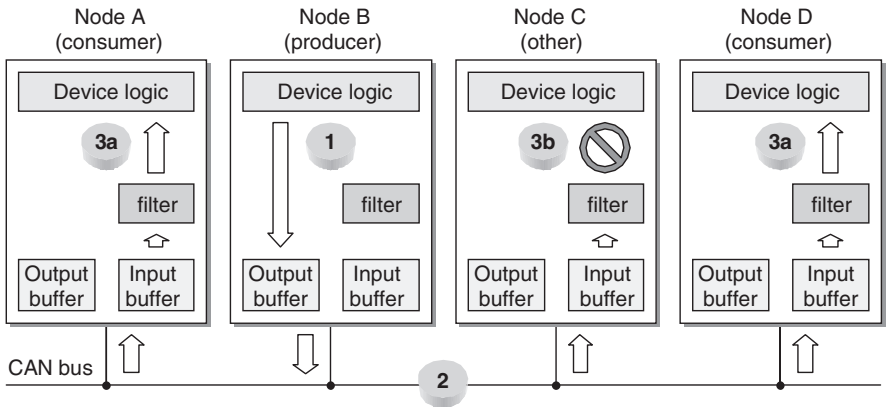

FIGURE 42.5 Producer/consumer model.

© 2005 by CRC Press LLC

3. the *frame acceptance filtering* function (FAF) in each node determines whether or not the information is relevant to the node itself. In the former case, the frame is passed to the upper communication layers (from a practical point of view, this means that the CAN controller raises an interrupt to the local device logic, which will then read the value of the object); on the contrary, the frame is simply ignored and discarded.

In the sample data exchange depicted in Figure 42.5, node B is the producer of some kind of information, which is relevant to (i.e., consumed by) nodes A and D. Node C, instead, is not interested in such data; hence, they are rejected by the filtering function (this is the default behavior of the FAF function).

Model for device interaction

The access technique of CAN makes this kind of network particularly suitable to be used in distributed systems that communicate according to the producer/consumer model. In this case, data frames are used by the producer nodes to broadcast new values over the network, each of which is identified unambiguously by means of its identifier. Unlike the networks based on the producer/consumer/arbiter model such as FIP, information is sent in CAN as soon as it becomes available from either the control applications or the actual system (by means of sensors), without the need for the intervention of a centralized arbiter. This noticeably improves the responsiveness of the whole system.

CAN networks also work equally well when they are used to interconnect devices in systems based on a more conventional master–slave communication model. In this case, the master can use remote frames to ask for some specific information to be remotely sent on the network. The producer of that information, as a consequence of this frame, will reply with a data frame carrying the related object.

It is worth noting that this kind of interaction is implemented in CAN in a fairly more flexible way than in the conventional master–slave networks, such as, for example, Profibus-DP. In CAN, in fact, it is not necessary for the reply (data frame) to follow the request (remote frame) immediately. In other words, the network is not kept busy while the device is trying to send the reply. This allows the entire bandwidth to be theoretically available to the applications. Furthermore, the reply containing the requested value is broadcast on the whole network, and hence it can be read by all the interested nodes, in addition to the one that transmitted the remote request.

42.3 Main features of CAN

The medium access technique on which CAN relies basically implements a nonpreemptive-distributed priority-based communication system, where each node is enabled to compete directly for the bus ownership, so that it can send messages on its own (this means that CAN is a true multimaster system). This can be advantageous for use in event-driven systems.

Advantages

CAN is by far more simple and robust than the token-based access schemes (such as, e.g., Profibus when used in multimaster configurations). In fact, there is no need to build or maintain the logical ring, nor to manage the circulation of the token around the master stations. In the same way, it is noticeably more flexible than the solutions based on the *time division multiple access* (TDMA) or *combined-message* approaches — two techniques adopted by Sercos and Interbus, respectively. This is because message exchanges do not have to be known in advance.

When compared to schemes based on *centralized-polling* such as FIP, finally, it is not necessary to have a node in the network that acts as the bus arbiter, which can become a point of failure of the whole system. Since in CAN all the nodes are masters (at least from the point of view of the MAC mechanism), it is very simple for them to notify asynchronous events, such as, for example, alarms or critical error conditions. In all the cases where this aspect is important, CAN is clearly better than the above-cited solutions.

Thanks to the arbitration scheme, it is certain that no message will be delayed by lower priority exchanges (this phenomenon is known as *priority inversion*). Since the CAN protocol is not preemptive

© 2005 by CRC Press LLC

(as in the case for almost all of the existing protocols), a message can still be delayed by a lower priority one whose transmission has already started. This is unavoidable in any nonpreemptive system. However, as the frame size in CAN is very small (standard frames are 135-bit long at most, including stuff bits), the blocking time experienced by the very urgent messages is in general quite low. This makes CAN a very responsive network, which explains why it is used in many real-time control applications despite its relatively low bandwidth.

The above characteristics have to be considered carefully when assigning identifiers to the different objects that have to be exchanged in distributed real-time control applications. From an intuitive point of view, the most urgent messages (i.e., the messages characterized by the tightest deadlines) should be assigned the lowest identifiers (e.g., identifier 0 labels the message that has the highest priority in any CAN network).

If the period of cyclic data exchanges (and the *minimum interarrival time* of the acyclic ones) is known in advance, a number of techniques based on either the rate monotonic or deadline monotonic approaches have appeared in the literature [TIN], which can be used to find (if it exists) a feasible assignment of identifiers to the objects, so that the resulting schedule is feasible (i.e., the deadlines of all the objects are always respected).

Drawbacks

Even though inherently elegant, the arbitration technique of CAN poses serious limitations in terms of the performances that can be obtained by the network. In fact, in order for the arbitration mechanism to operate correctly, it is necessary for the signal to be able to propagate from a node located at one end of the bus up to the farthest node (at the other end) and come back to the first node before this one samples the level on the bus.

Since the sampling point is located roughly after the middle of each bit (the exact position can be programmed by means of suitable registers), the end-to-end propagation delay, also including the hardware delay of transceivers, must be shorter than about one quarter of the bit time (the exact value depending on the bit timing configuration in the CAN controller).

As the propagation speed of signals is fixed (about 200 m/μsec on copper wires), this implies that the maximum length allowed for the bus is necessarily limited, and depends directly on the bit rate chosen for the network. For example, a 250 kb/s CAN network can span at most 200 m. Similarly, the maximum bus length allowed when the bit rate is selected as equal to 1 Mb/s is 40 m only. This, to some degree, explains why the maximum bit rate allowed by the CAN specifications [ISO1] has been limited to 1 Mb/s.

It is worth noting that this limitation depends on physical factors, and hence it cannot be overcome in any way by advances in the technology of transceivers (to make a comparison, it should be mentioned that, at present, several inexpensive communication technologies are available on the market that allow bit rates in the order of tens or hundreds of Mb/s).

Even though this can appear to be a very limiting factor, it will probably not have any relevant impact in the near future for several application areas — including automotive and process control applications — for which a cheap and well-assessed technology is more important than performance. However, there is no doubt that CAN will suffer in a couple of years from the higher bit rates of its competitors, that is, Profibus-DP (up to 12 Mb/s), Sercos (up to 16 Mb/s), Interbus (up to 2 Mb/s), or the networks based on industrial Ethernet (up to 100 Mb/s). Such solutions, in fact, are able to provide a noticeably higher data rate, which is necessary for the systems that have several devices and very short cycle times (1 msec or less).

Among the possible solutions conceived to enhance the performance of CAN, there is the so-called *time triggered CAN* (TTCAN) protocol [TTC], for which the first chips are becoming available. By adopting a common clock and a time-triggered approach, it is possible to reduce jitters and provide a fully deterministic behavior. If asynchronous transmissions are not allowed in the system (which means that the arbitration technique is not actually used), TTCAN effectively behaves like a TDMA system and thus there is no limitation on the bit rate (which could be increased above the theoretical limit of CAN). However, the behavior of the resulting network is noticeably different from CAN.

© 2005 by CRC Press LLC

Other solutions have appeared in the literature, such as, for example, WideCAN [WCAN], which provide higher bit rates and still rely on the conventional CAN arbitration technique. However, at present, their interest is mainly theoretical.

Implementation

According to the internal architecture, CAN controllers can be classified into two different categories: *BasicCAN* and *FullCAN*.

Conceptually, BasicCAN controllers are provided with one transmit and one receive buffer, as in conventional UARTs. The frame filtering function, in this case, is generally left to the application programs (i.e., it is under the control of the host controller), even though some kind of filtering can be done by the controller. To avoid overrun conditions, a double-buffering scheme based on shadow receive buffers is usually available, which permits a new frame to be received from the bus while the previous one is being read by the host controller. An example of a controller based on the BasicCAN scheme is given by the Philips PCA82C200.

FullCAN implementations, instead, foresee a number of internal buffers that can be configured to either receive or transmit some particular messages. In this case, the filtering function is implemented directly in the CAN controller. When a new frame that is of interest for the node is received from the network, it is stored in the related buffer, where it can then be read by the host controller. In general, new values simply overwrite the previous ones, and this does not lead to an overrun condition (the old value of a variable is superseded by a newer one). The Intel 82526 and 82527 CAN controllers are based on the FullCAN architecture.

FullCAN controllers, in general, free the host controller of a number of activities; hence, they are considered to be more powerful than BasicCAN controllers. It is worth noting, however, that the most recent CAN controllers embed the operating principles of both the above architectures; thus, the above classification is actually in the process of being superseded.

42.4 CAN-based application protocols

To reduce the costs of designing and implementing automated systems, a number of higher-level application protocols have been defined in the past few years, which rely on the CAN data link layer to exchange messages among the nodes (it is worth noting that all the functions of the data link layer of CAN are implemented directly in hardware in the current CAN controllers, which increases the efficiency and reliability of the data exchanges). The aim of such protocols is to provide a usable and well-defined set of service primitives, which can be used to interact in a standardized manner with the field devices.

At present, two of the most widely available solutions for the process control and automated manufacturing environments are CANopen [COP] and DeviceNet [DNET]. Both of them define an object model that describes the behavior of devices. This permits interoperability and interchangeability among devices coming from different manufacturers. In fact, as long as a device conforms to a given profile, it can be used in place of any other device (of a different brand) that adheres to the same profile.

CANopen

CANopen was originally conceived to rely on the communication services provided by the CAN Application layer (CAL). However, the latest specifications [DS301] no longer refer explicitly to CAL. Instead, the relevant communication services have been embedded directly in the CANopen documents.

In CANopen, information is exchanged by means of *communication objects* (COBs). A number of different COBs are foreseen, which are aimed at different functions:

- *process data objects* (PDOs), used for real-time exchanges, such as, for example, information used to control the physical system;

© 2005 by CRC Press LLC

- *service data objects* (SDOs), used for non-real-time communications (i.e., parameterization);
- *emergency objects* (EMCY), used by devices to notify the control application that some error condition has occurred;
- *synchronization object* (SYNC), used to achieve synchronized and coordinated operations in the system, and so on.

Even though the CAN access technique foresees that every node is a master, CANopen systems often rely on a master–slave approach, to simplify system configuration and network management. In most cases, in a CANopen network there is only one application master (which is responsible for actually controlling the operations of the automated system) and up to 127 slave devices (sensors and/or actuators). Each device is identified by means of a unique 7-bit address, called the node identifier, in a range from 1 to 127. The node identifier 0 is used in general for broadcast communications.

Object dictionary

The behavior of any CANopen device is described completely by means of a number of objects, each one tackling a particular aspect related to either the communications on the CAN bus or the available functions to interact with the physical controlled system (e.g., there are objects that define the device type, the manufacturer's name, the hardware and software version, and so on).

All the objects relevant to a given node are stored in the so-called *object dictionary* (OD) of that node. Here, each object is addressed by means of a 16-bit index. Each entry in the OD, in turn, may either be represented by a single value or consist of several components, which are accessible through an 8-bit subindex.

The object dictionary is split into four separate parts, according to the index of the entries. Entries below 1000_H are used to specify data types. Entries from 1000_H to $1FFF_H$, instead, are used to describe communication-specific parameters (i.e., the interface of the device as seen by the CAN network).

Entries from 2000_H to $5FFF_H$ are used by manufacturers to extend the basic set of functions of the device. Their use has to be considered carefully, in that they could make devices no longer interoperable. Finally, entries from 6000_H to $9FFF_H$ are used to describe all the aspects related to a specific category of devices (as defined in a device profile).

Process data objects

All the real-time process data involved in controlling a physical system are exchanged in CANopen by means of PDOs. Each PDO is mapped on exactly one CAN frame, so that it can be exchanged quickly and reliably. As a direct consequence, the amount of data that can be exchanged with one PDO is limited to 8 bytes at most. In most cases, this is more than sufficient to encode an item of process data. According to the *predefined connection set* (a standard assignment of identifiers to COBs), each node in CANopen can define up to four receive PDOs (from the application master to the device) and four transmit PDOs (from the device to the application master).

The transmission of PDOs from the slave devices can be triggered by some local event taking place on the node — including the expiration of some timeout — or it can be remotely requested from the master. This gives system designers a very high degree of flexibility in choosing how devices interact in the automated system, and enables the features offered by intelligent devices to be exploited better.

No additional control information is added to PDOs by CANopen, so that communication efficiency is as high as in CAN. This means that the meaning of each PDO is determined directly by the related identifier. As multicasting is allowed on PDOs, their transmission is unconfirmed, that is, the producer has no way to determine whether or not the PDO has been read by all the intended consumers.

Service data objects

SDOs are used in CANopen for parameterization and configuration, which usually take place at a lower priority than process data (hence, they are effectively non-real-time exchanges). In this case, a confirmed transmission service is provided for the applications, which ensures a reliable exchange of information. Furthermore, SDOs are only available on a peer-to-peer communication basis (multicasting is not allowed in this case).

© 2005 by CRC Press LLC

A fragmentation protocol has been adopted for SDOs — which derives directly from the domain transfer services of CAL — so that information of any size can be exchanged. This means that the SDO sender has to split the information into smaller chunks, which are then reassembled at the receiving side. From a practical point of view, SDOs are used to access the entries of the object dictionary directly, so that they can be read or modified by the configuration tools.

Network management

There are two kinds of functions related to network management: *node control* and *error control*. Node control services are used to control the operation of either a single node or the whole network. For example, they can be used to start/stop nodes, to reset their state, or to put a node in configuration (preoperational) mode. Such commands are definitely time-critical and hence they use the highest priority communication object available in CAN.

Error control services, instead, are used to monitor the correct operation of the network. Two mechanisms are available, that is, *node guarding* and *heartbeat*. In both cases, low-priority messages are exchanged periodically in background over the network by the different nodes. Should one device cease sending these messages, the network management layer is aware of the problem and can take appropriate action.

Device profiles

In order to provide interoperability, a number of device profiles have been standardized in CANopen. Each profile describes the common behavior of a particular class of devices, and is usually described in a separate document. Among the available profiles, there are the following:

- I/O devices [DS401], which include both digital and analog input/output devices.
- Drives and motion control, which is used to describe digital motion products, such as, for example, stepper motors and servo-drives.
- Human–machine interfaces, which describes the use of displays and operator interfaces.
- Measuring devices and closed-loop controllers, to measure and control physical quantities.
- IEC 61131-3 programmable device, for describing the behavior of PLCs and intelligent devices.
- Encoders, which define incremental/absolute linear and rotary encoders to measure both position and velocity, and so on.

DeviceNet

DeviceNet [DNET] is a very flexible protocol to be used at the field level in the automated environments. It is worth noting that the implementation of devices that comply to DeviceNet is, in general, slightly more complex than for CANopen devices. However, DeviceNet offers a number of additional features with respect to CANopen, which can be used, for example, in complex multimaster networks.

In addition to the services at the application level, the DeviceNet specification also defines the physical layer in detail, including aspects such as connectors and cables (thin, thick, and flat cables are foreseen). It should be noted that the cable in DeviceNet can be used for both the signal and power supply (by using four wires plus ground).

Each DeviceNet network can include up to 64 different devices, which means that each node is identified by means of a 6-bit MAC ID. The allowable bit rates are limited to 125, 250, and 500 kb/s, which means that a bus length of at least 100 m is allowed.

Object model

The behavior and functions of each device are described in detail in DeviceNet by means of objects. In particular, three kinds of objects are foreseen, that is to say communication, system, and application-specific objects. Two very important objects are, for example, the connection object, which defines all the aspects related to a connection (including the CAN identifier and the triggering mode), and the application object, which defines the standardized behavior of a class of devices.

© 2005 by CRC Press LLC

Data and services within each device are addressed by means of a hierarchical addressing scheme, which is based on the following components: MAC ID (i.e., the device's address), class ID, instance ID, Attribute ID, and service code. The first four identifiers are usually specified on 8 bits, while the service code is composed of a 7-bit integer.

Communication model

Communication among nodes (either point-to-point or multicast) takes place according to a connection-oriented scheme. By using the standard 11-bit CAN identifier, it is possible to provide an addressing scheme based on four message groups, in a decreasing order of priority:

- message group 1 includes the highest priority identifiers, and permits up to 16 different messages per node;
- message group 2 essentially refers to the predefined master/slave connection set;
- message group 3 is similar to message group 1, but it is composed of low-priority frames; and
- message group 4 is primarily used for network management.

Basically, two kinds of communications are possible: *explicit messages* and *I/O messages*. Explicit messages are used for general data exchanges among devices, such as, for example, configuration, management, and diagnostics. This kind of exchange takes place on the network at a low priority. I/O messages, instead, are used to exchange high-priority real-time messages according to the producer/consumer model.

Because the underlying communication system is based on a CAN network, each frame can include at most 8 bytes. Should one item of data exceed this size, a fragmentation protocol has been defined in DeviceNet that manages message splitting and the successive reassembly.

43.1 Introduction

One of the characteristics of LonWorks® is its unique seven-layer protocol implementation called LonTalk® or LonWorks protocol. Unlike other fieldbus protocols, all seven layers of the ISO/OSI reference model are actually defined and implemented in every single network node. One characteristic is its media-independent OSI Layer 2 that supports various communication media like twisted pair cables, power line communication, radio frequency channel, infrared connections, fiber optic channels, as well as IP connections based on the EIA-852 protocol standard. The basic frame layout for a twisted pair media is illustrated in Figure 43.1 The preamble allows for bit synchronization at the receiver and the start bit (SB) indicates the beginning of the byte boundary. The control field carries information about the importance of the data packet and an estimation about the expected network traffic in the near future. The source address holds the subnet/node address of the transmitting node and the destination address holds the address of the receiving node(s) followed by the user data that can be between 1 and 228 bytes long. Finally, a 16-bit CRC protects the frame from bit errors (Hamming Distance 4) and the code violation (CV) indicates the end of the frame. After the CV, a new round of bus arbitration can take place if nodes have data to be sent over the network [1]. On twisted pair cables, a p-persistent CSMA bus arbitration scheme is used. For other communication channels, for example, IP over Ethernet the arbitration scheme defined for this media is used by the EIA-709 protocol stack.

Another characteristic is its elaborated OSI Layer 3, which supports a variety of different addressing schemes and advanced routing capabilities as shown in Figure 43.2. Every node in the network can be identified with a unique 64-bit physical address (Neuron ID) and with a logical address composed of three address elements: the domain identifier, the subnet number, and the node number. Node numbers can be in the range of 1–127, subnet numbers within 1 and 255; hence, a maximum of 127×255−32,385 nodes

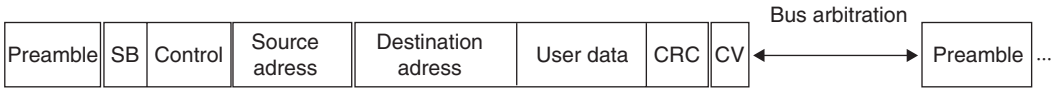

FIGURE 43.1 LonTalk frame layout on a twisted pair cable.

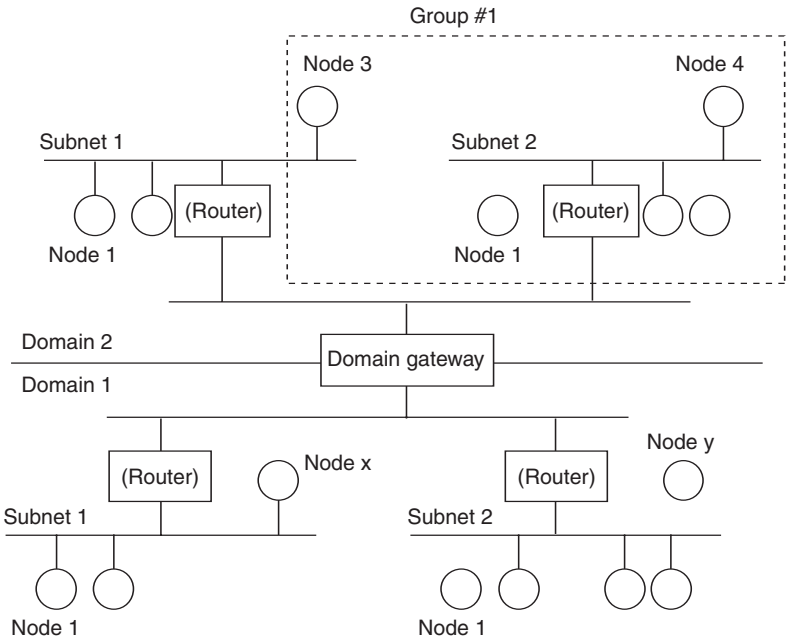

FIGURE 43.2 Addressing elements in EIA-709 networks. Up to 32,385 nodes can be addressed within one domain and up to 2^{48} domains are possible.

can be addressed within a single domain and up to 2^{48} domains can be addressed. Domain gateways can be built between logical domains in order to allow communication across domain boundaries. Groups can be formed to send a single data packet to a group of nodes with a multicast addressed message.

Optionally, routers can be used to keep local traffic within the subnet and only forward packets that are addressed to another subnet as shown in Figure 43.2. An EIA-709 node can send a unicast addressed message to exactly one node using either the physical Neuron ID or the logical subnet/node address or a multicast addressed message to either a group of nodes (group address) or to all nodes in the subnet or all nodes in the entire domain (broadcast address).

OSI Layer 4 supports four service types. The unacknowledged service simply transmits the data packet from the sender to the receiver and hopes that the message does not get lost. The unacknowledged repeated service transmits the same data packet a number of times and assumes that at least one data packet will get through to the receiver. The number of retries is programmable. The acknowledged service transmits the data packet and expects an acknowledgement to come back from the receiver. If the acknowledgement is not received, the transmitter retransmits the same data packet. The number of retries is again programmable. The request response service sends a request message to the receiver and the receiver must respond with a response message. This service type can be used to retrieve, for example, statistics information from a network node. Authentication can be used to authenticate the sender at the receiver side.

The interface to the application program are the so-called network variables (NVs). NVs are variables (like variables in a C program) that can be propagated over the network. NVs have a type, for example, SNVT_temp to represent a temperature in degree Celsius or SNVT_amp to represent an electric current

© 2005 by CRC Press LLC

in Amps or mA. SNVT is the acronym for Standard Network Variable Type. Each SNVT has a valid range defined by the upper and lower boundary, a resolution, and an SI unit. Network nodes communicate with each other by exchanging NVs.

43.2 LonWorks Node

For the last 10 years, the Neuron® chip manufactured by Motorola, Toshiba, and Cypress was the only microcontroller that supported the LonTalk protocol. Only in the last few years, with the adoption of the LonTalk protocol as a European and ANSI standard, some platform-independent implementations are available on the market [21]. The traditional LonWorks node is shown in Figure 43.3.

The Neuron chip executes the LonTalk protocol and the application program that interfaces to sensors and actuators through the Input/Output block. Two types of Neuron chips are available. The 3150 provides an external memory bus interface to expand the internal EEPROM and SRAM with external Flash and SRAM. The 3120 is optimized for low node cost applications and has a built-in 10 kbyte ROM, 2 kbyte EEPROM, and 2 kbyte SRAM but has no external memory interface [17].

An ANSI C derivative language called Neuron C is used to program the Neuron chip. Neuron C uses language extensions to schedule application events and to react to incoming data packets (network variables NVs) from the network interface. LonWorks supports a variety of different communication media. The most popular media today are 78 kbps (EIA-709.3) or 1.25 Mbps twisted pair communication, 4 kbps power line communication (EIA-709.2), a 1.25 Mbps fiber optics interface, and RS-485 interfaces at various bit rates between a few hundred bps and 1.25 Mbps. A brand new channel is the EIA-852 IP channel in order to tunnel EIA-709 data packets through IP (Intranet, Internet) networks.

43.3 Network Infrastructure

Great care must be take when designing the network infrastructure for an EIA-709 network. There are a number of requirements that must be met in order to guarantee reliable communication between all the nodes in the network. The maximum cable length must be met, the network cables must be properly terminated, the number of nodes on each physical channel must not exceed the specification, the expected network traffic must be estimated, and a network topology must be found that keeps local traffic local

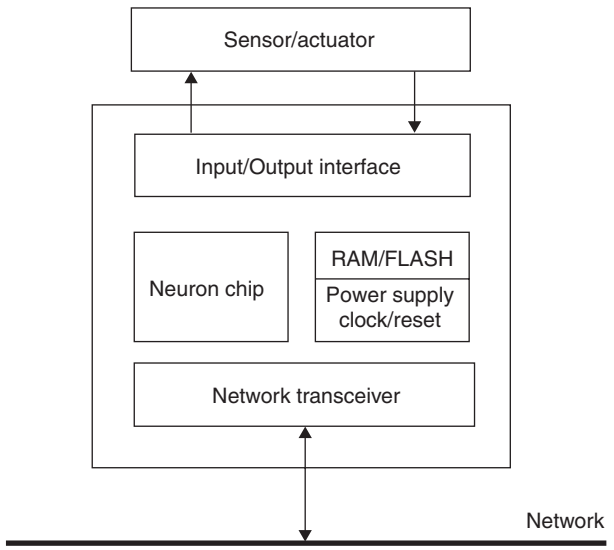

FIGURE 43.3 Typical LonWorks network node architecture.

© 2005 by CRC Press LLC

and only data packets that need to travel across network segments should leave the local segment. The bandwidth utilization must be kept below a certain limit and the number of CRC errors due to collisions and noise on the network media must be measured on each channel and kept within well-defined boundaries. Only a reliable network infrastructure with built-in diagnostics and troubleshooting functionality can guarantee reliable operation of the building or factory.

Depending on the network media and the network transceiver, a variety of network topologies are possible with LonWorks nodes. Traditional bus, ring, star, as well as free topology are supported. Complex networks require networking elements like repeaters, routers, and gateways available in EIA-709 to segment the local traffic from traffic crossing segment boundaries. Such networking elements include Layer 1 repeaters to extend the physical length of a network cable, Layer 2 bridges, and Layer 3 routers to decouple individual segments from a networking backbone, and gateways to bridge between the levels of hierarchy in the automation pyramid (see Figure 43.2).

Modern network infrastructure products [21] have built-in network diagnostics capabilities and can monitor the health state of the network 24 h a day and 7 days a week. They immediately report network malfunctions or deviations from the normal operation to the system operator. All monitoring and reporting can either be done local on site or from a remote through an Intranet or Internet connection.

43.4 Interoperability and Profiles

Open standards allow individual companies to build single pieces of a bigger puzzle and enable system integrators (SI) to design complete systems consisting of those building blocks. Node developers must follow certain rules in order to make the bigger picture work. These rules are defined in interoperability guidelines and in profiles. Compatible does not necessarily mean interoperable and not at all plug and play. More elaborate guidelines need to be established for plug and play, interchangeable, and interworkable products. Different committees have set guidelines to define those terms and to establish the rules. The LonMark organization, for example, has published interoperability guidelines for nodes that use the LonTalk protocol [18]. It is important to note that interoperability must be guaranteed on all seven OSI layers. Interoperability on all seven OSI layers is still not a guarantee to have interworkable products. A typical node only uses a subset of all the possible protocol features. Profiles define these subsets based on the intended use of the node. Task groups within LonMark define functional profiles for analog input, analog output, temperature sensor, humidity sensor, CO2 sensor, VAV controller, fan coil unit, chiller, thermostat, damper actuator, etc. As of today, LonMark hosts different task groups for fire, home/utility, petrol station, HVAC, lighting, sun blinds, security, etc., type applications.

43.5 Tools

In order to program the Neuron chip, the user has two tool options. For node manufacturers, it might be sufficient to buy the NodeBuilder from Echelon; the more advanced and also more expensive tool is the LonBuilder from Echelon. Both tools allow writing Neuron C programs, to compile and link them, and download the final application into the target node hardware. The LonBuilder supports simultaneous debugging of multiple nodes, whereas the Nodebuilder only supports debugging of one node at the time. The LonBuilder has a built-in protocol analyzer and a network binder to create communication relationships between network nodes.

System integrators (SI) need tools to design the network and define the communication relationships before the nodes are actually installed in the field. Similar to creating a schematic of resistors, capacitors, ICs, diodes, etc., the SI creates a floor plan of all the nodes in the network. After physically installing the nodes in the network, a network management tool is required to configure (also called commission) the nodes. During commissioning, nodes get a logical address (subnet/node/Domain) assigned and the binding is created. Binding is the name of the process to establish the communication relationships between sensors, actuators, and controller nodes. Protocol analyzers are used to debug communication problems and to gather traffic and error statistics. During the maintenance phase of the network, the network man-

agement tool also supports replacing faulty nodes and extending the network with additional nodes and changes in the communication relationships.

43.6 ANSI/EIA-709 Outlook

As mentioned earlier, until 1999, the Neuron chip was the only vehicle to execute the LonTalk protocol. Due to the limited resources available on the Neuron chip (CPU performance, memory space, I/O capabilities, etc.), many applications could not be solved with the existing technology. Recent hardware platform-independent implementations of the ANSI/EIA709 protocol allow for good scalability of the CPU performance and memory requirements tailored for the specific application. Furthermore, simulation of the network behavior before actual hardware exists is now possible as shown in Figure 43.4.

Different application programs 1–*n* run on top of the ANSI/EIA709 protocol stack that talks to an interface layer (LDI), which communicates with the virtual network devices. As shown on the right-hand side in Figure 43.4, the LDI can also talk to a real physical network; hence, existing nodes in a network can be part of the system simulation. The application programs on top do not see a difference if the node already exists as a physical device or if it is still a virtual device simulated on a PC or workstation [19, 20]. This architecture is fully portable between different hardware platforms and different operating systems and allows cross development, for example, on a Windows platform for an ARM7-based target hardware. Since the Application Programming Interface (API) on top of the EIA-709 protocol stack is the same on all hardware platforms and under all operating systems, the final application programs can easily be ported between different target systems. This approach allows full hardware software codesign since the application programs can be developed while the hardware development of the network node is still going on.

44.1 Introduction

Computer architectures establish a blueprint and a framework for the design of a class of computing systems that share a common set of characteristics. The time-triggered architecture (TTA) generates such a framework for the domain of large distributed real-time systems in high-dependability environments. It sets up the computing infrastructure for the implementation of applications and provides mechanisms and guidelines to partition a large application into nearly autonomous subsystems along small and well-defined interfaces in order to control the complexity of the evolving artifact. Architecture design is thus interface design. By defining an architectural style that is observed at all component interfaces, the architecture avoids property mismatches at the interfaces and eliminates the need for unproductive "glue" code.

Characteristic of the TTA is the treatment of (physical) time as a first-order quantity. The TTA decomposes a large application into clusters and nodes and provides a fault-tolerant global time base of known precision at every node. The TTA takes advantage of the availability of this global time to precisely specify the interfaces among the nodes, to simplify the communication and agreement protocols, to perform prompt error detection, and to guarantee the timeliness of real-time applications.

This article aims at giving a short yet concise introduction to the TTA in general and time-triggered communication networks in particular. We will discuss the basic concepts of the TTA in Section 44.2. Two representatives of time-triggered network protocols will be presented in Section 44.3. Section 44.4 will

© 2005 by CRC Press LLC

discuss fault-tolerance aspects of the TTA, Section 44.5 will elaborate on the design of TTA applications. Finally, the article ends with a conclusion in Section 44.6.

44.2 Fundamental Concepts

The computational model that guides the design of the TTA is the time-triggered (TT) model of computation [Kop98]. The following sections will discuss the fundamental concepts of this architectural model. A more detailed description of the concepts can be found in [KB03].

Model of Time

The model of time of the TTA is based on Newtonian physics. Real-time progresses along a dense timeline, consisting of an infinite set of instants, from the past to the future. A duration (or interval) is a section of the timeline, delimited by two instants. A happening that occurs at an instant (i.e. a cut of the timeline) is called an event. An observation of the state of the world is thus an event. The time stamp of an event is established by assigning the state of the node-local global time to the event immediately after the event occurrence. A fault-tolerant internal clock synchronization algorithm establishes the global time in the TTA. Due to the impossibility of synchronizing clocks perfectly and the denseness property of real time, there is always the possibility of the following sequence of events: clock of node j ticks, event e occurs, clock of node k ticks. In such a situation, the single event e is time-stamped by the two clocks j and k with a difference of one tick. In a distributed system, the finite precision of the global time base and the digitalization of time make it, in general, impossible to consistently order events on the basis of their global time stamps. The TTA solves this problem by the introduction of a sparse-time base [Kop97, p. 55]. In the sparse-time model, the continuum of time is partitioned into an infinite sequence of alternating durations of activity and silence as shown in Figure 44.1. The duration of the activity interval, that is, a granule of the global time, must be larger than the precision of the clock synchronization.

From the point of view of temporal ordering, all events that occur within an interval of activity are considered to happen at the same time. Events that happen in the distributed system at different nodes at the same global clock-tick are thus considered simultaneous. Events that happen during different durations of activity and that are separated by the required interval of silence can be consistently temporally ordered on the basis of their global time stamps. The architecture must make sure that significant events, such as the sending of a message, occur only during an interval of activity. The time stamps of events that are outside the control of the distributed computer system (and therefore happen on a dense timeline) must be assigned to an agreed duration of activity by an agreement protocol.

In the TTA there exists a uniform external representation of time that is modeled according to the Global Positioning System (GPS) time representation. The time stamp of an instant is represented by an eight-byte integer, that is, two words of a 32-bit architecture. The three lower bytes contain the binary fractions of the second, giving a granularity of about 60 nsec. This is the accuracy that can be achieved with a precise GPS receiver. The five upper bytes count the full seconds. The external TTA epoch assigns the value 2^{38} to the start of the GPS epoch, that is, 00:00:00 UTC on January 6, 1980. This offset has been chosen in order that also instants before January 6, 1980 can be represented by positive integers in the TTA. Thus, events that occurred between 8710 years before January 1980 and 26131 years after January 1980 can be time-stamped with an accuracy of 60 nsec. There are different internal time representations

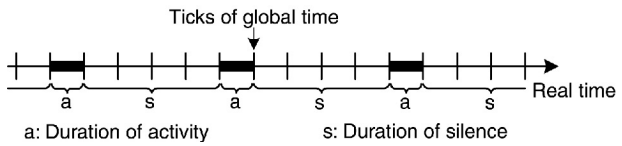

FIGURE 44.1 Sparse time base.

© 2005 by CRC Press LLC

in the TTA that match the time format to the capabilities of the hardware (8 bit, 16 bit, or 32 bit architectures) and the requirements of the application. Since not all time stamps are based on a global time with a precision of 60 nsec, an attribute field is introduced in the external representation indicating the precision of a time stamp.

State Information vs. Event Information

The information that is exchanged across an interface is either state information or event information. Any property of a real-time (RT) entity (i.e. a relevant state variable) that is observed by a node of the distributed RT system at a particular instant, for example, the temperature of a vessel, is called a state attribute and the corresponding information state information. A state observation records the value of a state variable at a particular instant, the point of observation. A state observation can be expressed by the atomic triple

$$< \textit{Name, value, time of observation} >$$

For example, the following is a state observation: "The position of control valve *A* was at 75 degrees at 10:42 a.m." State information is idempotent and requires an at-least-once semantics when transmitted to a client. At the sender, state information is not consumed on sending and at the receiver, state information requires an update-in-place and a nonconsuming read. State information is transmitted in state messages.

A sudden change of state of an RT entity that occurs at an instant is an event. Information that describes an event is called event information. Event information contains the difference between the state before the event and the state after the event. An event observation can be expressed by the atomic triple

$$< \textit{Name, value difference, time of event} >$$

For example, the following is an event observation: "The position of control valve *A* changed by 5 degrees at 10:42 a.m." Event observations require exactly-once semantics when transmitted to a consumer. At the sender, event information is consumed on sending and at the receiver, event information must be queued and consumed on reading. Event information is transmitted in event messages.

Periodic state observations or sporadic event observations are two alternative approaches for the observation of a dynamic environment in order to reconstruct the states and events of the environment at the observer. Periodic state observations produce a sequence of equidistant "snapshots" of the environment that can be used by the observer to reconstruct those events that occur within a minimum temporal distance that is longer than the duration of the sampling period. Starting from an initial state, a complete sequence of (sporadic) event observations can be used by the observer to reconstruct the complete sequence of states of the RT entity that occurred in the environment. However, if there is no minimum duration between events assumed, the observer and the communication system must be infinitely fast.

Temporal Firewalls

An extensible architecture must be based on a small number of orthogonal concepts that are reused in many different situations in order to reduce the mental load required for understanding large systems. In a large distributed system, the characteristics of the interfaces between subsystems determine to a large extent the comprehensibility of the architecture. In the TTA, the communication network interface (CNI, cf. Figure 44.2) between a host computer and the communication network is the most important interface. The CNI appears in every node of the architecture and separates the local processing within a node from the global interactions among the nodes. The CNI consists of two unidirectional data flow interfaces, one from the host computer to the communication system and the other one in the opposite direction.

© 2005 by CRC Press LLC

We call a unidirectional data flow interface elementary, if there is only a unidirectional control flow [Kop99] across this interface. An interface that supports periodic state messages with error detection at the receiver is an example of such an elementary interface. We call a unidirectional data flow interface composite, if even a unidirectional data flow requires a bidirectional control flow. An event message interface with error detection is an example for a composite interface. Composite interfaces are inherently more complex than elementary interfaces, since the correct operation of the sender depends on the control signals from all receivers. This can be a problem in multicast communication where many control messages are generated for every unidirectional data transfer, and each one of the receivers can affect the operation of the sender.

The basic CNI of the TTA as depicted in Figure 44.3 is an elementary interface. The TT transport protocol carries autonomously — driven by its TT schedule — state messages from the sender's CNI to the receiver's CNI. The sender can deposit the information into its local CNI memory according to the information push paradigm, while the receiver will pull the information out of its local CNI memory. From the point of view of temporal predictability, information push into a local memory at the sender and information pull from a local memory at the receiver are optimal, since no unpredictable task delays that extend the worst-case execution occur during reception of messages. A receiver that is working on a time-critical task is never interrupted by a control signal from the communication system. Since no control signals cross the CNI in the TTA (the communication system derives control signals for the fetch and delivery instants from the progress of global time and its local schedule exclusively), propagation of control errors is prohibited by design. We call an interface that prevents propagation of control errors by design a temporal firewall [KN97]. The integrity of the data in the temporal firewall is assured by the nonblocking write (NBW) concurrency control protocol [Kop97, p. 217].

44.3 Time-Triggered Networks

The very basic principle of TT communication is that transmission of messages is triggered by the clock rather than the availability of new information. The upcoming sections will present the view of the application of TT communication.

Principle of Operation

The instants at which information is delivered at or fetched from the CNIs of a node are determined *a priori* and are common knowledge to all nodes of a TTA. *A priori* common knowledge means that these instants are defined before the computation under consideration is started and that the instants are known to all nodes of a cluster beforehand. These instants are the deadlines for the application tasks within a host. Knowing these deadlines, it is in the responsibility of the host to produce the required results before the deadline has passed. Any node-local scheduling strategy that will satisfy these known deadlines is "fit for purpose." It is the responsibility of the TT communication service to transport the information from the sending CNI to the receiving CNI within the interval delimited by these *a priori* known fetch and delivery instants. The TTA contains two communication protocols that provide this communication service, the fault-tolerant TTP/C protocol and the low-cost fieldbus protocol TTP/A.

Communication Interface

From the point of view of complexity management and composability, it is useful to distinguish between three different types of interfaces of a node: the real-time service (RS) interface, the diagnostic and management (DM) interface, and the configuration and planning (CP) interface [Kop00]. These interface types serve different functions and have different characteristics. For the temporal composability, the most important interface is the RS interface.

The RS Interface: The RS interface provides the timely RS to the node environment during the operation of the system. In RT systems, it is a time-critical interface that must meet the temporal specification of the application in all specified load and fault scenarios. The composability of an architecture depends on the proper support of the specified RS interface properties (in the value and in the temporal domain) during operation. From the user's point of view, the internals of the node are not visible at the CNI, since they are hidden behind the RS interface.

The DM Interface: The DM interface opens a communication channel to the internals of a node. It is used for setting node parameters and for retrieving information about the internals of the node, for example, for the purpose of internal fault diagnosis. The maintenance engineer that accesses the internals of a node via the DM interface must have detailed knowledge about the internal objects and behavior of the node. The DM interface does not affect temporal composability. Usually, the DM interface is not time-critical.

The CP Interface: The CP interface is used to connect a node to other nodes of a system. It is used during the integration phase to generate the "glue" between the nearly autonomous nodes. The use of the CP interface does not require detailed knowledge about the internal operation of a node. The CP interface is not time-critical.

The CNI of the TTA can be directly used as the RS interface. On input, the precise interface specifications (in the temporal and value domain) are the preconditions for the correct operation of the host software. On output, the precise interface specifications are the postconditions that must be satisfied by the host, provided the preconditions have been satisfied by the host environment. Since the bandwidth is allocated statically to the host, no starvation of any host can occur due to high-priority message transmission from other hosts. The TTA implements an event-triggered communication service on top of the basic TT service to realize the DM and CP interfaces. Since the event-triggered communication is based on (but not executed in parallel to) the TT communication, it is possible to maintain and to use all predictability properties of the basic TT communication service in event-triggered communication.

The System Protocol TTP/C

The TTP/C protocol [TTT] is a fault-tolerant TT communication protocol that provides the following services:

- Autonomous fault-tolerant message transport with known delay and bounded jitter between the CNIs of the nodes of a cluster by employing a TDMA medium access strategy on replicated communication channels.
- Fault-tolerant clock synchronization that establishes the global time base without relying on a central time server.
- Membership service to inform every node consistently about the "health-state" of every other node of the cluster. This service can be used as an acknowledgement service in multicast communication. The membership service is also used to efficiently implement the fault-tolerant clock synchronization service.
- Clique avoidance to detect and eliminate the formation of cliques in case the fault hypothesis is violated.

In TTP/C the communication is organized into rounds, where every node must send a message in every round. A particular message may carry up to 240 bytes of data. The data are protected by a 24 bits CRC checksum. The message schedule is stored in the message-descriptor list (MEDL) within the communication controller of each node. In order to achieve high data efficiency, the sender name and the message name are derived from the send instant. The clock synchronization of TTP/C exploits the common knowledge of the send schedule: every node measures the difference between the *a priori* known expected and the actually observed arrival time of a correct message to learn about the difference between the clock of the sender and the clock of the receiver. This information is used by a fault-tolerant average algorithm to calculate periodically a correction term for the local clock in order to keep the clock in synchrony with all other clocks of the cluster. The membership service employs a distributed agreement algorithm to determine whether the outgoing link of the sender or the incoming link of the receiver has failed. Nodes that have suffered a transmission fault are excluded from the membership until they restart with a correct protocol state. Before each send operation of a node, the clique avoidance algorithm checks if the node is a member of the majority clique. The detailed specification of the TTP/C protocol can be found at [TTT].

The Fieldbus Protocol TTP/A

The TTP/A protocol is the TT fieldbus protocol of the TTA [OMG02]. It is used to connect low-cost smart transducers to a node of the TTA, which acts as the master of a transducer cluster. In TTP/A, the CNI memory element of Figure 44.3 has been expanded at the transducer side to hold a simple interface file system (IFS). Each interface file contains up to 256 records of 4 bytes each. The IFS forms the uniform name space for the exchange of data between a sensor and its environment (Figure 44.4).

The IFS holds the RT data, calibration data, diagnostic data, and configuration data. The information between the IFS of the smart transducer and the CNI of the TTA node is exchanged by the TT TTP/A protocol, which distinguishes between two types of rounds, the master–slave (MS) round and the

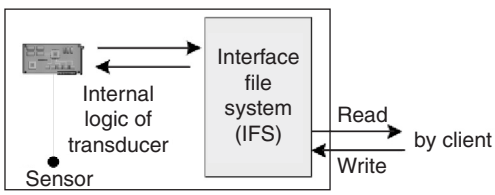

FIGURE 44.4 IFS in a smart transducer.

© 2005 by CRC Press LLC

multi-partner (MP) round. The MS rounds are used to read and write records from the IFS of a particular transducer to implement the DM and CP interfaces. The MP rounds are periodic and transport data from selected IFS records of several transducers across the TTP/A cluster to implement the RS service. MP rounds and MS rounds are interleaved, such that the time-critical RS implemented by means of MP rounds and the event-based MS service can coexist. It is thus possible to diagnose a smart transducer or to reconfigure or install a new smart transducer on-line, without disturbing the time-critical RS of the other nodes. The TTP/A protocol also supports a "plug-and-play" mode where new sensors are detected, configured, and integrated into a running system on-line and dynamically. The detailed specification of the TTP/A protocol can be found at [OMG02].

44.4 Fault Tolerance

In any fault-tolerant architecture, it is important to distinguish clearly between fault containment and error containment. Fault containment is concerned with limiting the immediate impact of a single fault to a defined region, while error containment tries to avoid the propagation of the consequences of a fault, the error. It must be prohibited that an error in one fault-containment region propagates into another fault-containment region that has not been directly affected by the original fault.

Fault Containment

In the field of fault-tolerant computing, the notion of a fault-containment region (FCR) is introduced in order to delimit the impact of a single fault. An FCR is defined as the set of subsystems that share one or more common resources. A fault in any one of these shared resources can thus impact all subsystems of the FCR, that is, the subsystems of an FCR cannot be considered to fail independently of each other. In the context of this article, we consider the following resources that can be impacted by a fault:

- Computing Hardware
- Power Supply
- Timing Source
- Clock Synchronization Service
- Physical Space.

For example, if two subsystems depend on a single timing source, for example, a single oscillator or a single clock synchronization algorithm, then these two subsystems are not considered to be independent and therefore belong to the same FCR. Since this definition of independence allows that two FCRs can share the same design, that is, the same software, software faults are not part of this fault model. In the TTA, a node is considered to form a single FCR.

In the TTA nodes communicate by the exchange of messages across replicated communication channels. Each one of the two channels transports independently its own copy of the message at about the same time from the sending CNI to the receiving CNI. The start of sending a message by the sender is called the message send instant. The termination of receiving a message by the receiver is called the message receive instant. In the TTA, the intended message send instants and the intended message receive instants are *a priori* known to all communicating partners. A message contains an atomic data structure that is protected by a CRC. We make the assumption that a CRC cannot be forged by a fault. A message is called a valid message if it contains a data structure with a correct CRC. A message is called a timely message if it is a valid message and conforms to the temporal specification. A message, which does not conform to the temporal specification, is an untimely message. A timely message is a correct message, if its data structure is in agreement, both at the syntactic and semantic level, with the specification. We call a message with a message length that differs from its specification or with an incorrect CRC an invalid message.

© 2005 by CRC Press LLC

Error Containment in the Temporal Domain

An error that is caused by a fault in the sending FCR can propagate to another FCR via a message failure, that is, the FCR sends a message that deviates from the specification. A message failure can be a message value failure or a message timing failure. A message value failure implies either that a message is invalid or that the data structure contained in a valid message is incorrect. A message timing failure implies that the message send instant or the message receive instant are not in agreement with the specification.

In order to avoid error propagation of a sent message, we need error detection mechanisms that are in different FCRs than the message sender. Otherwise, the error detection mechanism may be impacted by the same fault that caused the message failure. In the TTA, we distinguish between timing failure detection and value failure detection. The timing-failure detection is performed by a guardian (Figure 44.5), which is part of the TTA. Value failure detection is in the responsibility of the host computer.

The guardian is an autonomous unit that has *a priori* knowledge of all intended message send and receive instants. Each one of the two replicated communication channels has its own independent guardian. A receiving node within the TTA judges a sending node as operational, if it has received at least one timely message from the sender around the specified receive instant. It is assumed that a guardian cannot forge a CRC and cannot store messages, that is, it can only output a valid message at one of its output ports if it has received a valid message on one of its input ports within the last d time units. A guardian transforms a message, which it judges untimely into an invalid message by cutting off its tail. Such a truncated message will be recognized as invalid by all correct receivers and will then be discarded. The guardian may truncate a message either because it detected a message timing failure or because the guardian itself is faulty. In the latter case, it is assumed that the sender of the message is correct and thus the correct message will proceed to the receivers via the replicated channel of the TTA.

Error Handling in the Value Domain

Detection of value failures is not in responsibility of the TTA, but in the responsibility of the host computers. For example, detection and correction of value failures can be performed in a single step by triple modular redundancy (TMR). In this case, three replicated senders, placed in three different FCRs, perform the same operations in their host computers. They produce — in the fault-free case — correct messages with the same content that are sent to three replicated receivers that perform a majority vote on these three messages (actually, at the communication-level six messages will be transported, one from each sender on each of its two channels).

Detection of value failures and detection of timing failures are not independent in the TTA. In order to implement a TMR structure at the application level, the integrity of the timing of the architecture must

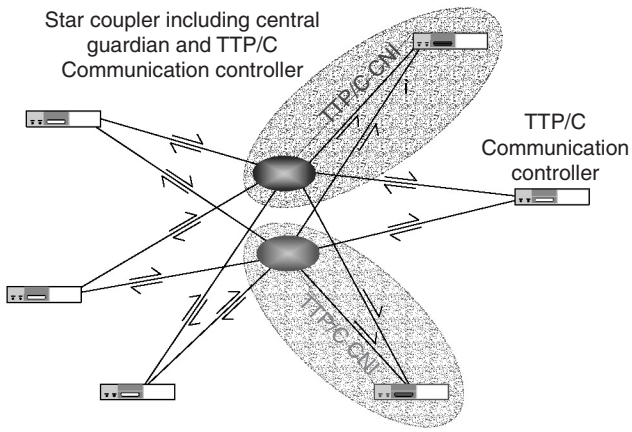

FIGURE 44.5 TTA star topology with central guardian.

© 2005 by CRC Press LLC

be assumed. An intact sparse global time base is a prerequisite for the system-wide definition of the distributed state, which again is a prerequisite for masking value failures by voting. The separation of handling timing failures from handling value failures has beneficial implications for resource requirements. To handle k arbitrary failing nodes, $3k + 1$ nodes are required. All nodes of a cluster, independent of their involvement in a particular application system, can contribute to handling timing failures at the architectural level. Once a proper global time is available, TMR for masking of value failures can be implemented using only $2k + 1$ synchronized nodes in a particular application subsystem. This separation of timing failures and value failures thus reduces the number of components needed for fault tolerance of an application from $3k + 1$ to $2k + 1$.

To summarize, fault containment and error detection is achieved in the TTA in three distinct steps. At first, fault containment is achieved by proper architectural decisions concerning resource sharing in order to provide independent fault containment regions. In a second step, propagation of timing errors is avoided at the architecture level by the guardians. In a third step, handling of value failures is performed at the application level by voting.

44.5 The Design of TTA Applications

Composability and the associated reuse of nodes and software can only be realized if the architecture supports a two-level design methodology. In the TTA such a methodology is supported: the TTA distinguishes between the architecture design (cluster design) and the component design (node design).

Architecture Design

In the cluster design phase, an application is decomposed into clusters and nodes. This decomposition will be guided by engineering insight and the structure inherent in the application, in accordance with the proven architecture principle of "form follows function." For example, in an automotive environment, a "drive-by-wire" system may be decomposed into functional units as depicted in Figure 44.6.

If a system is developed "on the green lawn," then a top-down decomposition will be pursued. After the decomposition has been completed, the CNIs of the nodes must be specified in the temporal and in the value domain. The data elements that are to be exchanged across the CNIs are identified and the precise fetch instants and delivery instants of the data at the CNI must be determined. Given these data, the schedules of the TTP/C communication system can be calculated and verified. At the end of the

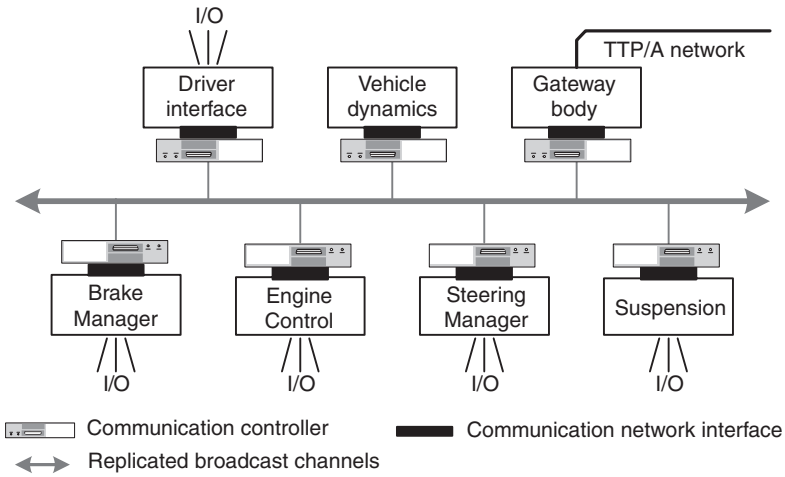

FIGURE 44.6 Decomposition of a "drive-by-wire" application.

© 2005 by CRC Press LLC

architecture design phase, the precise interface specifications of the nodes are available. These interface specifications are the inputs and constraints for the node design.

Given a set of available nodes with their temporal specification (nodes that are available for reuse), a bottom-up design approach must be followed. Given the constraints of the nodes at hand (how much time they need to calculate an output from an input), a TTP/C schedule must be found that meets the application requirements and satisfies the node constraints.

Component Design

During the node design phase, the application software of the host computers is developed. The delivery and fetch instants established during the architecture design phase are the preconditions and postconditions for the temporal validation of the application software. The host operating system can employ any reasonable scheduling strategy, as long as the given deadlines are satisfied and the replica determinism of the host system is maintained.

Node testing proceeds bottom-up. A new node must be tested with respect to the given CNI specifications in all anticipated load and fault conditions. The composability properties of the TTA (stability of prior service achieved by the strict adherence to information pull interfaces) ensure that a property that has been validated at the node level will also hold at the system level. At the system level, testing will focus on validating the emerging services that are result of the integration.

Validation

Today, the integration and validation phases are probably the most expensive phases in the implementation of a large distributed RT system. The TTA has been designed to reduce this integration and validation effort by providing the following mechanisms:

- The architecture provides a consistent distributed computing base to the application and informs the application in case a loss of consistency is caused by a violation of the fault hypothesis. The basic algorithms that provide this consistent distributed computing base (clock synchronization and membership) have been analyzed by formal methods and are implemented once and for all in silicon. The application need not be concerned with the implementation and validation of the complex distributed agreement protocols that are needed to establish consistency in a distributed system.
- The architecture is replica deterministic, which means that any observed deficiency can be reproduced in order to diagnose the cause of the observed problem.
- The interaction pattern between the nodes and the contents of the exchanged messages can be observed by an independent observer without the probe effect. It is thus possible to determine whether a node complies with its preconditions and postconditions without interfering with the operation of the observed node.
- The internal state of a node can be observed and controlled by the DM interface.
- In the TTA, it is straightforward to provide a RT simulation test bench that reproduces the environment to any node in RT. Deterministic automatic regression testing can thus be implemented.

44.6 Conclusions

The TTA is the result of more than 20 years of research in the field of dependable distributed RT systems. During this period, many ideas have been developed, implemented, evaluated, and finally discarded. What survived is a small set of orthogonal concepts that center around the availability of a dependable global time base. The guiding principle during the development of the TTA has always been to take maximum advantage of the availability of this global time, which is part of the world, even if we do not use it. The TTA spans the whole spectrum of dependable distributed RT systems, from the low-cost deeply

© 2005 by CRC Press LLC

embedded sensor nodes to high-performance nodes that communicate at gigabits per second speeds, persistently assuming that a global time of appropriate precision is available in every node of the TTA.

At present, the TTA occupies a niche position, since in the experimental as well as in the theoretical realm of main-line computing, time is considered a nuisance that makes life difficult and should be dismissed at the earliest moment [Lee00]. However, as more and more application designers start to realize that RT is an integrated part of the real-world that cannot be abstracted away, the future prospects for the TTA look encouraging.

45.1 Introduction

Almost every modern distributed technical system requires some kind of digital communication infrastructure with high bandwidth, no matter whether it concerns consumer electronics or industrial applications. On the one hand, computers and devices for acquisition and reproduction of digital images and sound converge to so-called multimedia systems. On the other, industrial control systems incorporate multiple sensors like cameras for optical quality inspection, while control and status information, normally distributed via field busses, shall run along the same cable as mass data. All these systems have one common characteristic: they require an efficient peer-to-peer data communication mechanism, since they do not inevitably include a computer that can act as a data hub. Even if such a central node exists, sending data from one node to the computer and then forwarding it to another external device is often not the optimum communication pattern.

Modern consumer electronics and communication systems for industrial and factory automation applications have some more features and requirements in common:

High bandwidth: An industrial black and white camera with VGA resolution, 12-bit color depth per pixel, and a frame rate of 25 Hz, which is often used for automated optical quality inspection, produces a data rate of almost 100 Mbit/sec, which can easily be increased by higher geometrical resolution and use of multicamera systems.

Real-time streaming: If the communication system supports a special type of data transfer that ensures bandwidth for real-time streaming of data or a well-defined latency for message transmission, the definition of higher layer protocols can be significantly simplified. Standard Ethernet does not fulfill this requirement, which makes it difficult to implement hard real-time applications using this bus technology.

One single cabling: Mass data as well as status and control information shall be exchanged via the same cable that is used for all purposes within the system. In order to reduce the costs for cabling and connectors, a serial data transmission is preferred.

© 2005 by CRC Press LLC

Easy reconfiguration: While plug-and-play capability is self-evident for consumer electronics, this feature can also be very helpful in industrial environments, like a complex measurement system with several different signal acquisition and processing devices. If the user just plugs them together without any elaborate setup, the setup time is significantly reduced. This requirement also includes that no specific network topology be enforced.

All these requirements are fulfilled by the bus as defined in the IEEE 1394 standard for a High Performance Serial Bus [1–3], short "IEEE 1394" with commercial implementations known as FireWire and i.LINK.[1] Therefore, it is obvious that this bus standard originally used for consumer electronics and computer peripherals becomes more and more popular for industrial and factory automation applications. The following sections describe the fundamental facts of IEEE 1394, a reference design for industrial IEEE 1394 nodes, and some real-world applications for industrial environments.

45.2 IEEE 1394 Basics

IEEE 1394 is a serial bus connecting nodes with data rates up to 800 Mbit/sec that can be mixed with older devices running at data rates of 100, 200, and 400 Mbit/sec. The standard supports two completely different types of data transfer:

1. Asynchronous transfers are rather short messages that are mainly used for control and setup purposes. Their exchange is controlled by a request and response scheme that guarantees a data delivery for read or write operations, respectively, generating well-defined error codes. This type of communication is used if reliability is more important than timing, as it cannot be exactly determined at which time an asynchronous request of the application is actually sent to the connected node.
2. Isochronous channels are used for mass data that require a fixed, guaranteed bandwidth. The streaming data are divided into packets that are sent every 125 μsec. This 8 kHz clock is distributed across the network by a special packet called Cycle Start Packet. Typical examples of isochronous transfers are real-time video streams where late data are useless. The reception of the data is not secured; the sender does not even know if any other node is listening to the data.

These two transfer types use a common Physical and Link Layers of the IEEE 1394 protocol stack as depicted in Figure 45.1. The Link Layer provides addressing, data checking, and data framing for packet transmission and reception, whereas the Physical Layer transforms the logical symbols used by the Link Layer into electrical signals, which includes bus arbitration in case several nodes want to send data at the same time. The isochronous data are directly fed into the Link Layer; for asynchronous data, there is an additional Transaction Layer as a standard interface for the application on top of the protocol stack. Its main task is to implement the secure request/response protocol for asynchronous transactions. All three layers exchange data with the so-called Serial Bus Management that incorporates some special functions for managing and optimizing the bus. Normally, Physical and Link Layers are realized by dedicated chip sets, whereas Transaction Layer and Serial Bus Management are implemented in firmware. Serial Bus Management is optional and can normally be omitted for design of embedded nodes if a host computer with a common operating system is part of the network.

Until 2002, the physical medium used for IEEE 1394 was restricted to special copper cables and IEEE 1394 specific sockets and connectors. The situation has changed with the passing of the new standard amendment IEEE 1394b-2002 [4]. A matrix with all supported speeds and reach for different kinds of media is shown in Table 45.1. IEEE 1394b offers two promising options for IEEE 1394 in industrial applications. On the one hand, existing CAT5 cabling can be used if a data rate of 100 Mbit/sec is sufficient, for example, if only short status and control messages have to be exchanged. On the other, optical media

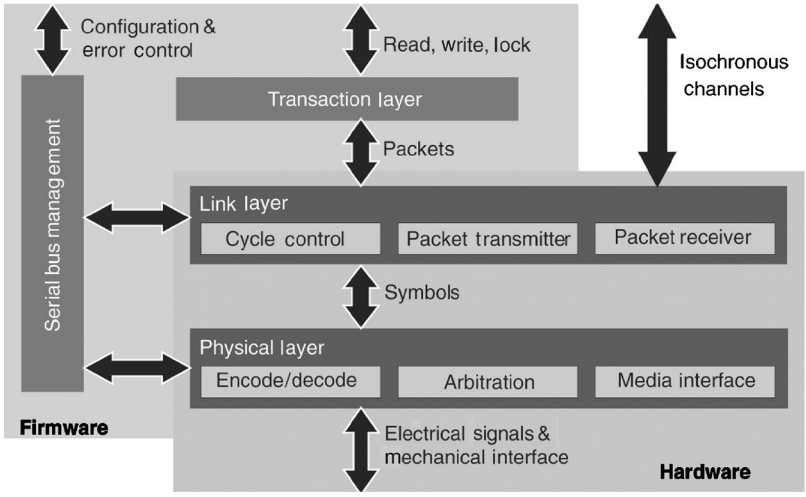

FIGURE 45.1 Layered protocol architecture of IEEE 1394.

TABLE 45.1 Supported media by IEEE 1394

Media	Reach(m)	S100	S200	S400	S800	S1600	S3200
IEEE 1394a STP Copper	4.5	✓	✓	✓			
CAT-5 (Ethernet)	100	✓					
Plastic Optic Fiber	50	✓	✓	(✓)			
Glass Optic Fiber	100			✓	✓	✓	(✓)
IEEE 1394b STP Copper	4.5			✓	✓	✓	(✓)

combine the advantages of high data rates with long distance. If the special Shielded Twisted Pair (STP) IEEE 1394 cables, both IEEE 1394a and IEEE 1394b, are used, not only data but also power can be provided. A maximum current of 1.5 A at a typical voltage of 12 V is sufficient for several applications, so that a separate power supply can be omitted for most nodes. IEEE 1394b only affects the Physical Layer: existing applications that use the original IEEE 1394-1995 standard and the first amendment IEEE 1394a-2000 can easily migrate to IEEE 1394b by just replacing the Physical Layer; no change of software is required.

Every data are transmitted as packets consisting of a header that describes the type and destination address of the packets and the payload. The receiver can check the integrity by means of CRC sums that are also included. The IEEE 1394 standard only specifies how packets are transmitted from one node to another, that is, it covers only the lower layers of the ISO/OSI architecture. The definition of common interpretation of the payload is left to application-specific transport protocols. Currently, more than 60 additional specifications exist, most of them for audio and video consumer electronics. Only a few of them are actually of interest for industrial applications:

1. Serial Bus Protocol 2 (SBP-2) [5] defines a generic method for asynchronous data exchange between two nodes. Principally, it encapsulates an arbitrary command set, but is mainly used for the implementation of the SCSI-2 protocol via IEEE 1394. SBP-2 is a very versatile protocol but has a significant administrative overhead, so that it is not well suited for extremely high-performance applications. This limitation is overcome by a new version of this standard, called SBP-3, which significantly reduces the amount of overhead and also allows isochronous transport of data.
2. The Industrial and Instrumentation Digital Camera (IIDC) 1394-based Digital Camera Specification [6] (short DCAM) describes how industrial cameras delivering uncompressed video

© 2005 by CRC Press LLC

data are accessed by other components as well as the data format of the image data. The main applications are industrial inspection systems for quality control or the like.

3. The Instrument & Industrial Control Protocol IICP Specification [7] defines how to implement the IEEE 488 protocol on IEEE 1394.

The situation concerning IEEE 1394 for high-performance industrial control systems is somewhat complicated. Of course, IEEE 1394 is already used for this application area, but existing solutions are based on proprietary protocols. In the meantime, leading European companies selling products for factory automation, motion control, and the like as well as research institutes working on IEEE 1394, factory automation, and production technologies have formed the "1394 Automation" Association. Their main task was to develop and is to maintain a standard called "1394AP (1394 Automation Protocol)," that allows controllers from different vendors to communicate with each other via IEEE 1394. Additionally, DCAM-compliant commands and video streams can be embedded into the 1394AP packets. More details and issues concerning the implementation of "1394AP" are described below in Section 45.5 However, the exact specification of "1394AP" will only be accessible to members of the "1394 Automation" Association until first products using "1394AP" become available on the market. Afterwards, the responsibility for the protocol will be handed over to the 1394 Trade Association. All this should happen until end of 2004.

45.3 IEEE 1394 System Design

This section describes a generic architecture of an embedded IEEE 1394 device, that is, everything that is not a conventional computer. As stated above, only the lower layers of the IEEE 1394 protocol are realized by dedicated hardware; the upper layers are firmware. Therefore, every IEEE 1394 node must contain some kind of processor that executes the higher layers. This leads to the system architecture as depicted in Figure 45.2. Here, still an IEEE 1394a solution is described. However, if IEEE 1394b is necessary either for speed or because of the necessity of alternative media, only a different hardware for Link and Physical Layers has to be chosen; the overall architecture remains the same.

For the Physical Layer, any standard PHY chip can be used. A three-port PHY gives most flexibility for the network topology. IEEE 1394a forbids closed loops with the system that results in a tree-like network topology, whereas IEEE 1394b automatically breaks up loops and also favors tree-like networks. A variety of Link Layer Controllers (LLC) from different manufacturers exist. For industrial applications, the TSB12LV32 "GP2Lynx" by Texas Instruments is well suited. It provides a memory mapped interface to a microcontroller for asynchronous data and setup of the IEEE 1394 data transmission as well as a 16-Bit high-speed data port that can send or receive data at a full speed of 400 Mbit/sec. Unfortunately, until

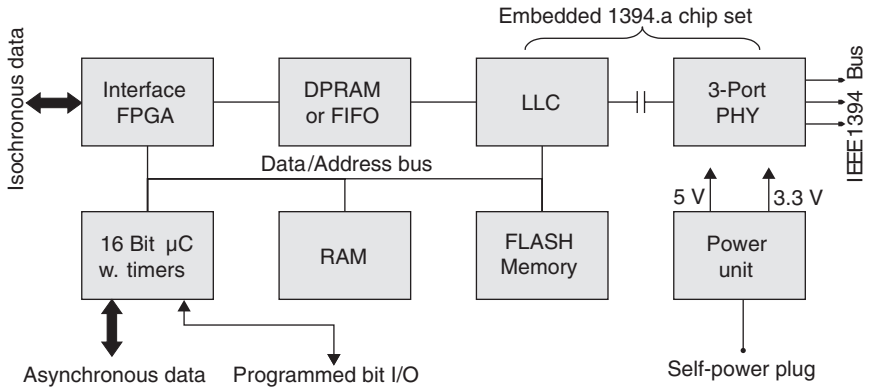

FIGURE 45.2 Hardware architecture of embedded IEEE 1394 device.

© 2005 by CRC Press LLC

now (July 2004) no embedded IEEE 1394b LLC capable of handling 800 Mbit/sec and dedicated to isochronous transmission is available. Oxford Semiconductor produces a chip called OXUF922 that supports 800 Mbit/sec, but is mainly intended for mass storage devices like hard drives as it includes some hardware support for SBP-2 but not for isochronous streaming. One solution might be to use the TSB82AA2 LLC of Texas Instruments that is IEEE 1394b compliant and has a PCI bus interface. If just one application-specific hardware is connected to the PCI interface, it can be treated as a general-purpose 32-bit wide interface. The complexity of PCI only arises if it is actually used as a bus accessed by numerous components.

An important issue, especially for industrial applications, is the electrical interface between PHY and LLC. Since DC voltage levels in IEEE 1394a communicate some information between the PHYs, all PHYs are directly connected with each other. If the nodes are powered from an external supply, they might operate at different ground levels, which may produce a current flow on the IEEE 1394 cables. In order to prevent a faulty operation of the bus or even a damage of the nodes, a galvanic isolation between the LLC and the PHY is strongly recommended. Normally, if the chips include some busholder circuitry, a capacitor inserted into the data and control lines is sufficient. Of course, the problem of additional galvanic isolation disappears if IEEE 1394b and optical media are used.

A crucial point is the choice of the processor for the IEEE 1394 node. Usually, the data handling is split: the processor executes the IEEE 1394 stack, cares about the asynchronous data, and controls additional low bandwidth hardware via programmed bit Input/Output (I/O), whereas the isochronous mass data are processed by some application-specific hardware. In this case, a 16-Bit microcontroller like the SAB-C161PI by Infineon gives sufficient computing power. Another processor that has become very popular for embedded IEEE 1394 devices is the ARM7 type. Of course, the necessary amount of memory depends on the application; for the IEEE 1394 stack, 64 kbyte of both RAM and ROM are sufficient. The use of an FPGA for the hardware processing of mass data provides flexibility, so that the same design can be used for a broad range of applications. Some buffering of data is required at the high-speed port of the LLC in order to transform the streaming data into isochronous packets or *vice versa*. Some LLCs have a sufficient amount of internal FIFO memory; others like the GP2Lynx require an external buffer realized by a Dual Ported RAM or a FIFO. Another solution is to implement the FIFO inside the FPGA.

The architecture of the software implementation of the protocol stack (see Figure 45.3) represents the layer structure as defined in the standard. However, two additional layers are inserted, both of which provide a universal programming interface. The embedded application closely interacts with the Serial Bus Management, the Transaction Layer, and the Link Layer. In order to ease the coding of the application for the user, a common Application Programming Interface (API) must be provided. API calls

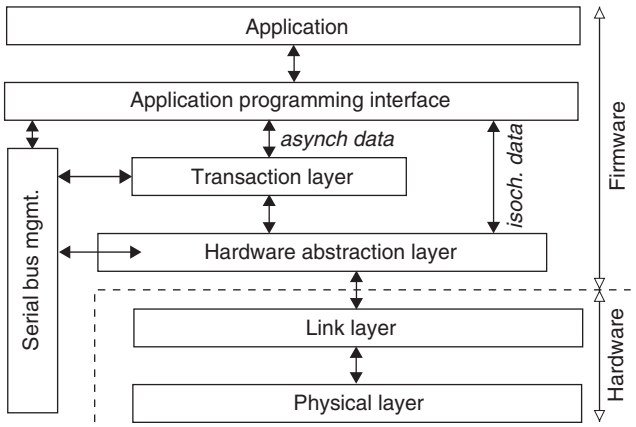

FIGURE 45.3 Embedded IEEE 1394 protocol stack.

© 2005 by CRC Press LLC

include routines for initialization of the bus, the basic asynchronous transactions (Read, Write, and Lock), setup of isochronous transfers, and inquiry of information on the status of the bus and the local node as well as callback functions that are automatically executed in case of external bus events. The latter generate responses to incoming requests without explicit programming in the application. However, the API, the Transaction Layer, and the Serial Bus Management shall be independent of the Link Layer Controller in order to be usable for different embedded systems. Therefore, an additional Hardware Abstraction Layer (HAL) is used that transforms services requested to the Link Layer into corresponding hardware accesses. No embedded real-time operating system is required; time-critical tasks are scheduled via timers of the microcontroller.

For proper operation of IEEE 1394 in industrial environments, a number of requirements must be fulfilled. Firstly, it is important to follow the rules of the PHY manufacturers for PCB design, which include short distance between PHY and LLC, etch traces that match the line impedance of the cable, and avoidance of vias between the PHY and the IEEE 1394 connectors. Secondly, galvanic isolation is self-evident for IEEE 1394a, as described above. Thirdly, EMI protection of the power supply must be applied. Fourthly, shielding and grounding have to be accurate. If these rules are considered, a stable operation of IEEE 1394 nodes can be guaranteed even under harsh industrial conditions. Some examples are described in the following sections.

45.4 Industrial Applications of IEEE 1394

Since the most distinguished feature of IEEE 1394 is its high bandwidth of maximum 50 Mbyte/sec for IEEE 1394a, respectively 100 Mbyte/sec for IEEE 1394b; currently, it is mainly used in industrial systems that comprise some kind of image sensors. They produce a large amount of data that must be transmitted to an image processing system in real time. A typical example is an automated optical quality control of goods. Therefore, the following examples refer to this kind of application. All of them still use IEEE 1394a. The application of IEEE 1394 as field bus replacement will be covered in a separate section.

The first example is an industrial camera that comprises a CMOS image sensor. By using special readout electronics, a dynamic range of 120 dB per pixel is achieved, which allows to capture images with both extremely bright and dark regions, like the welding scene in Figure 45.4. The comparison with an equivalent CCD image (also in Figure 45.4) shows that no artifacts like blooming or smearing occur for the CMOS image. The main applications of this camera will be optical inspection of industrial production like the welding scene in Figure 45.4, but also automotive applications like driver assistance. Here, intensive sun lighting and shadows produce images with enormous contrast that cannot be acquired with conventional CCD cameras.

The IEEE 1394 interface of this camera uses the hardware and software described in the previous section. The camera operates in accordance to the DCAM standard. Since there are already a number of interface cards, image processing systems, and software tools available that support the DCAM standard, this camera can be used for a broad range of industrial inspection systems. Since another application is driver assistance in passenger cars, the special requirements of automotive electronics must be fulfilled. Special IEEE 1394 latching connectors and chip sets for extended temperature range are commercially available.

A second application is a so-called Datalogger for a machine that measures the outer contours of rotation symmetrical workpieces like crankshafts. The piece is placed between an IR lighting unit and some CCD line cameras, whose number (maximum of 10) depends on the diameter of the workpiece. Both the lighting and the cameras are moved along the axis of the workpiece in a synchronous manner, as shown in Figure 45.5. The plug-and-play capability of IEEE 1394 allows an easy reconfiguration of the system for different types of workpieces. Another reason for the use of IEEE 1394 in this application is bandwidth: each camera has 2048 pixels with a 12-Bit color depth and operates at a maximum pixel clock of 20 MHz. The resulting data rate exceeds the bandwidth of IEEE 1394a already for one camera so that areas outside the region of interest are clipped using a lookup table and run length encoded by hardware.

(a)

(b)

FIGURE 45.4 Welding scene acquired with conventional CCD camera (left image) and advanced CMOS camera (right image).

This task, together with the transformation of pixel and additional mechanical data into IEEE 1394 packets, is performed by circuitry implemented in the FPGA. The packets are written into the FIFO and transmitted via the IEEE 1394 subsystem shown in Figure 45.2. With respect to the type of transaction, a trade-off must be made between asynchronous packets that guarantee a secure transmission at the cost of bandwidth for response packets and isochronous transfers that lead to high bus throughput with the lack of feedback upon success or failure. For reasons of security, asynchronous transfers in combination with a proprietary transport protocol have been chosen. However, first experiments have been shown that

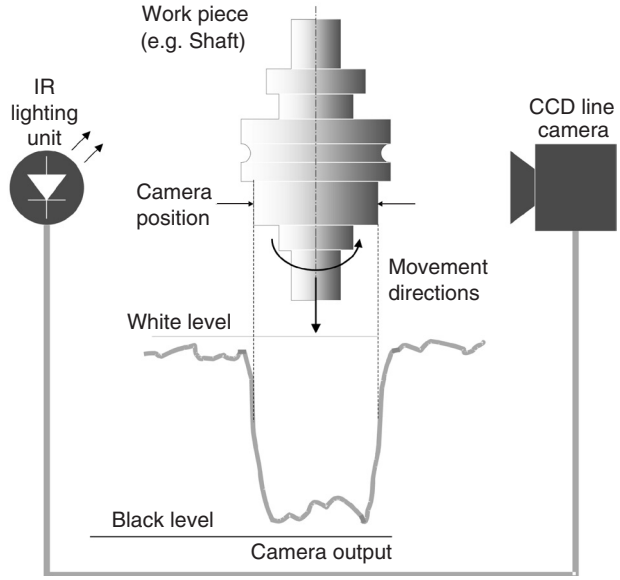

FIGURE 45.5 Working principle of optical measurement system.

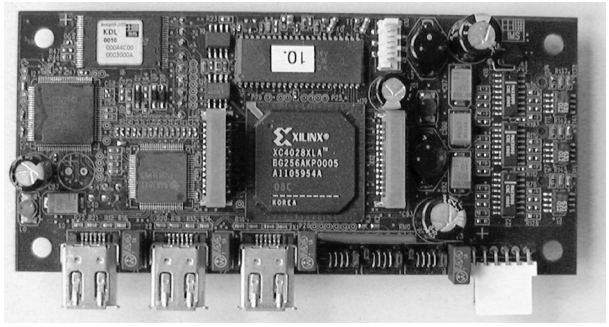

FIGURE 45.6 Module for data compression and transmission used in optical measurement machine.

the Datalogger is able to generate data up to 30 MByte/sec; but the connected PC that performs the image analysis cannot handle such amount of data over a longer period of time. Therefore, it is likely that a second version will use isochronous channels for data transmission.

Prototype systems of the Datalogger have been realized (see Figure 45.6) and successfully tested. Due to constructive reasons, only 6 in.^{2} PCB area can be used per camera. The complete system has passed intensive EMC/ESD testing since all rules mentioned in the previous section have been strictly followed. The machine operates in the direct neighborhood of machine tools; but no faulty operation of the IEEE 1394a bus has been observed so far.

The third device is a so-called Color Photo Scanner for extremely high-resolution image acquisition. It is used for applications in which short acquisition time is not the most important issue, but a precise imaging of fine details, like in optical inspection of printed circuit boards. The design goal has been a geometrical resolution of more than 8000 pixels for the shorter edge of the image area and a color depth of 12 bits per elementary color. In order to avoid the enormous costs of a corresponding CCD area sensor, a mixed mechanical–optical principle has been chosen. An arbitrary 3D scene is projected onto a focusing screen via a lens and the resulting 2D image is scanned with a CCD line sensor that is moved by a step

© 2005 by CRC Press LLC

FIGURE 45.7 Color Photo Scanner.

motor. This results in an image size of 8192 times 12,000 pixels per image. In order to reduce the scanning time to the physically minimum duration — integration time per line times number of lines — two hardware tasks must operate in parallel: one must control the CCD sensor, the motor, and the analog, respectively digital image processing circuitry, and the other one the transmission of data via IEEE 1394.

The architecture of the Color Photo Scanner (see photo of the final product in Figure 45.7) is derived from the reference design described in the previous section. The two hardware tasks are implemented inside the FPGA. Instead of the FIFO, a fast SRAM organized as a cyclic buffer is used as an interface between these two tasks. The design makes use of the fact that the high-speed port of the LLC can also handle asynchronous packets at high speed, so that the controller does not care about the mass data. It only executes the IEEE 1394 protocol stack and an implementation of the SBP-2 protocol that is used for the control and setup of the scanner. The microcontroller provides enough computing power for that purpose. The device that has become a commercial product is able to capture a complete image within 90 sec, which can only be achieved by hardware support of the FPGA. All necessary parts fit into the modified housing of an SLR camera.

45.5 IEEE 1394 Automation Protocol

The previous section describes some industrial applications of IEEE 1394 but leaves real industrial communication networks out of consideration. This application field has been dominated by proprietary solutions in the past. Only recently, situation has changed with the passing of the "1394 Automation Protocol," short 1394AP. Its theoretical principles are defined in [8]

In industrial automation, a trend toward decentralized systems can be observed over the last few years. In conjunction with the growing capabilities of embedded hardware, more and more of the system functionality is transferred from the central control unit to distributed control units. A typical example is motion control: the system consists of several I/O modules and decentralized control units to drive the axes. One control node is designated as the host control. This node is responsible for maintaining the network, which includes startup and parameterization, control and supervision of all system components, and network management. Most of the time, the host control is implemented on an industrial computer, but this task may be assigned to an; one of the control units.

Several buses have been established in industrial control in order to connect the decentralized modules, like Ethernet and its derivates, Profibus, CANBus, SerCos, and others. All these technologies lack one important feature: there is no method for cyclic, deterministic distribution of control information with guaranteed delivery at fixed intervals, which is a prerequisite for industrial, especially motion control systems. However, this type of information exchange is one of the characteristics of IEEE 1394: its isochronous mode for data transmission. Therefore, a number of companies selling products for factory

© 2005 by CRC Press LLC

automation have integrated IEEE 1394 in their equipment, but are still using proprietary protocols, so that interoperability is not ensured. This limitation shall be overcome by the 1394AP. Its specification as well as the development of a reference implementation have been initiated by the European "1394 Automation" association, which consists of more than a dozen factory automation companies and research institutes.

IEEE 1394 matches the requirements on communication in industrial control systems:

- Communication network has to be fast, robust, and inexpensive.
- IEEE 1394 supports distributed architecture as a tree structure. Isochronous and asynchronous transmission schemes permit unrestricted communication between the system components.
- IEEE 1394 itself already provides the cycle clock synchronization, which has to be expanded to control specific data exchange.
- Low jitter of IEEE 1394 is one reason that makes this bus attractive for industrial control.
- The variety of IEEE 1394 devices guarantee independence from a single supplier and its price policy.

Therefore, IEEE 1394 is an almost ideal choice for industrial communication networks. However, specific features like Network Topology, Application-Specific Control and Status Registers, Packet Payload, Network Management, and Message Synchronization have to be defined, which makes up 1394AP. Because of the special requirements of industrial communication, 1394AP differs somehow from the usual properties of an IEEE 1394-based transport protocol.

One node of the network acts as the so-called Application Master. Most of the times it will be the control PC of the network; but any other node with sufficient computing power may fulfill this function. The capability of becoming Application Master is stated by special entries in the Configuration ROM of the 1394AP node. Since the Application Master is responsible for synchronization of all nodes and the usual IEEE 1394 cycle start packets are used for this purpose, the root of the tree-like network shall become the Application Master. All nonroot nodes are called slaves.

The main task of the Application Master is the cyclic transfer of input data to the slaves. This information is summarized in the Master Data Telegram (MDT), which is the payload of an IEEE 1394 packet. The update rate of the control variables can be adjusted via the 1394AP-specific Application Cycle. Its length is based on the requirements of the application. For high-speed applications, the Application Cycle is identical to the standard IEEE 1394 isochronous cycle of 125 μsec. In this case, the MDT is the payload of isochronous packets, which are sent immediately after the Cycle Start Packet. In case of reduced performance requirements, the Application Cycle is spread over several isochronous cycles. Then, for the MDT, both isochronous and asynchronous packets can be used. In the first case, each packet only carries part of the complete MDT; in the second case, asynchronous broadcast write requests are used. The MDT of 1394AP only defines a data structure for transmission of application-specific variables, but does not specify the meaning of the variables itself. This is left to the application, which gives flexibility for the use of 1394AP. While the slaves receive the MDT and extract the data that are necessary for proper operation, they output their data via the Device Data Telegrams, short DDT. The DDTs transfer the output data both to the master and to the other slaves, so that an actual peer-to-peer data transfer is ensured. The remarks on Application Cycle for the MDTs are also valid for DDTs. Each node provides Network Management services, which include Node activation, suspension, configuration, initialization, and reset as well as Error handling. The Network Master — identical to the Application Master — controls changes in the state of the nodes.

One of the main reasons why IEEE 1394 has been chosen as a control bus for real-time systems is due to its deterministic timing via isochronous data transfer. The clocks running in each individual node are synchronized every 125 μsec by the Cycle Start Packets. Data to be sent either as MDT or DDT are held in local buffers and marked with a time stamp. The time information contained in the Cycle Start Packets is used as a trigger that releases the data for transmission. One problem has to be overcome if isochronous and asynchronous data transfers are mixed. After a cycle starts, first all isochronous packets are sent, and the remaining part of the cycle is used for asynchronous data. However, IEEE 1394 does not check if the transfer of one asynchronous packet can be terminated within 125 μsec since the last cycle start. If

© 2005 by CRC Press LLC

not, the next Cycle Start Packet will be delayed. For 1394AP, this results in nondeterministic timing, which is not acceptable. Therefore, the root note also implements some functionality summarized as Asynchronous Resource Manager that prevents the delay by managing the limited asynchronous resources between all nodes of the network.

For first experiments, a communication node that supports features of a preliminary version of the 1394AP protocol by hardware has been designed. It can only be used as a slave node. Principally, it again uses the system design depicted in Section 45.3, but comprises a different Link Layer Controller because of the special communication pattern defined in 1394AP. The "GP2Lynx" is only capable of either sending or receiving isochronous data, but not both simultaneously as required for MDTs and DDTs. Therefore, the Texas Instruments TSB42AB4 "CeLynx" device is used in this design. Originally targeted to consumer electronics, it is also well suited for industrial applications and supports full duplex isochronous streaming.

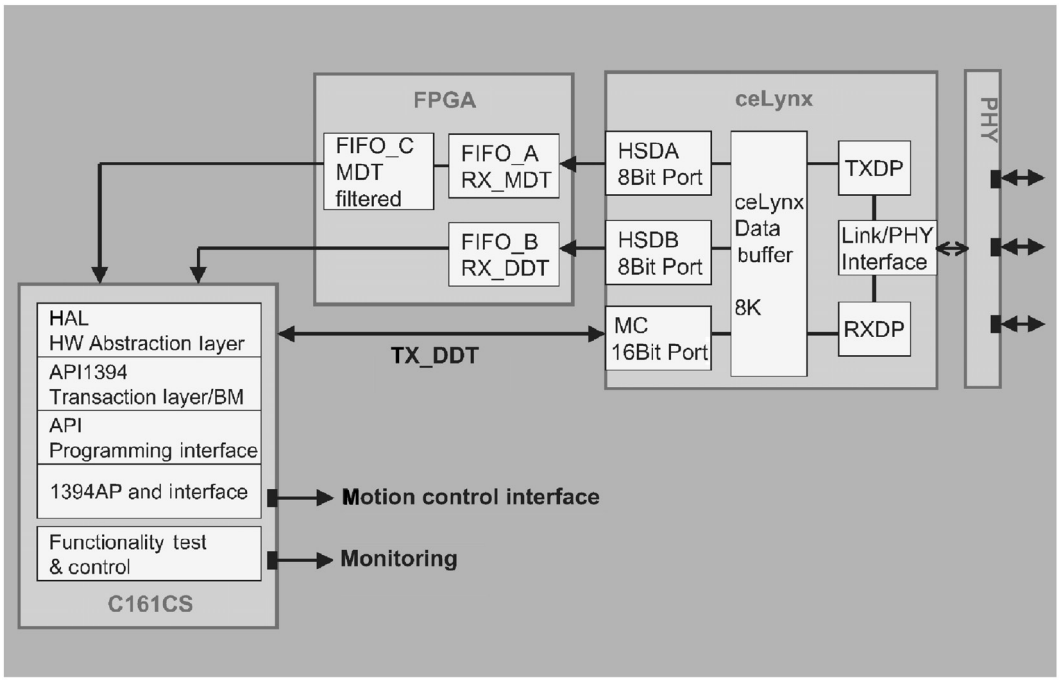

FIGURE 45.8 Architecture of node for synchronous industrial communication via 1394AP.

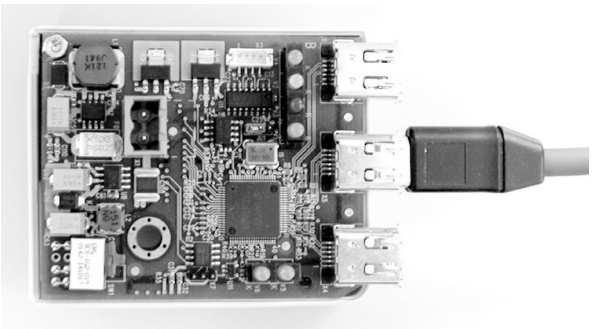

FIGURE 45.9 Node for synchronous industrial communication via IEEE 1394.

© 2005 by CRC Press LLC

The resulting schematic of the node is shown in Figure 45.8. The FPGA filters the data of incoming MDTs and DDTs, so that the microcontroller of type Infineon C167CS only has to handle relevant data. Outgoing DDTs are sent as asynchronous packets and directly written into the Link Layer Controller by the microcontroller. Figure 45.9 shows the industrial communication node. It is a stacked design using two PCBs; therefore, part of the circuitry is not visible in Figure 45.9. Experiments with this embedded system have shown that 1394AP is suited for industrial real-time communications, especially for motion-control systems.

45.6 Summary

The four examples in the last two sections show that IEEE 1394 is an emergent and well-suited technology for industrial applications. However, some minor problems exist:

1. Currently, almost all IEEE 1394 devices use IEEE 1394a, which limits the distance between two nodes to 4.5 m as defined by the standard, while high-quality cables allow up to 10 m. But for large industrial systems, this might still be not sufficient.
2. The DC coupling of physical layers in IEEE 1394a implies the danger of disturbance problems, especially in harsh environments.
3. The number of devices on one bus is limited to 63, which may be not enough for certain applications. IEEE 1394 bridges that can connect up to 1023 buses are currently in the specification phase, but it will take some time since first devices are available.
4. If IEEE 1394 is used inside machines with little space left for cabling, the conventional cables and connectors are not optimal. Smaller IEEE 1394 connections for short distances, like, for instance, PCB stacks or flexible printed tapes, are desirable.

The first two items will disappear with the widespread use of the IEEE 1394b amendment; the third one is tackled by the upcoming 1394.1 specification. Unfortunately, the last item remains a field of design experiments, because a standardized solution does not exist at the moment.

These items shall not prevent the use of IEEE 1394 for industrial and factory automation applications. The basic technology consisting of IEEE 1394 chip sets, hardware reference designs, as well as software protocol stacks are already available, and first commercial applications have been realized. Therefore, it is very likely that a large number of industrial systems will incorporate IEEE 1394 for data transmission in the near future. The most important limitation of the original standard — limited reach of 4.5 m between two nodes via copper cables — has been overcome by the new IEEE 1394b amendment. In summary, IEEE 1394 is already more than an emergent technology nowadays, since it will be widely used in industrial applications very soon.

46.1 Introduction

Since the advent of industrial communications, dozens of solutions have been designed that all claim to solve the problem. This is true but most of the time in a given context. The reason for this is that there is no single case in industrial communications. Most of the time, industrial processes are organized in a hierarchical manner and, depending on the location in the hierarchy, needs will differ. The manner in which the control software is written also introduces different needs in the communication networks. To select a communication network, it is thus important to understand the different views that the network designers have when they build their solution.

In this chapter, we will first describe the way industrial production is organized. In the second part, the differences of approaches in architecturing control applications will be explained. When introducing a network to support communication between control entities, a number of constraints are added, such as errors and delays. As they have an impact on the system, they will be detailed in the third part. The last section will present selected industrial networks and show which type of application they may support and how well they do the required job.

© 2005 by CRC Press LLC

46.2 Production Hierarchies

Control of a production system is performed by numerous computers organized along several hierarchical levels. Computer networks provide communications between the computers within a level and with some of the computers at adjacent levels.

Before presenting the different levels in more details, let us say that the closer an application is to the process, the higher the temporal constraints (ISO 1994). Conversely, the quantity of transferred data increases with the level in the hierarchy. The position of an application in the production hierarchy also influences the way the application software is built. Applications at the lowest levels often adopt a time-triggered approach (see Section 46.4), while at higher levels an event-driven approach is used in most of the cases.

Numerous factory models, also known as CIM models, have been described in the literature (for a summary, see [Jones et al. 1989]). In terms of hierarchy, all the above proposals do not differ very much. Differences exist mainly with respect to the number and the labeling of the levels. Figure 46.1 depicts a possible summary of these proposals. This figure shows that there exists a more profound difference between process control and manufacturing.

The primary purpose of a plant control system, organized in a hierarchical manner as in Figure 46.1, is to manage the process as seen through the sensors (level 0) by acting upon it through actuators.

Sensors and actuators are linked to the first level of automation (level 1), where each automation device controls a variable of the process in such a way that it stays within limits or follows set point data given by the next level of automation (level 2). Level 1 corresponds to an "axis," control of a single entity, in manufacturing or a local loop in process control. The variable may be discrete, such as a tool changing mechanism in a machine-tool, or continuous such as an axis in a robot or a heater in a distillation column.

Units at level 2 elaborate the set point data or the limits for variables that have to be linked or related to ensure a proper operation. This is typically the purpose of an interpolator in Computer Numerical Controller (CNC) or a tool magazine controller for a machine-tool or, a robot path controller that gives the set point data for joints in order to follow a given path. These units receive their commands from and return their status to the machine or process level (level 3).

Units at level 3 coordinate the actions on, or the operating conditions of, several elements or groups of elements in order to realize or optimize operations or sequences of operations on objects, either solid or fluid. They receive their commands and report to the line or Distributed Control System (DCS) level (level 4).

Units at levels 1 to 3 also have to perform diagnostics on themselves, detect emergency conditions, and take an immediate decision if they have enough information to do so. Otherwise, they report to the next upper level for decisions.

Level 4 units are responsible for optimizing the production, that is, scheduling when and where given operations are performed on objects, and for ensuring that all necessary resources are present.

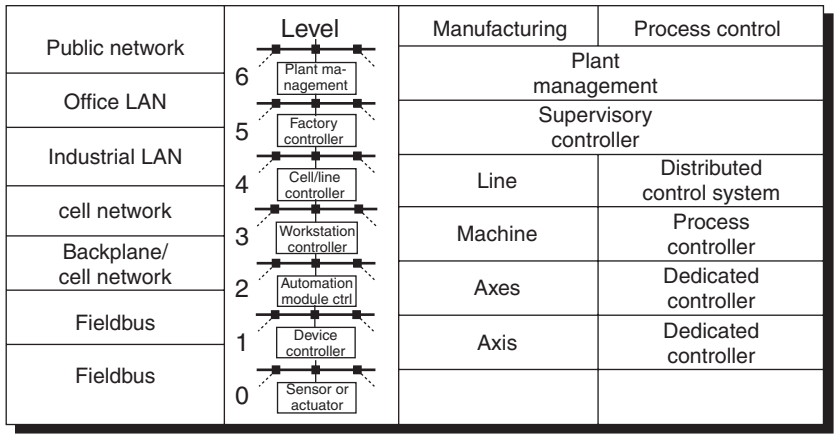

FIGURE 46.1 Production hierarchy.

© 2005 by CRC Press LLC

Level 5 normally corresponds to the elaboration of a single product or a family of products on the same devices. That is where process planning for products is performed.

Level 6 represents the top level of a plant. Basic functions performed at this level are product design, resource management, high-level production management with interarea production scheduling, plant policies establishment, etc.

At the top, we may find a corporate management level (not shown in Figure 46.1) that is linked to the different sites or plants via public or corporate networks. At this level, all the nonproduction activities (research, finances, ...) of the enterprise can be linked.

It should be noted that some of these levels might be absent in a given enterprise. Depending on the level of automation and the control structure, level 2 and even level 1 might be included in level 3. Levels 5 and 6 might also be collapsed into a single level. Today, there is a clear tendency to reduce the number of levels. However, the functions described above are always present whatever the number of levels.

46.3 Processes Types

Processes controlled by computers are usually classified according to two paradigms: continuous systems and discrete event systems (Halang and Sacha 1992).

An example of a continuous process is a temperature regulator that keeps the temperature in a reactor within preset limits around a given set point value. Such a system reads the temperature as given by a sensor, compares it with the set point value, computes the necessary correction using an adequate control algorithm, and energizes a heating actuator accordingly. This sequence of operations is repeated at regular intervals, often periodically. The period is set according to the dynamics of the controlled process.

On the other hand, the control of an elevator pertains to the class of discrete systems. Let us describe a part of a typical sequence of operations. While the elevator is approaching its destination floor, the system is expecting that the floor deceleration sensor turns on, in which case, the control system has to react by decreasing the speed of the elevator. In the next step, it has to stop the elevator when the floor sensor indicates that the floor has been reached. During this sequence, other events may occur such as summons requests from external passengers. Such requests may either alter the current sequence of operations or just need to be memorized for later treatment. In addition, a given event may not be interesting at all times. In the above example, the deceleration event is only of interest if the elevator has to stop on the corresponding floor. Event detection needs to be disabled sometimes and enabled again later. An essential characteristic of discrete event systems is that, if the action triggered by the occurrence of an event is perfectly known, the point in time at which this event will occur is *a priori* unknown. Furthermore, the order in which two or more events occur is often very important.

Batch Systems

Several physical systems present both of these aspects, they are called batch, "MIXT" systems.

46.4 Control Systems

Continuous systems and discrete event systems implemented by cyclic or periodic polling are often called time-triggered systems or sampled data systems.

Discrete events systems implemented using interrupts or internal software events are referred as event-triggered systems (Kopetz 1991).

Time-Triggered Systems

From the control system viewpoint, continuous systems will be implemented as looping tasks that wait the beginning of the period, sample their inputs, compute the new output values, and set the actuators according to the new values. Periodicity is not mandatory but is often assumed as it leads to simpler algorithms and more stable and secure systems. Most of the algorithms developed with this assumption are

© 2005 by CRC Press LLC

very sensitive to period duration variations, jitters in the starting instant. This is especially the case in motor controllers in precision machines. Simultaneous sampling of inputs is also an important stability factor. Let us assume that the controller implements a state-space control algorithm in which the state vector includes the position, the speed, and the acceleration of a mobile, and that the actual values are obtained by three sensors, a position encoder, a tachometer, and an accelerometer. The control algorithm assumes that measured values were acquired at the same instant. For the control systems, this translates into what is called simultaneous sampling. The acquisitions are indeed not really simultaneous if only one processor is devoted to the three operations. Their instants must, however, be as close as possible and remain apart under a given limit, which may be roughly estimated to two orders of magnitude below the period.

Discrete Event Control Systems

Discrete event systems may be implemented as a set of tasks activated by event occurrences. Let us define an event as a significant change (or a sequence of significant changes) of state of the process (the so-called occurrences). This change, the event, is detected by some input circuitry that continuously monitors the input and is transformed into an interrupt (detection may also been done by software). The event is handled by a task that undertakes the required actions. The time elapsed between the occurrence of the event and the corresponding reaction, often called reaction time, is bounded and given in the requirements. Reaction times may depend on the kind of event. Reactions to events are normally handled according to the order of arrival of the events. However, some events may be more important than others. The emergency stop in an elevator is clearly more important than a summon request. This will translate into priorities in the event handling. In any case, the order in which events occur is important for the application.

The above implementation technique is conventional but is not the only one. It is always possible to implement a discrete event system as a continuous one. In such a case, all the inputs are sampled at regular intervals by the control software that detects the changes and undertakes the necessary reactions. This is the way most Programmable Logic Controllers (PLCs) are implemented. With such an implementation, precedence between events may only be asserted if the events are detected during different polling cycles. If two events are detected during the same cycle or period, they will be considered as simultaneous. The cycle duration or the period should be selected in such a way that all events can be detected. In the elevator example, if the deceleration switch closes during a minimum of 20 msec, the polling period should clearly be lower in order to detect the close event.

In summary, continuous control systems exhibit four important characteristics:

- they are cyclic and often periodic, and period values are set according to the process dynamics,
- jitters in the period should be limited to a few percent of the period,
- the instants of input acquisition and output settings are known in advance and dictated by the control system, and
- all inputs need to be sampled nearly simultaneously.

Discrete event systems may be implemented as continuous ones are. They then exhibit the same characteristics but are not necessarily periodic. However, the cycle time should be kept low enough so that all events may be sensed. These systems may also be implemented using interrupts with the following characteristics:

- event occurrence instants are not known,
- the reaction time to an event is bounded,
- the order of occurrence of events is important,
- reaction to some events may have a higher priority,
- detection of a given event may be temporarily disabled, and
- there is a limit in the density of event occurrence that may be handled by the control system.

From the control point of view, a control system is often composed of a part that is time triggered and of a part that is event triggered.

© 2005 by CRC Press LLC

46.5 Communication Systems

The communication system is there to support the interaction between the control applications. On a given computer, different applications may coexist, some being time triggered some being event triggered. They may communicate with distant applications of the other kind (a time-triggered application may communicate with an event-triggered application).

The communication network itself may be built according to the event-triggered or time-triggered paradigm or a combination of both. Matching a time-triggered application with a time-triggered network is obviously more easily performed than with an event-triggered communication system. The latter requires some additional adaptation. Ideally, the communication system should support both views.

Communications Models

Communications models define how the different application processes may cooperate (Thomesse 1993). The most widely used communication model is the client–server model. In this model, processes interact through requests and responses. The client is the process that requests that an action be performed by another process, the server. The server carries out the work and returns a message with the result. Client and server only refer to the role the processes play during the remote operation. A process that is a client in some operation may become the server for another one. Hence, this model is clearly a point-to-point model.

This model exhibits a number of drawbacks for control applications. First, time is not taken into account. It is impossible to specify a delay between the request and the response and have some means to check that this delay would be respected because the server application is involved in the response. Second, if a client wants to make simultaneous requests to several servers, this may only be performed sequentially, one request after the other. Finally, if two clients make the same request to a server; this one will treat the requests in sequence and the answers may be different. For example, two control nodes may request the value of a sensor attached to a server node. The value returned to the first client may differ from the value returned to the second. The last two problems may be solved by adequate algorithms running on top of the client–server interaction. This results in heavy implementations with often poor performances. However, for a number of remote operations, in particular, during the configuration and setup phases, these problems do not appear and the client–server model is a good solution. For real-time operations, industrial networks need to offer performing and simple solutions that solve the problems of the client–server model. This has led to the "producer–consumer" model (sometimes called publisher–subscriber model), which is a multipoint model. This model is restricted to the transfer of information values and as such well suited to time-triggered systems.

In the producer–consumer model, each piece of information has a producer and one or more consumers. When the producer has some information ready, it gives it to the network. This one transfers the information and makes it available to the consumers. This has some advantages over the client–server model:

- The producer and the consumers need not be synchronized. The consumer need not wait for the response of the producer as in the client–server model. If the information is already transferred, it may use it; otherwise, it considers that no new information is available.
- The same information can be transferred at the same time to all the consumers. The network may thus be used in a more efficient way.
- Two or more consumers will work with the same value at a given time.
- Flow control is no longer necessary as a new information overwrites the previous one. This assumes that the production of a new information outdates the previous one.
- Synchronization between applications can be implemented as production of a synchronization variable.

However, this model comes with a price. As the consumer has no way to relate the information with an explicit request (as in the client–server model), it should be able to know the age of the information. Networks implementing the producer–consumer model should be able to tag the information with some attributes from which this information can be extracted.

© 2005 by CRC Press LLC

The producer–distributor–consumer model is an extension of the producer–consumer model that adds an extra level of separation between the production and the transfer of information. The additional role, the distributor, is in charge of transferring the information from the producer site to the consuming sites. In such a way, transfers are no longer triggered by production but are done according to rules defined for the distributor. This offers more flexibility in the scheduling of transfers in the network and results in an improved efficiency.

Temporal Consistency

Temporal consistency has two facets: absolute temporal consistency and relative temporal consistency.

Absolute time consistency is related to the age of information. A piece of data has been produced at a given time. It is later transmitted over the communication system. It is finally used at some point in time. A piece of data is said to be time consistent in the absolute way as long as the difference between the instant of production and the current instant does not exceed its validity duration. In other words, a piece of data should not be used if it is too old. This behavior is easy to ensure when all takes place on the same computer. When the data are transported over a network, the information is often lost.

In a time-triggered application, the control application expects that all input data have been acquired at the same time. The measurements have been done in a given time window. This property is called "production time coherence" in the Field Instrumentation Protocol (FIP) standard, and more generally, we can speak of "time consistency" each time that some actions must be done in a time interval (ISO 1994). It is called temporal (or relative temporal) consistency (Kopetz and Kim 1990, Kopetz 1988).

It is defined as follows. Let us consider two variables a and b. Let $[a, ta, va]$ and $[b, tb, vb]$ be two observations of a and b, where va and vb are two samples of a and b taken at times ta and tb. The samples are said to be temporally coherent from the production point of view if $| ta - tb | < R$, for a given R, where R is the temporal consistency threshold.

Spatial Consistency

As defined by Le Lann (1990), a distributed system is "A computing system whose behavior is determined by algorithms explicitly designed to work with multiple loci of control." In such systems, there are a number of control nodes that do not work independently but cooperate to perform common tasks. Cooperation may be needed to achieve a certain degree of fault tolerance or because the overall control task is too large to be handled on a single node.

Time-triggered distributed systems work periodically and the various loci of control synchronize their operations according to the passage of time. To do so, they cannot rely on local timers and need to share a common sense of time (Verissimo 1994). This may be achieved through a distributed clock synchronization algorithm (Kopetz and Ochsenreiter 1987) or, with some restrictions, using temporal "events" generated by the networks (He et al. 1990). In such systems, the various loci of control only exchange data, or state information. Obviously, all data necessary for the computations should be available to all loci of control before the synchronization instants; flow control is done statically. A single unit of data may be needed by several control nodes. As these nodes do not share a common memory, the data unit needs to be replicated in each node. This may be done by a broadcast transfer; but we need to have some guarantee that all replicas are identical at the time they are used. This property is called spatial consistency. It may be obtained by a reliable broadcast algorithm (Hadzilacos and Toueg 1993) or, as in FIP, if only an indication of spatial consistency is necessary (Decotignie and Prasad 1994).

Event Ordering

Event-triggered control systems are often very sensitive to the order in which events occur. Networks do not guarantee that requests for information transfers are handled in the order they are submitted. This means that the applications cannot rely on the order in which they receive the events from the networks to establish the order of occurrence of events in time.

© 2005 by CRC Press LLC

Influence of Failures

Failures cannot be avoided but their influence must be minimized. In the value domain, possible failures may be undefined values or defined values considered as correct but incorrect *vis-à-vis* the related input. In the time domain, crash failures, omission failures, and timing, early or late, failures may occur. Coping with failures is the subject of fault-tolerant computing (Le Lann 1992) and, as such, beyond our scope. However, it is worth discussing the impact of the network on the system with regard to failures. With the introduction of a network, faults may occur in a number of additional entities, links, emission and reception circuits, and software. Links may be cut intermittently or permanently and may be subject to perturbations that mutilate the transmitted information. Emission and reception parts in nodes may stop, respond too quickly or too early, and emit when they are not allowed to or even constantly. Networks have been designed to resist faults by detecting and correcting errors using three types of redundancy: time redundancy, physical resource redundancy, and information redundancy. For example, redundant information is added to each message transferred on the network in the form of an error detection code, parity, or Cyclic Redundancy Check (CRC). Each code exhibits a given detection capacity, which means that there are a number of errors that may not be detected at the network level. Crash, omission, and timing failures are normally detected through the use of timers. In time-triggered systems, this detection is easy because each node has to transmit periodically. The absence of message arrival in the period indicates a possible failure, and appropriate countermeasures may be taken in the application. Furthermore, error correction may be based on temporal redundancy by retaining the previous value and just waiting for a new value at the next period. Event-triggered systems are more difficult to handle. Mutilated frames may be detected as previously and signaled to the sender by a negative acknowledgment from the receiver. The sender waits for the acknowledgment, either positive or negative. Omission failures are detected by the absence of acknowledgment in a given delay. In case of negative or absent acknowledgment, the emitter retransmits the same message. This process is repeated until success or a maximum number of retries have been reached. This means that, to cope with possible faults, acknowledgments are necessary. Furthermore, the time necessary to transfer a message from a sender to a receiver may greatly vary with a corresponding degradation of the application response time. It also introduces a delay in the transmission of other messages. A second potential problem in event-triggered systems is the difficulty to distinguish a node crash or an omission failure from an absence of event occurrence. A receiver node, for instance, an actuator node, that does not receive any message may either assume that the control node has failed or that there is no new command. In the first case, the actuator should be put in some safe mode, while in the latter no special treatment is to be done. This means that liveness messages should be sent at regular intervals in addition to normal messages.

Some failures may prevent the network from functioning if the network has not been designed properly. For instance, if all traffic is ruled by a single node, the case of centralized medium access control, a crash, or an omission failure of this node causes the network to stop unless this node is duplicated and some recovery protocol is implemented. Some node may also start transmitting messages constantly or at point in time where they are not allowed to do so. This may be the case with some deterministic Carrier Sense Multiple Access (CSMA) protocols where collision resolution is based on a priority.

46.6 Parameters to Consider in a Choice

When selecting a network for a given application, there are a number of parameters to consider:

Communication models: As described above, two main models are used in building an application layer: the client–server model and the producer–distributed–consumer model (sometimes also called the publishe–subscribe model). Distributed applications are likely to use the latter, while hierarchically organized applications may use the former.

Traffic types: Information transfers may be sporadic (event-triggered), cyclic, or periodic. In the last case, the application may impose strict limits in the jitter between consecutive transmissions of the same data.

© 2005 by CRC Press LLC

Topology and transmission medium: If most solutions permit a tree-like topology, there might be restrictions in the branch lengths and the number of nodes in the tree. Some solutions also offer transmission media other than copper-based twisted pairs. Examples are optical fibers or radio transmissions.

Immunity to noise, environment: Networks can be used in difficult environments. This is often the case in transportation and petrochemical applications. The physical layer may be more or less resistant to such environments. Selecting an inadequate solution may lead to an increase in error rate in the transmission or even a complete fading in some cases.

Errors: As described above (Section 46.5), transmission errors cannot be avoided even if, with proper cabling and an adequate physical layer, their level can be kept very low. In many applications, temporary errors can be tolerated even if the application is not informed of the occurrence of the error. However, in some cases, this is not acceptable and the network should provide ways to inform the application that an error has occurred.

Throughput: The raw bit rate of a given network is a poor measure of the actual throughput as seen from the application. Overheads in the protocols, response delay in the network stack, medium access control schemes, traffic scheduling algorithms, and delays in the application reduce the actual throughput. As an example, transferring a 16-bit value requires the actual transfer of around 1000 bits with Ethernet, 450 bits with Profibus FMS, 200 bits with CAN, and 90 bits with FIP. Due to the other effects, the actual throughput may be one or two orders of magnitude below the raw bit rate.

Guarantees: Considerable research work has been devoted to calculating the guarantees offered by industrial networks as this is of prime importance to the applications. Guarantees give answers to different questions such as:

- will the network be able to withstand a given traffic load?
- what will be the maximum transfer time of a sporadic event?
- what happens in case of network overload?
- what will be the maximum jitter of a periodic transmission?

If most solutions offer some guarantees, few give answers to all of the questions listed above. Furthermore, most of the time, guarantees are given under the assumption that no transmission error will occur, which cannot be taken for granted.

Consistency: As mentioned above, temporal consistency is assumed in most control applications. Unfortunately, most solutions do not offer any support for temporal consistency and spatial consistency. This implies that this aspect should be added on top of the selected network.

Horizontal vs. vertical traffic: As described above, a network may be used to support traffic between computers of adjacent levels (vertical traffic). It may also be used to ensure communication between control devices of the same level to ensure coordination. Traffic patterns and communication relationships are often different in each case, and the network solution should be able to sustain both.

Services: The application layer of a network provides a number of services to the applications. Services that are not available will need to be implemented in the application. Examples of such services are:

- read and writing typed variables (or objects) with possible indication of freshness,
- read sets of data with possible indication of temporal consistency,
- download of data and programs,
- remote invocation (start, stop, pause, resume) of programs,
- synchronization between applications, and
- receive, send, or subscribe to events with possible indication of time of occurrence.

Configuration ease: For most networks, vendors offer tools that allow configuring a network. This may include setting addresses, initial values to the timers used in the network, periods, priorities, etc. Tools are also available to monitor the network. The availability of such tools may greatly reduce commissioning and management efforts.

Connection with the Internet: With the wide spread of web browsers, it is tempting to put a web server inside each industrial device. This server is used to access non-real-time information such as configuration,

© 2005 by CRC Press LLC

user manual, etc. To implement such a capability, the transport protocol should be able to carry the HTTP protocol messages. However, Transport Control Protocol (TCP) is not mandatory.

46.7 An Overview of Some Solutions

There are dozens of networks used in the industrial domain. Here, we present briefly some of the most well-known solutions. The objective is to put in light the features that make them fit a type of application rather than another.

Actuator Sensor Interface

Actuator Sensor Interface (ASi) (IEC 62026-2) (EN 50295) is a communication bus targeted at simple remote inputs and outputs for a single industrial computer. It is based on a low-cost electromechanical multidrop connection system designed to operate over a two-wire cable, over a distance of up to 100 m, or more if repeaters are used. Data and power are transmitted on the same two-wire cable. It is especially suitable for lower levels of plant automation where simple, often binary, field devices such as switches need to interoperate in a stand-alone local area automation network controlled by PLC or PC.

The master polls the network by issuing commands and receiving and processing replies from the slaves. Connected slaves are polled cyclically by the master with a data rate of 1666 kbit/sec, which gives a maximum latency of 5148 μsec on a fully loaded network (31 slaves). Sixty two slaves can be connected in the extended addressing mode. Each slave may receive or transmit four data bits. There is provision for automatic slave detection.

ASi does not define any application layer but provides management functions to configure or reset slaves and detect new slaves.

Controller Area Network

Controller Area Network (CAN) results from an effort from Robert BOSCH to provide a serial communication multiplexer for transmission of information inside a vehicle. CAN layer 1 and 2 are normalized by ISO (ISO 1993). Strictly speaking, there are a few application layers for CAN, among which CAN Open is the most well known.

CAN is a bus without repeaters that restricts the possible topologies. Up to 30 stations can be connected. Every message to be transmitted is uniquely identified and there is no means to address directly a given station unless a unique identifier is attached to this station. Every station may access the bus when no other station is transmitting. If two stations start transmitting at the same time, there is an arbitration, and the message with the lowest identifier will win. This means that the transmission of a message bearing a high value as an identifier may be deferred for a long period of time and time constraints may only be fulfilled statistically unless an additional protocol (time slots or central access controller) is added.

It should be noted that by using an "open collector" connection to the cable, CAN implements an immediate and collective acknowledge to any transmitted frame. Hence, the protocol is efficient and spatial consistency may be easily implemented.

At the application layer, CAN Open offers adequate services for sporadic (event) transfers using the producer–consumer model with minimal support of consistency. CAN is not adequate for periodic transfers. As a response, TT-CAN has been developed.

Through its deterministic collision resolution mechanism, CAN offers ways to determine the guarantees offered by the network. Its behavior in the presence of overload is known: low-priority messages cannot access the network any longer. This implies a careful configuration of the network.

DeviceNet (IEC 62026-3 2000) and SDS (Smart Distributed System) (IEC 62026-5 2000) are partly based on CAN.

© 2005 by CRC Press LLC

HART

HART (Rosemount 1991) has been designed by ROSEMOUNT to interconnect transmitters in process control applications. HART may run over existing 4–20 mA lines on a point-to-point mode or on twisted pairs in a bus configuration. In the first case, process values are usually transmitted by analog means and HART is used for configuration and tests.

In the multipoint (bus) mode, up to 15 devices may be remotely powered from the master station while fulfilling intrinsic safety requirements. If they are powered locally, much larger number of devices may be connected. All traffic either comes from or goes to the master station. An additional master station (Hand Held Terminal) may be connected to the bus mainly for management purposes.

HART defines an application layer suited to process control applications and is well established in the field.

Beyond this, HART is restricted to very slow master–slave applications.

INTERBUS

Interbus has been developed by Phoenix Contact to implement distributed inputs and outputs on a PLC. It complies with the collapsed 3-layer OSI model and has been standardized by CENELEC (EN50254).

Interbus uses a ring topology with a master station (PLC) and up to 256 slave stations. Twisted pairs are used; but fiber optic cable may be used easily. Topologies are slightly restricted by the ring cabling.

In Interbus, most of the traffic is cyclic or periodic with a single period for all traffic. The traffic is from the master to slaves and *vice versa*. As such, Interbus is targeted to remote inputs and outputs for time-triggered applications.

Simultaneous sampling is available and network guarantees can be easily determined.

LON

LON has been designed by ECHELON especially with building control in mind. It complies with the full seven-layer OSI model and provides a variety of transmission media, including wireless at limited speed (5 kbit/sec). It has been standardized by the Electronic Industries Alliance (EIA-709.1).

On twisted pairs, LON uses the RS485 standard. Repeaters are permitted and a rather general topology may be implemented.

The medium access control is decentralized and contention based (predictive CSMA). Time constraints may hence only be fulfilled statistically. LON has a network layer, and routers are available to interconnect up to 255 subnetworks.

The application layer provides services for sporadic variable and message exchanges without temporal relationship (no support for time stamping). Variables and messages may have different priorities and may be authenticated. The authentication key is assigned to the node. LON has no support for cyclic transfers and cannot ensure periodicity.

Variable may be typed by using one of the predefined types or a C declaration. In the former case, a remote station will be able to read the variable type. Each node may define a variable as an input from or output to the network. In the latter case, when the value of the variable is updated, the new value may be automatically sent to all nodes that have declared the variable as input. Such transmissions seem to take place in a series of point-to-point transfers and not in a broadcast mode as in FIP. A second difference is that the same variable may be updated (declared as output) by several nodes.

Messages may be sent with or without acknowledge in point-to-point or multipoint mode. The content of a message is user defined. Messages provide the means to extend the LON functionality. Loss of interoperability is the price to pay.

MIL-STD-1553

MIL-STD-1553 has been developed for the U.S. air force and the U.S. navy (Haverty 1986). It may be considered as the precursor of fieldbuses, and most of the concepts have been used in other proposals.

© 2005 by CRC Press LLC

Information is communicated over a bus in Manchester II bi-phase encoding at a rate of 1 Mbits/sec. A maximum of 31 Remote Terminals (RTs) can be connected to the bus. Each RT can have up to 30 sub-addresses. They are coupled to the Bus Controller (BC) either directly or via transformers, over a screened twisted pair.

The BC initiates all message transfers. It issues a command frame to a given RT to transmit or receive data. The RT responds by sending a data frame if necessary and terminates the transfer with a status frame. The BC may simultaneously issue a command to receive data to a given RT and a command to transmit data to another RT. This mechanism allows cross-communication between RTs. Command, data, and status frames consist of 16 data bits, 1 parity bit, and 3 bits of Manchester code violation for synchronization at the beginning of the frame.

Very strong requirements are set for cables, coupling transformers, and isolation resistors to ensure very good noise immunity.

MIL-STD-1553 does not define any application layer. There are, however, some attempts to use it in the industry. Due to the high interface cost, its success is very limited.

PROFIBUS-FMS

PROFIBUS is a European standard (EN50170) that adopts a three-layer architecture and includes a full network management part. PROFIBUS has strong analogies with MiniMAP (CCE-CNMA 1995) and may be considered as a rather cheap implementation of this network. It makes the difference between master stations that may transmit on their own and slave stations that may only respond to inquiries from master stations. This allows simple devices to be implemented in an economic manner.

A rather general topology is possible with up to 127 devices connected. Intrinsically safe devices are available from some vendors. Medium redundancy is supported.

PROFIBUS relies on a simplified token passing mechanism that does not offer any guaranteed transfer time. Elaboration of spatial and temporal consistency indications as well as age of data is not standardized and is left to the users.

The application layer may be considered as a subset MMS (MAP application layer) (CCE-CNMA 1995a) even if the syntax in somehow different. There is room for profiles that are more or less equivalent to Companion Standards in MMS. In addition, data access protection is defined and applies to all objects (variables, programs, domains) manipulated by the application services.

PROFIBUS FMS introduces the idea of cyclic exchanges of data. However, this has very little impact on the application services. In fact, cyclic data exchanges are added to handle data transfers from slave stations and not for cyclic user data transfers.

As a cell network, PROFIBUS fulfills most of the requirements. One may regret the absence of application services for event management and application synchronizations (semaphores).

As a fieldbus, i.e., a network placed between sensors and actuators, whether intelligent or not, and the first level of automation, PROFIBUS suffers from five main drawbacks:

- it does not offer periodic services,
- it does not offer any services related to temporal and spatial consistency,
- it does not offer any services for evaluation of the age of a data sample,
- it only fulfills time constraints statistically, in other words there no guaranteed response time, and
- it forces an equal traffic volume on all masters.

Other problems are the absence of standardization of the maximum response delay, the absence of segmentation and the exclusive use of a client-server model (point-to-point) although the Information Report service on a broadcast or multicast connection may be used to implement a *producer-distributor-consumer* model. To overcome these problems, the easiest solution is to design a single master PROFIBUS network which is far from a good use of the standard.

However, PROFIBUS is a very serious replacement for MiniMAP. Efficient implementations exist at a reasonable price. It should be carefully considered when looking for a cell-like network implementation.

© 2005 by CRC Press LLC

PROFIBUS-DP

PROFIBUS-DP is also covered by European standard EN50170. It shares its physical and data link layers with PROFIBUS-FMS. DP is targeted at remote inputs and outputs and has normally one master station and a number of slave stations.

Traffic is essentially cyclic from the master to the slaves and vice versa. In the absence of other master stations, some real-time guarantees can be calculated.

SERCOS

SERCOS results from a common effort of the German Machine-Tool (VDW) and Drive Manufacturers (ZVEI) to design a communication means between CNC and motor drives. It has been standardized by IEC (IEC 61491 2002) and CENELEC (CENELEC 1998a).

SERCOS is a ring where the link between each node is an optical fiber. High noise immunity is thus provided. There is a central station in the CNC and all traffic either comes from or goes to this master station. However, medium access control is not under the control of the master, which would have rendered the network much more efficient. Rather, every slave (drive) has a time slot in which it may transmit information. The selection of the slot is done at startup and takes into account the response time of each device (drive).

Each transmitted frame may contain real-time data as well as messages for configuration. As a maximum of 2 bytes may be sent per frame, messages must be segmented in a large number of segments and reassembled at reception.

Even if SERCOS is not really structured according to the OSI model, a large number of application-layer services are defined. These services mainly apply to drives.

SERCOS provides simultaneous sampling of the inputs and handles periodic traffic at a minimum of 62.5 msec. Real-time traffic is guaranteed. Up to 254 drives can be connected.

WorldFIP

FIP is a European standard (CENELEC 1996) that complies with the ISO collapsed three-layer model. Its physical layer conforms with the Fieldbus international standard (IEC61158) and provides IEC level 3 EMC noise immunity. It includes a full network management part.

FIP assumes that most of the traffic is cyclic or periodic. In this case, each transfer is from a producer to a number of consumers. For real-time data, the producer–consumer model is used. Different periods or cycle durations may coexist on the same network.

The deterministic nature of the traffic justifies a central medium access controller, the *distributor,* or *Bus Arbiter*. For reliability purposes, redundant Bus Arbiters can be added. In FIP, cyclic traffic scheduling is performed by the Bus Arbiter based on the needs expressed during the initialization phase by each communicating entity. Sporadic traffic is scheduled based on the needs expressed at run time.

FIP supports two transmission media: shielded twisted pair and fiber optics. The topology is very flexible. Medium and line-driver redundancy are supported. Up to 64 stations can be connected without repeaters.

As mentioned above, FIP medium access control is centralized. All transfers are under the control of the Bus Arbiter that schedules transfers to comply with timing requirements.

The data link layer provides two types of transmission services: those for variable exchange and those for message transfer. Transfers of variables and messages may take place under request from any station or cyclically (or periodically) according to system configuration.

Variables are exchanged according to the *producer–distributor–consumer* model, and identified by a unique 16-bit identifier known from the producer and the consumer. The identifier is not related to any physical address.

© 2005 by CRC Press LLC

Messages are transferred from a source station to a single or all destination stations according to a *client–server* model. Each message holds its source and its destination address. These addresses are 24 bit long and identify the segment number and the address of the station on the segment (in fact, the link service access point). Messages are optionally acknowledged.

For real-time data exchange, FIP behaves like a distributed database being refreshed by the network periodically or upon demand. All the application services related to periodic and sporadic data exchange are called Manufacturing Periodical/Aperiodical Services (MPS). MPS provides local read/write services (periodic) as well as remote read/write services (sporadic). Accessed objects are variables or lists of variables. For variables, information on freshness is available. For lists of variables, FIP provides information on temporal and spatial consistency status.

In addition, FIP provides a conventional client–server model for messages and events with a subset of MMS as the application layer. The available services are defined according to classes: sensor, actuator, I/O concentrator, PLC, Operator Console, and Programming Console. The MMS subset covers Domain Management, Program Invocation, Variable Access, Semaphore and Journal Management, and the basics of Event Management. Syntax and encoding rules conform to ASN-1.

Ethernet-Based Solutions

Ethernet has been used since the beginning of the 1980s in industrial communications. Even if a few solutions (Le Lann and Rivierre 1993) introducing some degree of predictability in this technology have been designed and produced, users in the industrial domain were reluctant to use Ethernet due to its lack of guarantees. More recently, due to its low cost and wide spread, there is a revival in the interest in using Ethernet (IEEE 802.3) as a communication network in factories.

Ethernet (IEEE 2000) defines the lowest two protocol layers of the OSI model. Its topology is a tree in which each node is either a switch or a hub. This decreases cabling flexibility and increases the cost of the solution. The main question is: which protocol to use over Ethernet? Layer 3 (network layer) is often Internet Protocol (IP) (IETF 1981), which is adequate for real time. Selecting TCP (IETF 1981a) as a transport protocol is not really adequate for real-time use (Decotignie 2001). Other solutions such as XTP (Sanders and Weaver 1990) do a much better job. TCP may still be used for non-real-time traffic. If adequate application layers can be found easily, the missing part is what we could call a real-time layer that can provide an indication of consistency and event ordering. For the time being, a number of organizations are pushing for Ethernet-based solutions including a Profibus version. Unfortunately, there is no compatibility between these solutions. Let us just state that it is certainly possible to build adequate solutions on top of Ethernet but this is still to come.

Solutions from Nonindustrial Markets

It is tempting to use, in the industrial domain, solutions that were designed for the consumer market. They are often cheaper and several tools exist to support them. Universal Serial Bus (USB) and Firewire or IEEE 1394 are examples of such technologies. They were not designed for computer-to-computer networking but as remote input and output media for a single computer. The main questions are:

- is the solution able to withstand industrial use?
- is there a clear advantage over other solutions?

The answer to the first question is case dependent. Successful experiences were obtained with Firewire (Ruiz et al. 1999). However, the physical layer of both USB and Firewire was not designed for industrial use.

The second question has several facets. In terms of throughput, there is no definitive advantage over other high-speed solutions (Dallemagne and Decotignie 2001). The main problem is that most of the functionality is missing. These networks only define the lowest two layers of the OSI model and completely lack the other layers.

© 2005 by CRC Press LLC

46.8 Conclusion

The selection of a communication system to interconnect industrial applications on different computers depends on the type of application. We have presented taxonomy of control applications and have shown that a related taxonomy exists for the industrial communication networks. However, distributing industrial application over several sites connected by a network introduces a number of problems that differ depending on the type of application. Industrial networks should support the resolution of these problems. Finally, selected examples of networks were briefly described and the ability to support the different types of applications and problems related to distribution were outlined.

47.1 Introduction

Networked Control Systems (NCS) can contain a large number of interconnected control devices that exchange data through communication networks; examples of application areas include industrial and building automation, office and home automation, intelligent vehicle and transportation systems, and advanced aircraft and spacecraft, among other automated systems. NCS provide several advantages such as modular and flexible system design (e.g., distributed processing and interoperability), simple and fast implementation (e.g., small volume of wiring and powerful easy-to-use configuration tools), and powerful system diagnosis and maintenance utilities (e.g., alarm handling and supervisory packets). However, the combination of sensors, controllers, and actuators with communication networks also makes the analysis and design of NCS a complex task [WIT95] because it requires the integration and good understanding of several disciplines including control systems, communications systems, and real-time systems.

First of all, by distributing the three main functions of the closed-loop operation (sampling, control computation, and actuation) across a communication network, the conventional control theory that supports the control strategy must be reconsidered. Traditionally, the control community has seen the computing platform as providing the determinism that discrete-time control theory requires [AST97]. Control theory has considered implementation other than dedicated processors systems only to a very small extent. Consequently, when computing resources (processor time and communication bandwidth) are limited, control theory rarely advises on how to design controllers to take these limitations into

© 2005 by CRC Press LLC

account [ARZ00]. In order to ensure system performance, communication-induced time delays have to be considered at the controller design stage [MAR01].

In addition, the choice of the communication network will be subject to the timing requirements imposed by the closed-loop control application. The use of communication networks such as field buses [LIA01] and more recently TCP/IP-based networks, typically using Ethernet [DEC01], is an increasing tendency in all automation fields. However, each type of network has properties that may preclude its utilization in an NCS or may affect the performance of the closed-loop operation if not properly analyzed.

Moreover, the performance of NCS depends not only on the control strategy and reliable communication network but also on the message scheduling algorithm [WAL01]. When the communication resources are limited, sensors, controllers, and actuators, along with other nodes, have to compete for accessing the network. The criterion to assign the network to nodes (or messages), that is, message scheduling, is aimed to solve this problem. However, different scheduling strategies will derive in shortening or increasing the message latencies, thus influencing system performance [NIL98].

The contribution of this paper is to review fundamental aspects of control systems, communications systems, and real-time systems in order to make NCS analysis and design easier. In Section 47.2, we review the basics of computer-based control systems and characterize NCS with other computer-based control systems. In Section 47.3, we review control aspects of NCS, focusing on the timing required by well-known control strategies that are typically used when designing discrete-time controllers. In Section 47.4, we analyze communication networks with respect to NCS as well as message scheduling strategies. Finally, Section 47.5 concludes and points out open research topics.

47.2 Fundamental Issues in Networked Control Systems

The objective of *computer-based control* is to use computers (and associated technologies, e.g., networks) to manipulate the available inputs of a dynamic system in order to cause this system to behave in a manner more desirable than it otherwise would [LUE79]. The general functionality of a computer-based closed-loop control system can be split into three main activities: *sampling*, *control algorithm computation* (*calculation* for short), and *actuation*.

The basic concepts of control systems, like the idea of feedback, are reviewed in the next section. In the subsequent section, we describe the closed-loop operation of a computer-based control system and further we analyze different types of architectures (based on processing on devices and networks) in order to characterize the role that a communication network may play in control applications.

The Idea of Feedback for Control Systems

A *control system* is an interconnection of components forming a system configuration that will provide a desired system response [DOR95]. The basis for analysis of a system is the foundation provided by linear system theory, which assumes a cause–effect relationship for the components of the systems. A component or process to be controlled (also called a physical system or plant) can be represented by a block (as shown in Figure 47.1, top) where the input–output relationship represents the cause–effect relationship.

In control terms, the *controlled* variable is the quantity or condition that is measured and controlled (i.e., process output). The *manipulated* variable is the quantity or condition (i.e., process input) that is varied by the controller so as to affect the value of the controlled variable. Depending on the type of information that the controller uses to vary the manipulated variable, we distinguish between *open-loop* control and *closed-loop* control. The defining feature of an open-loop control is that the controller function that varies the manipulated variable is determined completely by an external process that it alone accounts only for the desired output response (Figure 47.1, middle).

A *closed-loop* control system (also called a closed-loop system) utilizes an additional measure of the controlled variable (the actual outputs or other significant variables) to compare it with the desired output. Consequently, the controller function is determined on a continuing basis by the behavior of the

© 2005 by CRC Press LLC

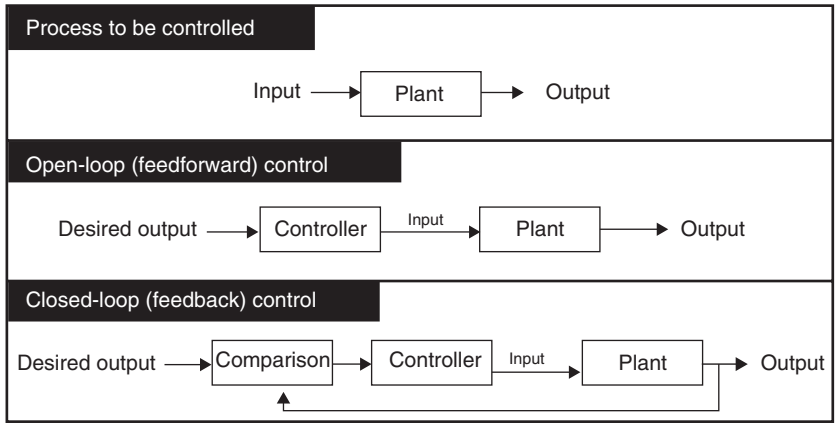

FIGURE 47.1 Feedback in control systems.

system itself (as expressed by the behavior of the outputs). The measure of the output is called the *feedback signal*, because it is fed back (possibly in a modified form due to the controller action) to the process. In summary, in closed-loop systems, *to control* means measuring the value of the controlled variable of the system and applying the manipulated variable to the system to correct or limit deviation of the measured value from a desired value. A simple closed-loop control system is shown in Figure 47.1, bottom.

There are many reasons why closed-loop control is often preferable to open-loop control. Feedback is often superior to open-loop from a performance standpoint and it can automatically adjust to unforeseen system changes or to unanticipated disturbance inputs. A *disturbance* is a signal that tends to adversely affect the value of the output of the system.

The *feedback* concept has been the foundation for control systems analysis and design, which enables us to control the desired output and improve *accuracy* while maintaining *stability*. Traditionally, closed-loop systems were *analog-control systems* (also called *continuous-time systems*); practically all the control systems implemented today are based on computer control, that is, they are *computer-controlled systems* (also called *discrete-time systems*).

An Overview to Computer-Based Control

A computer-based control system (see, e.g., [AST97]), containing both continuous-time signals and discrete-time signals, can be described schematically as in Figure 47.2.

The functionality of such a system can be described as follows:

Sampling: The *controlled* variable, $y(t)$ (the quantity or condition that is measured and controlled, i.e., process output) is usually a continuous-time signal. It is converted to digital form by the Analog-to-Digital (A/D) converter that provides a sequence $\{y(t_k)\}$ at the sampling instants, t_k. The elapsed time between successive sampling instants is called the sampling period and is denoted by h. The A/D converter acts as a sampler that returns a digital snapshot value of a continuous-time signal in the form of an n-bit word.

Calculation: The computer interprets the converted signal, $\{y(t_k)\}$, as a sequence of numbers, processes the input sequence using the control algorithm (implementing a previously designed control law), and gives a new sequence of numbers, $\{u(t_k)\}$.

Actuation: This sequence is converted to an analog signal, $u(t)$, by a Digital-to-Analog (D/A) converter in order to be applied to the process. The D/A converter acts as a hold circuit that takes a discrete-time signal and converts it into a continuous-time signal. Usually, a zero-order hold is used, in which case the resulting continuous-time signal is piecewise constant between successive D/A conversions. The *manipulated* variable $u(t)$ is the quantity or condition (i.e., process input) that is varied by the controller so as to affect the value of the controlled variable.

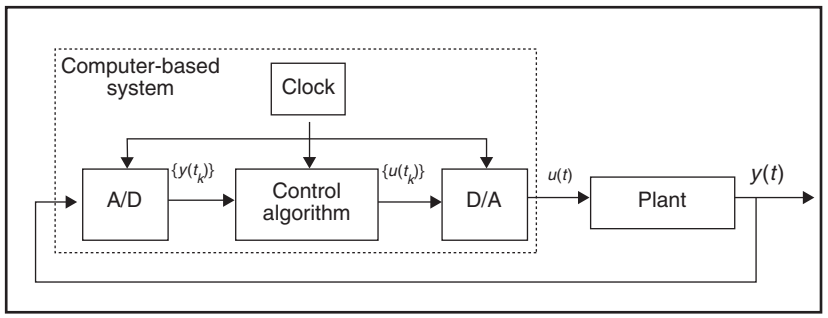

FIGURE 47.2 Diagram of a computer-based control system.

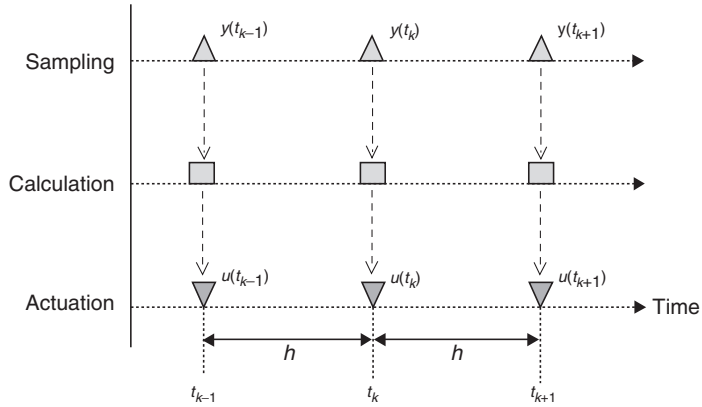

FIGURE 47.3 Diagram of the three main operations in a closed-loop system.

Note that a real-time clock in the computer-based system synchronizes the events.

In summary, we can describe the functionality of a computer-based closed-loop system as the sequence of the three main operations (sampling, calculation, and actuation) that have to be repeatedly executed at every sampling period h, as illustrated in Figure 47.3. The sampling period h, beyond conforming to the Shannon sampling theorem [SHA48], can be chosen following one of various rules-of-thumb, depending on the desired performance of the closed-loop system and the dynamics of the plant to be controlled. An accepted rule-of-thumb is that the sampling frequency should be 4 to 20 times the system's cut-off frequency (which is usually approximated by the system natural frequency ω_n). See [AST97] for further discussion on the selection of the sampling period.

Architectures for Control Systems

Computer-based control is used in many application areas, such as factory automation, process control, robotics, automotive systems, and others. In such applications, different types of computer-based platforms are used to control processes, and are expected to react within precise time constraints to external events according to the application requirements. They are expected to behave correctly both in the value and timing domains: inputs are processed and the adequate outputs are provided with an accurate timing. Therefore, the computer-based architecture that supports the control application, and that will provide the different timings, is of main concern in terms of system performance. Basic architectures for computer-control are discussed next.

The traditional communication architecture for control systems in all fields of automation has been point-to-point (see [BEN00] for a short review of the history of digital computers for control systems). In such an architecture, systems components (sensors and actuators) that interact with the physical process are directly

© 2005 by CRC Press LLC

wired to controllers using the traditional 4 to 20 mA current loop. Systems of this type are also referred to as direct digital control systems or local closed-loop systems (see Figure 47.4, top). In point-to-point architectures, each sensor or actuator exchanges data with the controller using a dedicated communication link. Therefore, control data (sensor data and command data) do not suffer delays other than the one expected when transmitting in a point-to-point link. Nowadays, for digital data, this architecture is widely used for Programmable Logic Controller (PLC)-based control architectures. For analog data, point-to-point architectures based on Proportional, Integral and Derivative (PID) controllers are commonly used in the automation field (as stressed in [AST00], PID controller is the first solution that should be tried when feedback is used).

However, such isolated point-to-point architectures do not suit modern automation systems [SCH97] where the goal is to design flexible systems that can accomplish various tasks with small reconfiguration cost. The reconfiguration of a point-to-point architecture to expand physical setups and functionality is not an easy task and it is often easier to build a completely new system than to rewire all the existing system components. In addition, for such systems, diagnosis and maintenance have to be performed locally as no remote operation (control and supervision) is allowed. In the end, this results in inefficient systems and increased costs.

The common bus network architecture can solve the problems of the point-to-point architecture for control systems [LEN93]. Depending on how the control tasks are distributed across the network, we can distinguish two architectures: Distributed Control Systems (DCS) (Figure 47.4, middle) and NCS (Figure 47.4, bottom). Such architectures, main goal is to reduce maintenance, lower cost, reduce weight and power, simplify installation, and improve reliability.

In DCS, most of the real-time control tasks (sensing, calculation, and actuation) are carried out within the individual control nodes. The interconnected nodes mainly use the network to transmit alarm signals, monitoring information and local control actions. The network is also used for system configuration and setup. Therefore, a DCS can be viewed as a networked collection of point-to-point control systems. Note that for such architectures, the control data suffer the same delays as for point-to-point architectures, because it does not travel in the network. DCS are widely spread in all fields of automation.

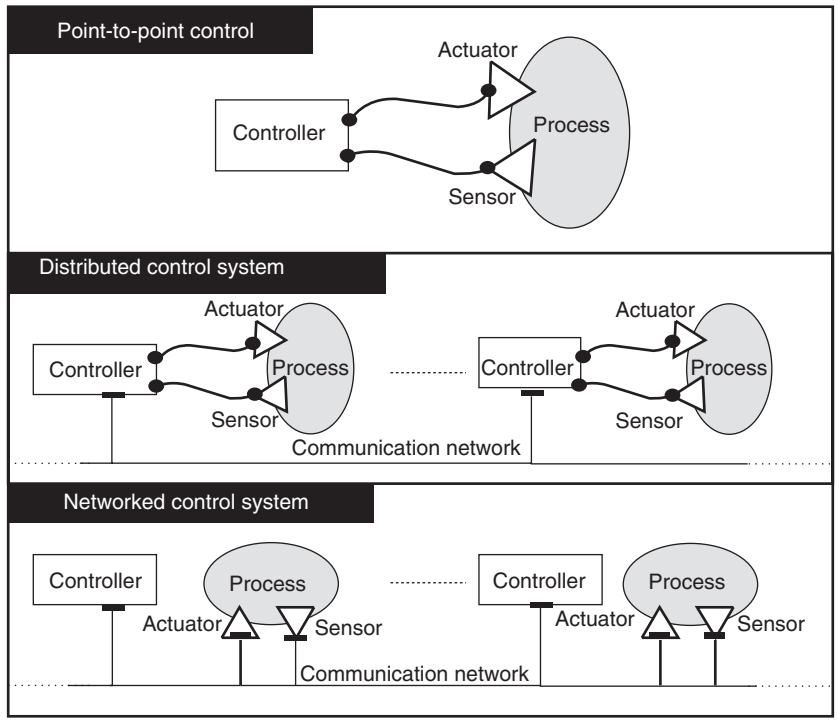

FIGURE 47.4 Architectures for control systems.

© 2005 by CRC Press LLC

One step further in distributing the processing intelligence are NCS. NCS are the application of the intelligent network concept (where all nodes have processing power, allowing for the modularization of the functionality and standard interfaces for interchangeability and interoperability) to control systems [RAY89]. An NCS is a completely distributed and networked feedback control system, where plant sensor–controller–actuator nodes in closed-loop operation drive the network principal traffic. In such architectures, all processing control nodes (sensors, controllers, and actuators) are interconnected through the communication network and, apart from the data typically exchanged in DCS (mainly supervisory data), they transmit sensory and command messages. Note that sensory and command messages (which we also call control data) carry the information required to accomplish the closed-loop operation: sensory messages carry the sampled data, which are used by the controller node to compute the control signal, and command messages carry the command signals that are applied to the process by the actuator node. Therefore, for such architectures, control data are subject to delays caused by the communication network (apart from necessary transmission and propagation delays).[1] Depending on the network and the message scheduling policy, the induced delays will take different values, thus affecting the quality of the closed-loop control operation at different levels.

47.3 Timing Analysis of Control Systems

In this section, we summarize the timing assumptions considered by discrete-time control theory in the closed-loop operation and compare them with the timing analysis that different architectures for computer control provide for closed-loop systems.

Timing Assumptions in the Closed-Loop Operation

From classical discrete-time control operation (which we briefly described in the section An overview to computer-based control), we can derive the following timing assumptions about the three main parts of a closed loop (recall Figure 47.2):

- The *input data collection or sampling* is performed by the sampler at equidistant time instants given by the *sampling period, h.*
- The *time delay*, τ, that is, time elapsed between related[2] sampling and actuation instants (which should include the execution time spent by the control algorithm calculation) is *constant* (either *instantaneous*[3] or not, depending on how the controller was designed).
- The *output data transmission or actuation* is performed at the *actuation instants*, which occurs at the time delay completion.

Although these assumptions are the basis for discrete-time control theory, in practice, it is not possible to keep all of them in a computer-based implementation (as we further discuss in the next section). For example, it is clear that calculations take time, therefore the time delay, which includes the calculation of the control law, cannot be *zero*. The implementation approach underlying the assumption of an

[1]The transmission and propagation delays are constant parameters that characterize any transmission of data through a communication media [STA03]. The transmission delay is the time taken by each device — sensor or controller — to send each message given a transmission rate and the propagation delay is the time taken by the communication link to transport each message.

[2]Related sampling and actuation instants refer to the sampling and actuation actions performed at each execution of a closed-loop algorithm for each sampling period.

[3]Recall that the idea of using digital computers as components in control systems started around 1950 [AST97]. The notion of instantaneousness comes from the theory of linear time-invariant continuous-time systems, from which discrete-time systems theory emerged. In continuous-time systems, analog controllers compute almost instantaneously. As a consequence, some of the models and methods used in discrete-time theory, coming from continuous-time theory, maintain the instantaneous assumption.

© 2005 by CRC Press LLC

instantaneous time delay is to build the system in such a way that the time delay is minimized in order to ignore it in the controller design. However, this does not mean that the control computation execution time is zero. It means that the control computation execution time is not relevant to the controlling purposes if compared to the closed-loop system dynamics.

Note that *sampling period* and *time delay* are the timing parameters of interest in the analysis and design of discrete-time controllers. In fact, the well-known control models and methods used in discrete-time control theory were developed for systems characterized with a constant sampling period (h) and a constant time delay (τ).

Timing Analysis of Different Architectures that can Support the Closed-Loop Operation

In the previous section, we have explained the timing assumptions that discrete-time control theory expects in the closed-loop operation. In this section, we give an overview of the real expected timing behavior of closed-loop systems that are either implemented using the point-to-point architecture or the networked architecture. Note that we do not discuss distributed control systems architectures because as we argued in the section Architectures for control systems, in this architecture, control data (sensor and command messages) suffer the same delays as for point-to-point architectures.

Looking at the closed-loop operation for any of the two architectures (Figure 47.5), the following functionality is expected: the sensor samples the process to be controlled with a given sampling period h. Each time the data have been collected, the sensor forwards it to the controller using the corresponding communication link, introducing a communication delay τ_{sc} (sampler to controller delay). The kth control computation execution start time is given by the sampling time t_k plus the τ_{sc} delay. The control computation introduces a delay (τ_c) used to calculate the command signal(s). The controller forwards the command signal(s) to the actuator, introducing another communication delay τ_{ca} (controller to actuator delay). Finally, the actuator performs the actuation at the time given by $t_k + \tau_{sc} + \tau_c + \tau_{ca}$.

In both architectures, the time delay τ (time elapsed between related sampling and actuation instants) is given by $\tau = \tau_{sc} + \tau_c + \tau_{ca}$. However, depending on the architecture, this delay will be either constant or time varying. Note that in most of the actual closed-loop implementations, controllers are implemented in dedicated processors. Therefore, we will also consider the time delay τ_c introduced by the controller to

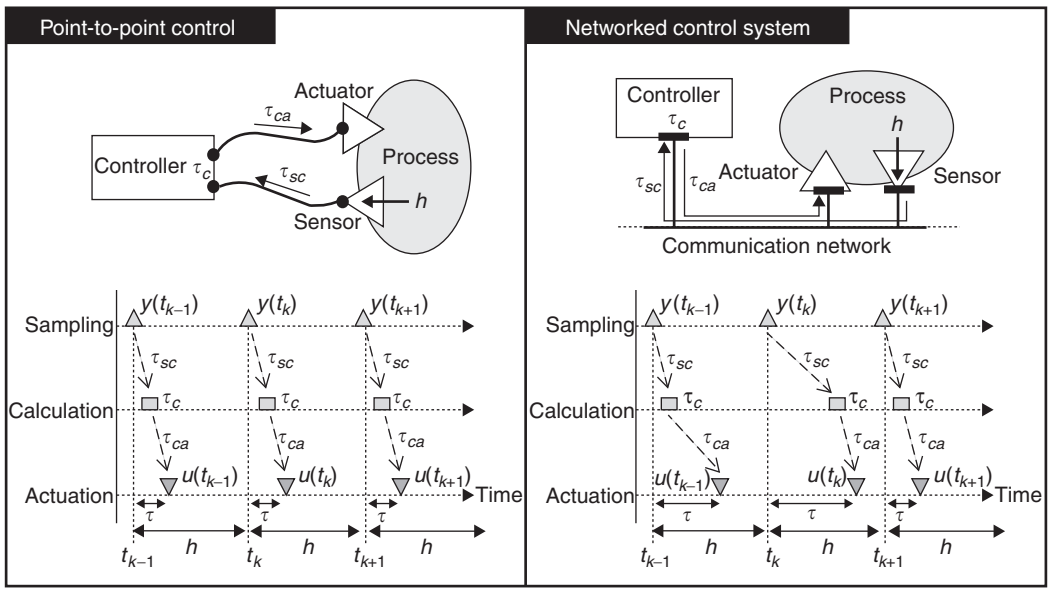

FIGURE 47.5 Timing analysis of the closed-loop operation: point-to-point (left) vs. networked (right) architecture.

© 2005 by CRC Press LLC

be almost constant. We regard the conversion operation delay for A/D conversion in the sensor and D/A conversion in the actuator to be negligible. If these operations take too long a time, they could be included for the timing analysis in the time delay τ_c. For implementations other than dedicated processors, the τ_c delay will depend on the concurrency of the other executing tasks (see [MAR02] for further reading).

Note also that the sampling period is constant for both architectures (Figure 47.5). Samples, $y(t_k)$, are taken at equidistant times, given by h. Therefore, the sampling period does not raise challenges other than the usual ones that are found in the analysis and design of traditional computer-based closed-loop control systems. Consequently, from now on, we will focus on the time delay as a critical timing parameter for ensuring system performance. Specifically, we are interested in the communication-induced time delays, τ_{sc} and τ_{ca}.

If we focus on the point-to-point architecture (Figure 47.5, left), we can model the time delays (τ) introduced by the point-to-point communication links as constant delays. Both τ_{sc} and τ_{ca} will depend on constant parameters such as the transmission time and the propagation delay of the link. Therefore, the control signal $u(t_k)$ is applied to the process at equidistant times, given by the sampling time plus the time delay.

However, looking at the networked architecture (Figure 47.5, right), communication-induced time delays may vary at each closed-loop instantiation. Such delays, apart from being characterized by constant parameters such as the transmission time and propagation delay (as for the previous point-to-point architecture), will depend on new parameters because control nodes exchange data (sampling and controlling messages) through a shared communication link. Issues like the network medium access protocol and the message scheduling will also determine τ_{sc} and τ_{ca} (see the section Network type and message scheduling vs. system performance for further discussion). Therefore, the actuation signals $u(t_k)$ are sent at nonequidistant time instants, given by the sampling time plus a time delay that may vary at each execution, as illustrated in Figure 47.5, right.

After this timing analysis, we can conclude that the theoretical expected timing, constant time delays, assumed by discrete-time control theory is not realistic if compared to the timing derived from networked architectures, varying time delays (see [TÖR98] for further reading in timing analysis). This mismatch will degrade system performance, as we illustrate in the next section.

47.4 Effect of Time Delays in the Performance of Control Systems

In classic control theory, several properties are used to evaluate the performance of closed-loop systems. After discussing them, we will evaluate the effect of communication-induced time delays in system performance. For illustrative purposes, we will use a specific example: an inverted pendulum controlled by a set of control nodes that exchange control data through a communication network.

Performance of Control Systems

The primary evaluation is concerned with meeting the closed-loop response performance specifications[4] and stability[5] (see, e.g., [DOR95]). Beyond these requirements, looking at the closed-loop response, since controller designs attempt to minimize the *system error* to certain anticipated inputs or perturbations,

[4]The desired controlled system characteristics, in a formal specification of the problem, are given through the design parameters, which can be met by specifying the closed-loop poles location. However, rather than specifying design parameters, usually it is more meaningful to specify quantities, such as at which time the controlled system recovers from a perturbation (settling time), or the allowed error of the controlled system response to certain anticipated inputs.

[5]The concept of stability is very important when analyzing dynamic systems. From a conceptual point of view, a controlled system is said to be in an equilibrium state if in the absence of any perturbation, the system output remains in the same state. And stability is related to the ability to return to an equilibrium state from a perturbation. For more reading on stability, see [AST97].

© 2005 by CRC Press LLC

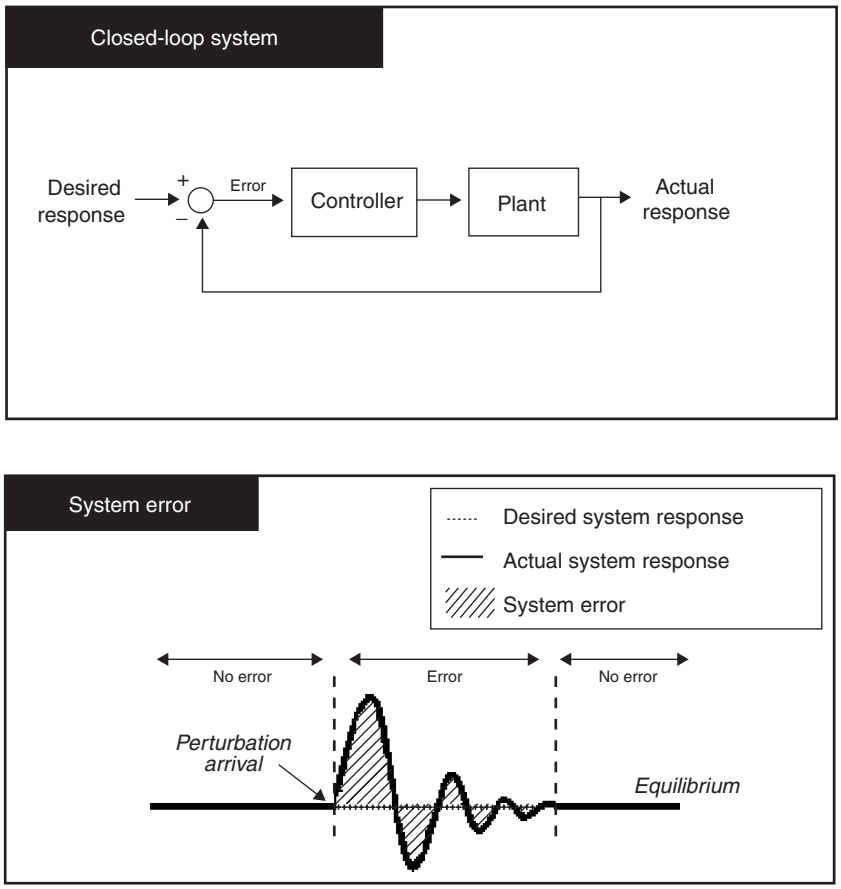

FIGURE 47.6 Performance of closed-loop control systems.

traditional performance criteria focus on the system error. The system error is defined as the difference between the desired response of the system and the actual response of the system. The smaller the difference, the better the performance. Figure 47.6 illustrates these concepts. In Figure 47.6, right, we represent the response of a process that is being controlled. Before the perturbation arrival, the system is in equilibrium. Upon perturbation arrival, the system loses its equilibrium state. Therefore, the actual controlled system response is different from the desired system response, causing the system error. From this moment on, the controller action tries to correct the deviation in order to bring the controlled system back to the equilibrium state again (this is illustrated by the oscillatory curve with decreasing amplitude). The time it takes to reach again the equilibrium state and the maximum amplitude of the deviation determine the performance of the controller.

Constant Communication-Induced Time Delays vs. System Performance

In the section Timing assumptions in the closed-loop operation, we have discussed that controllers designed using classical discrete time control theory are dependent on the sampling period and time delay and that for NCS, as we saw in the section Timing analysis of different architectures that can support the closed-loop operation, time delays are the timing parameters of main concern. Therefore, it is interesting to outline which are the effects of communication-induced time delays on the performance of closed-loop control systems. Recall that we are evaluating time delays in the sense of the time elapsed from sampling to actuation. To do so, in this section, we will focus on constant time delays, because such type of

© 2005 by CRC Press LLC

delays can easily be accounted for in the controller design and included in the closed-loop operation (see [MAR01] or [YEP02] for more details). In the next section, we will focus on varying time delays.

Consequently, for illustrative purposes, if we experiment with constant sampling-to-actuation delays (multiples of a nominal delay τ_n) and include them in the controller algorithm that is executing in a controller node of an NCS, we can summarize the effect they have in the closed-loop operation as shown in Figure 47.7. Note that the system we consider is an NCS that consist of a set of processing nodes (sensor, controller and actuator) that communicate data across a communication network, which introduces a constant time delay for the sampling message (form sensor to controller) and for the command message (from controller to actuator).

In Figure 47.7, we show four responses ($y(t)$) of a generic controlled system affected by a perturbation (of magnitude 1 in the error axis) for four different constant sampling-to-actuation delays (τ_n, $2\tau_n$, $3\tau_n$, and $4\tau_n$). Although the controller has been designed to account for the delays, there will always be degrading effects on the controlled system response. The degrading effects on system performance can be summarized as follows:

Delayed response: The first effect is that a sampling-to-actuation delay delays the application of each control action to the plant. Therefore, as it can be seen from Figure 47.7, left, if the time elapsed from sampling to actuation is longer at each one of the four system responses, the more delayed each closed-loop system has its response (in terms of recovering from the perturbation). Note that the response of the system labeled with a nominal delay τ_n (the shortest one) always reacts before (its curve precedes) than all the others, which have longer delays.

Increased error: The second effect is that the later the control action is applied to the process (the longer the delay), the larger the error the closed-loop system response has. As it can also be seen in Figure 47.7, left, the initial error is 1. However, looking at the detailed view (Figure 47.7, right), the error that has to be corrected is not 1 but $1+E_i$, where E_i is the added error due to each delay. Note that the added error of the system labeled with a delay of $4\tau_n$ is larger than the others, as it suffers the longest delay.

These two effects can be clearly seen in Figure 47.7 right, where we show the detailed initial response of each system. In each system, the first sampling that detects a perturbation (error equal to 1) on the system is performed at time 0. While the sample travels across the network in the sensory message to the controller, the controller calculates the control action, and sends it to the actuator, the error of the controlled system increases. It is when the actuator applies the command action to the system (at the delay completion) that the error starts being corrected. The later this action is performed, the larger the system error that must be corrected. Compare, for example, E_4 with E_2. E_4 is the error of the fourth system (with a $4\tau_n$ delay) at the first actuation instant. E_2 is the error of the second system (with a $2\tau_n$ delay) at the first

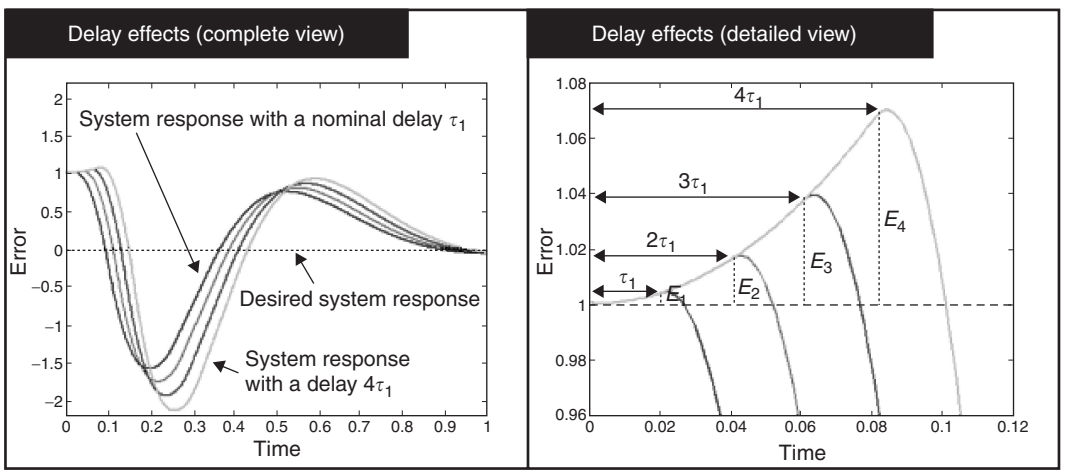

FIGURE 47.7 Performance of a generic controlled system for different time delays.

© 2005 by CRC Press LLC

actuation instant. As it can be seen, the error E_4 is more than twice E_2. However, $4\tau_n$ is exactly $2\times2\tau_n$. The error increases faster than the delay increases. For further reading on this topic, see, for example, [YOO00].

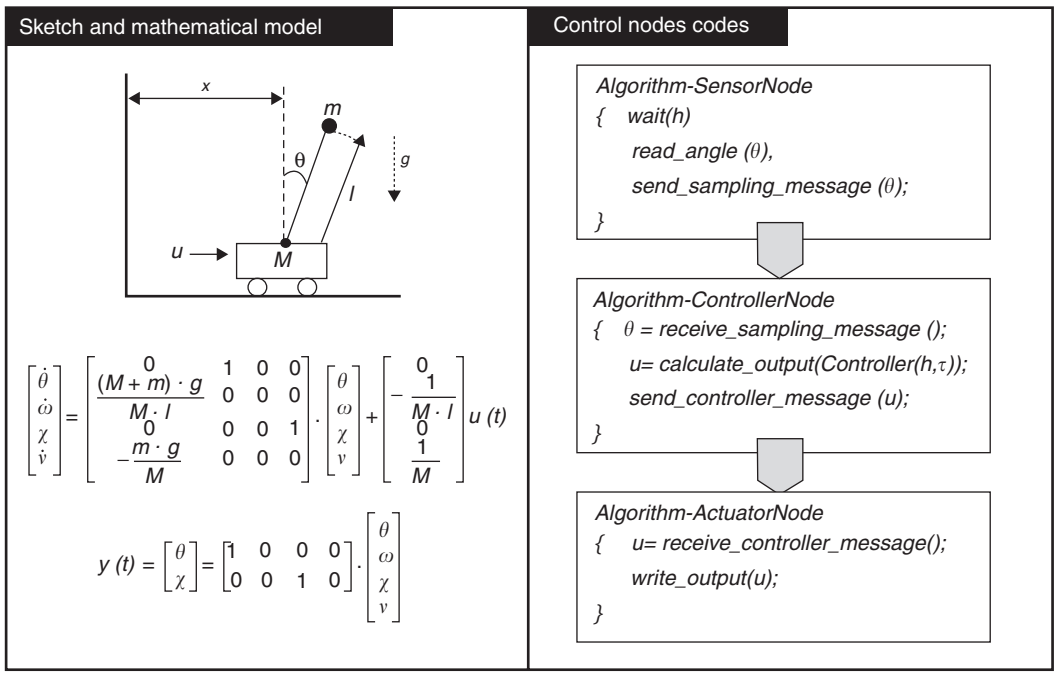
From this generic study, it has been shown that the system error generated by a perturbation (which has to be corrected by a controller) may dramatically increase if, from the corresponding sampling, the actuation occurs too late. And this will depend on the network-induced time delays. However, it has to be pointed out that time delays can be assumed in closed-loop systems as far as they are constant, known at design stage, and that the degradation they introduce can be made to conform to the performance specifications. Alternatively, if the communication delays are not constant but exhibit fluctuations, care must be taken because the system performance may drastically decrease as we show in the next section. As we will discuss in the subsequent section, the type of network that supports the networked application and the message scheduling policy will determine the delay pattern that should be accounted for in the analysis and design of networked controllers.

Varying Communication-Induced Time Delays vs. System Performance

In this section, we illustrate, using an example, the problems that varying communication time delays can introduce in control loops closed over communication networks. First of all, we introduce the setup. Afterwards, we analyze the effect of varying time delays in the system performance.

The system we consider is an NCS that consist of a set of control and noncontrol nodes that communicate data across a communication network. The control nodes (sensor, controller, and actuator) are in charge of controlling an *inverted pendulum* mounted on a motor-driven cart (see Figure 47.8, left). Each control node executes the corresponding control law code shown in Figure 47.8, right. The noncontrol nodes do not participate in the closed-loop operation but use the network whenever needed, increasing the traffic load and introducing unexpected longer message latencies. Therefore, the network introduces varying time delays for the sampling message (from sensor to controller) and for the command message (from controller to actuator) due to the interferences of the other noncontrol nodes.

The inverted pendulum control problem can be stated as follows: the inverted pendulum (of length l and mass m) can only swing in a vertical plane parallel to the direction of the cart (of mass M). In the



$$\begin{bmatrix}\dot{\theta}\\ \dot{\omega}\\ \dot{\chi}\\ \dot{v}\end{bmatrix} = \begin{bmatrix}0 & 1 & 0 & 0\\ \frac{(M+m)\cdot g}{M\cdot l} & 0 & 0 & 0\\ 0 & 0 & 0 & 1\\ -\frac{m\cdot g}{M} & 0 & 0 & 0\end{bmatrix}\cdot\begin{bmatrix}\theta\\ \omega\\ \chi\\ v\end{bmatrix} + \begin{bmatrix}0\\ -\frac{1}{M\cdot l}\\ 0\\ \frac{1}{M}\end{bmatrix} u(t)$$

$$y(t) = \begin{bmatrix}\theta\\ \chi\end{bmatrix} = \begin{bmatrix}1 & 0 & 0 & 0\\ 0 & 0 & 1 & 0\end{bmatrix}\cdot\begin{bmatrix}\theta\\ \omega\\ \chi\\ v\end{bmatrix}$$

FIGURE 47.8 Inverted pendulum model (left) and algorithms for the distributed operation (right).

© 2005 by CRC Press LLC

presence of a perturbation, to balance the pendulum, the cart is pushed back and forth on a track of limited length. Balancing fails when the inclination of the pendulum exceeds preset limits, or when the cart hits the stops at the end of the track. The aim is to find a controller to balance the inverted pendulum, preventing it from failing, and to bring the cart to the center of the track.

The state of the inverted pendulum on a cart is described by the cart position (x), its velocity (v), the pendulum angle (θ), and its angular velocity (ω). The force applied to the cart, (u), is the manipulated controlling command calculated by the controller according to the actual angle and position (controlled variables). A linear time-invariant state-space model of the inverted pendulum, used for the control design can be viewed in Figure 47.8 (where, e.g., we take M=2 kg, m=0.1 kg, l=0.5 m, and g=9.81 m/sec^2).

For the sake of simplicity, we will focus only on the angle (θ). The goal of our controller is to maintain the desired vertical position of the inverted pendulum at all times. Specifically, the performance requirement is to recover from a perturbation in less than 1 sec. To do so, we close the networked loop by using a state-feedback controller designed using classical methods, with strictly periodic sampling h, and accounting for a constant time delay τ.

The inverted pendulum response obtained by the distributed controller if it would execute in isolation (on a networked architecture but with no competitors, thus, with a constant time delay) in the presence of a perturbation (modeled as an initial condition) can be seen in Figure 47.9, left. Since it is beyond the scope of this work to specifically discuss state-feedback controller design, we assume that our design is good enough for illustrative purposes (we call it ideal). Note that the performance requirement is met; that is, the pendulum recovers from the perturbation in less than 1 sec.

The inverted pendulum response obtained by the distributed controller executing in the networked architecture and suffering varying time delays due to the competitor's interferences is quite different. As it can be seen in Figure 47.9, right, the inverted pendulum response suffers different degrees of degradation depending on the randomly induced communication delays of different magnitudes that we have generated (simulating the interference produced by the messaging from the noncontrol nodes). Concretely, in Figure 47.9, right, we show four curves: the dotted line corresponds to the ideal response of the inverted pendulum, with a constant time delay of τ. The other three curves correspond to three responses obtained by three controllers, each one suffering random delays of different magnitudes (delays longer than the nominal τ but bounded by 10, 25 or 50% of τ). As it can be seen, the longer the random generated delay, the larger the degradation. Note that for the case with longest delays (delays bounded by 50% of τ), the system becomes unstable (the inverted pendulum falls).

The degradation caused by varying time delays can be explained as follows. From a control perspective, the control system with varying delays is no longer time-invariant. That is, the controller designed to account for a constant time delay (time invariant system) is not effective when delays vary (time

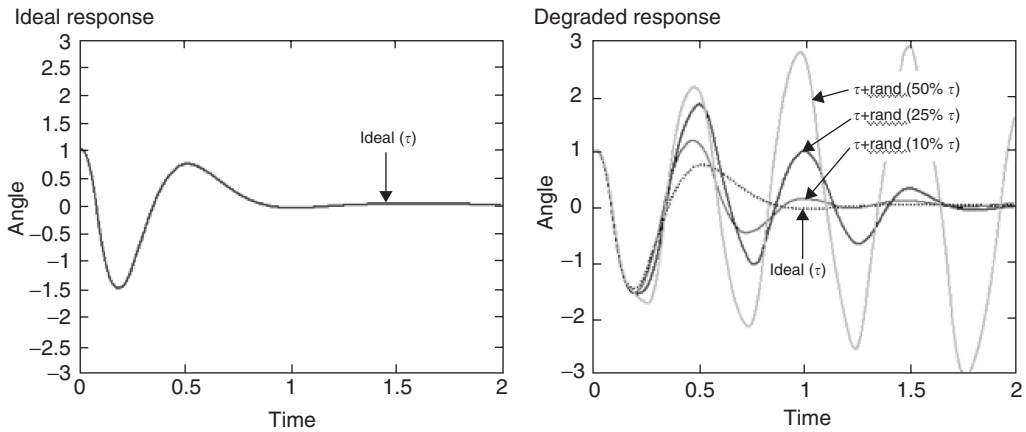


FIGURE 47.9 Inverted pendulum system response: ideal (left) vs. degradation (right) due to varying time delays.

© 2005 by CRC Press LLC

varying system). Therefore, the standard computer control theory (targeted for time-invariant systems) cannot be used in the analysis and design of NCS with varying time delays. The problem of analysis and design of control systems when the communication delays are varying in a random manner is complex and it is still an open research field (see [CHO01] for an introductory tutorial).

Following the seminal work on communication and control [HAL90], an approach to overcome these problems is to model the communication delays as probabilistic distributions. The design of the controller has to account for those delays or alternatively has to view the temporal nondeterminism of network-induced delays as an uncertainty, similar to a plant uncertainty, or a disturbance, and then design the control systems to be robust against such uncertainty.

For example, [NIL98] presents various probabilistic communication delays models and accordingly, solves an LQG optimal control problem for them. Using similar techniques, in [XIA01] communication resources allocation and linear systems design are jointly optimized.

Another approach is to assume a constant sampling-actuation delay, forcing a synchronous actuation (synchronous with respect to the sampling) [WIT98]. This can be achieved by forcing the actuation to occur at equidistant times, given by the worst-case-message-latency. However, this may unnecessarily impose a longer time delay than the actual ones that appear during system runtime, thus forcing a pessimistic timing behavior in the closed-loop system that may result in a graceful but unnecessarily system performance degradation [YEP02].

Up to now, we have not discussed stability issues. As can be seen in Figure 47.9, right, the degradation that the controlled system suffers drives the system to almost instability. It is well known that delays can cause instability. Therefore, in the analysis of control loops closed over communication networks, delays have to be included for the stability analysis. See [ZHA01] for a starting reading point.

Note, however, that the randomness of the communication-induced delays will depend on the type of communication network and message scheduling that supports the closed-loop operation, as introduced in [LIA02]. This is discussed next.

Network Type and Message Scheduling vs. System Performance

Varying communication time delays can seriously degrade the performance of the controlled system, as outlined in the previous section (see Figure 47.9, right). Moreover, when delays appear in a random manner, the lack of well-established control techniques for time-varying systems makes the analysis and design of NCS a complex task. Taking into account that the type of delays determine system performance, the type of network and more concretely, the rules that allow the exchange of messages, that is, message scheduling policy, is a key issue in terms of system performance. By choosing the adequate message scheduling (or protocol), the impact of communication-induced time delays can be drastically reduced because delays can be somehow controlled.

It is well known that random-based scheduling policies (e.g., Ethernet [DEC01]) conflict with the determinism that control theory imposes on an implementation. Standard Ethernet communication introduces random delays and no guarantee can be given on the maximum message latency. Therefore, to design NCS with Ethernet as a communication backbone is not appropriate from the control tractability point of view. However, there is a strong interest in using the cheap and simple Ethernet technology for industrial and embedded systems. This far, however, the lack of real-time services has prevented this change in the used network technology. Nevertheless, in recent literature, works can be found addressing the lack of determinism by using switched Ethernet techniques (see [LOB01] for further reading on Ethernet and control issues in the automation field).

To overcome this problem of the lack of determinism in Ethernet, we can think of well-known communication networks with deterministic scheduling policies such as table-driven (e.g., WorldFIP [ALM02]), master/slave (e.g., Profibus [TOV99]), or nonpreemptive fixed priority-based (e.g., Controller Area Network, CAN [TIN94]) scheduling policies. Such scheduling policies limit message latencies, thus facilitating the analysis and design of closed loops over communication networks and also ensuring average or priority-based levels of performance.

© 2005 by CRC Press LLC

For example, table-driven or master/slave scheduling policies can guarantee constant message latencies. Moreover, latencies (delays) are known before runtime. For example, in a master/slave configuration, the order of the polling determines the order in which nodes have access to the network. And when a node is accessing the network, it uses all the available bandwidth. Therefore, the network-induced delays depend on known parameters (transmission time and propagation time). If delays are known before run time, the analysis and design of the distributed controller taking into account the delay induced by the networked architecture are straightforward [AST97]. Note that such protocols, although providing constant time delays (which makes the control design job easy), may not provide the optimum performance. This is because they may be enforcing delays longer than the ones that could be obtained using other protocols based on more flexible priority-based mechanisms such as CAN. Recall that a delay is always a source of degradation, as we outlined in the section Constant communication-induced time delays vs. system performance.

For nonpreemptive fixed priority-based scheduling policies such as CAN, although message latencies are bounded, they are not known before system runtime. This is because messages may suffer collisions. In this case, the deterministic collision resolution mechanism that CAN incorporate ensures that the message with highest priority will continue being transmitted. Moreover, using [TIN94], the maximum latencies for all messages can be precalculated. Therefore, although message delays are not exactly known, the known upper bounds can be used for the analysis and design of the networked controller. Moreover, such scheduling techniques can be used to shorten the message latencies by adequately assigning the priorities.

47.5 Conclusions

NCS constitute a particular type of applications over communication networks where the principal traffic is driven by plant sensor–controller–actuator nodes in closed-loop systems. As we have reviewed in this chapter, the analysis and design of such systems are complex tasks involving the integration and good understanding of several disciplines: control systems, communication systems, and real-time systems. In particular, when a network is used dedicated just for one control loop, without any external or other node interferences, the resulting networked system becomes trivial. But when the network is shared among different nodes and there is even just one sensor–controller–actuator closed-loop control subnetwork, care must be taken on how the expected or unexpected delays can affect the controlled system performance. This chapter has shown the way to characterize the different architecture issues in a networked control system, mainly in what refers to the different delays that occur in the messaging related to the control actions. In general, if those delays are negligible with respect to the dominant dynamics of the controlled plant, they can be overcomed; but when those time delays are significant, a more precise analysis has to be conducted, both in the design or redesign of the control algorithm, on the network characteristics, and on the system's scheduling. These last topics are still an open issue that is currently being investigated by several research groups.

48.1 Introduction

Nowadays, intelligent nodes, that is, microprocessor-based with communication capabilities, are extensively used in the lower layers of both process control and manufacturing industries [8]. In these environments, applications range from embedded command and control systems, to image processing, monitoring, human–machine interface, etc. Moreover, the communication between the different nodes has specific requirements [9] which are quite different from, and sometimes opposed to, those found in office environments. For instance, predictability is favored against average throughput, and message transmission is typically time and precedence constrained. Furthermore, the nonrespect of such constraints can have a significant negative impact on the quality of the control action in Distributed Computer Control Systems (DCCS), or on the quality of the observation of the system state in Distributed Monitoring Systems (DMS). Therefore, to deliver the adequate quality of service, special-purpose networks have been developed, essentially during the last two decades, which are generically called fieldbuses and are particularly adapted to support frequent exchanges of small amounts of data under time, precedence, and dependability constraints [8]. Probably, the most well-known examples existing today are Controller Area Network (CAN), DeviceNet, ProfiBus, WorldFip, P-Net, and Foundation Fieldbus.

In the early days of DCCS, network nodes presented simple interfaces, and supported limited sets of actions. However, the quantity, complexity, and functionality of the nodes on a DCCS have been increasing steadily. As a consequence of this evolution, the amount of information that must be exchanged over the network has also increased, either for configuration or for operational purposes.

[1]This work was partially supported by the Portuguese Government through project CIDER-POSI/1999/CHS/33139.

© 2005 by CRC Press LLC

The increase in the amount of data exchanged between DCCS nodes is reaching the limits that are achievable using traditional fieldbuses due to limited bandwidth, typically between 1 and 5 Mbps [9]. Machine vision, and its growing use, is just one example of a killer application for those systems. Therefore, other alternatives are required to support higher bandwidth demands while retaining the main requirements of a Real-Time (RT) communication system: predictability, timeliness, bounded delays, and jitter.

Starting in the 1980s, several general-purpose networks, exhibiting bandwidth higher than the traditional fieldbus protocols, have also been proposed for use at the field level. For example, two prominent networks, FDDI and ATM, have been extensively analyzed, for both hard RT and soft RT communication systems. However, due to high complexity, high cost, lack of flexibility, and interconnection capacity, these protocols have not gained general acceptance [10].

Another communication protocol that has been evaluated for use at the field level is Ethernet. The main factors that favor the use of this protocol are [9]: cheap silicon available, easy integration with Internet, clear path for future expandability, and compatibility with networks used at higher layers on the factory structure.

However, the nondeterministic arbitration mechanism used by Ethernet prevents its direct use at field level, at least for hard RT communications. Therefore, in the past, several attempts have been made to allow Ethernet to support time-constrained communications. The methods that have been used to achieve deterministic message transmission over Ethernet range from modifications to the Medium Access Control (MAC) layer (e.g., [11]), to the addition of sublayers over the Ethernet layer to control the instants of message transmission (e.g., [12]) and therefore avoid collisions. More recently, with the advent of switched Ethernet, and therefore the intrinsic absence of collisions, a new set of works with respect to the ability of this topology to carry time-constrained communications has appeared (e.g., [10]).

This chapter presents a brief description of the Ethernet protocol, followed by a discussion of several techniques that have been proposed or used to enforce RT communication capabilities over Ethernet in the last two decades. The techniques referred to include those that support either probabilistic or deterministic analysis of the network access delay. The paper concludes with a reference to recent work that concerns the use of the Ethernet protocol, highlighting current trends.

48.2 Ethernet Roots

Ethernet originated about 30 years ago, invented by Bob Metcalfe at the Xerox's Palo Alto Research Center. Its initial purpose was to connect two products developed by Xerox: a personal computer and a brand new laser printer. Since then, this protocol has evolved in many ways. For instance, concerning the transmission speed, it has grown from the original 2.94 to 10 Mbps [1–3, 5], then to 100 Mbps [6] and more recently to 1 Gbps [7] and 10 Gbps [26]. With respect to physical medium and network topology, Ethernet also has evolved: it started with a bus topology based firstly on thick coaxial cable [2] and afterwards on thin coaxial cable [3]. In the mid-1980s, a more structured and fault-tolerant approach, based on a star topology, was standardized [4], running, however, only at 1 Mbps. In the beginning of the 1990s, an improvement on this latter technology was also standardized [5], running at 10 Mbps over category 5 unshielded twisted pair cable.

Along this way, two fundamental properties have been kept unchanged:

1. Single collision domain, that is, frames are broadcast on the physical medium and all the Network Interface Cards (NIC) connected to it receive them.
2. The arbitration mechanism, which is called Carrier Sense Multiple Access with Collision Detection (CSMA/CD).

According to the CSMA/CD mechanism (Figure 48.1), an NIC with a message to be transmitted must wait for the bus to become idle and, only then it starts transmitting. However, several NICs may have sensed the bus during the current transmission and then attempted to transmit simultaneously thereafter, causing a collision. In this case, all the stations abort the transmission of the current message, wait for a random time interval, and try again. The number of retries is limited to sixteen.

© 2005 by CRC Press LLC

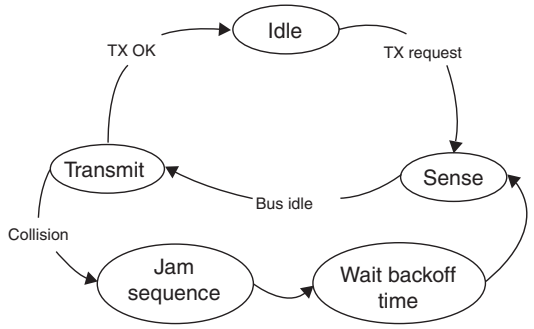

FIGURE 48.1 Ethernet CSMA/CD simplified state diagram.

The use of a single broadcast domain and the CSMA/CD arbitration mechanism has created a bottleneck when encountering highly loaded networks: above a certain threshold, as the submitted load increases, the throughput of the bus decreases, a phenomenon referred to as *thrashing*. In the beginning of the 1990s, the use of switches in place of hubs has been proposed as an effective way to deal with thrashing. A switch creates a single collision domain for each of its ports. If a single node is connected to each port, collisions never actually occur unless they are created on purpose, for example, for flow control. Switches also keep track of the addresses of the NICs connected at each port by inspecting the source address in the incoming messages. This allows forwarding incoming messages directly to the respective outgoing ports according to the respective destination address, a mechanism generally known as *forwarding*. When a match between a destination address and a port cannot be established, the switch forwards the respective message to all ports, a process commonly referred to as *flooding*. The former mechanism, forwarding, allows a higher degree of traffic isolation so that each NIC receives the traffic addressed to it, only. Moreover, since each forwarding action uses a single output port, several of these actions can be carried out in parallel, resulting in multiple simultaneous transmission paths across the switch and, consequently, in a significant increase in the global throughput.

48.3 Why Use Ethernet at Fieldbus Level

The first question that should be answered concerns the reasons that make Ethernet appealing for use at the field level, to convey time-constrained traffic. In fact, its designer has not envisaged this kind of applications, and therefore some properties of this protocol, such as the nondeterministic arbitration mechanism, pose serious challenges concerning its use for this purpose.

Several works address this subject (e.g., [9, 12, 17]). In [9], Decotignie presents a thorough reasoning on the pros and cons on this issue, highlighting two concise sets of arguments, one in favor and the other against the adoption of Ethernet as a fieldbus. Commonly referred arguments in favor can be summarized as follows:

- It is cheap, due to mass production.
- Integration with Internet is easy (TCP/IP stacks over Ethernet are widely available, allowing the use of application layer protocols such as FTP, HTTP, and so on).
- Steady increases in the transmission speed have occured in the past, and are expected to occur in the near future.
- Due to its inherent compatibility with the communication protocols used at higher levels, the information exchange with plant level becomes easier.
- The bandwidth made available by existing fieldbuses is insufficient to support some recent developments, like the use of multimedia (e.g., machine vision) at the field level.
- Availability of technicians familiar with this protocol.
- Wide availability of test equipment from different sources.
- Mature technology, well specified, and with equipment available from many sources, without incompatibility issues.

© 2005 by CRC Press LLC

On the other hand, Ethernet does not fulfill some fundamental requirements that are expected from a communication protocol operating at field level. In particular, the destructive and nondeterministic arbitration mechanism has been regarded as the main obstacle faced by Ethernet concerning this applications domain. The answer to this concern is the use of switched Ethernet, which allows bypassing the native CSMA/CD arbitration mechanism. In these cases, provided that a single NIC is connected to each port, and the operation is full duplex, no collisions occur.

However, just avoiding collisions does not make Ethernet deterministic: for example, if a burst of messages destined to a single port arrive at the switch in a given time interval, they must be serialized and transmitted one after the other. If the arriving rate is greater than the transmission rate, buffers will be exhausted and messages will be lost. Therefore, even with switched Ethernet, full RT behavior still requires some kind of higher-level transmission control. Moreover, bounded transmission delay is not the only requirement of a fieldbus; some other important factors commonly referred to in the literature are: temporal consistency indication, precedence constraints, efficient handling of periodic, and sporadic traffic. Clearly, Ethernet, even with switches, does not provide answers to all these demands.

48.4 Making Ethernet RT

In the previous years, a considerably large amount of work has been carried out, leading to many different proposals for adaptations and add-ons to Ethernet in order to support RT communication. In the remainder of this section, some paradigmatic efforts are presented, with a brief discussion of the strong and weak points of each one.

Modification of the Medium Access Control Sublayer

One of the possible approaches consists in modifying the Ethernet MAC sublayer so that a bounded access to the bus may be achieved (e.g., [11, 18]). For instance, the solution presented in [11] (CSMA/DCR) consists of a binary tree search of colliding messages, that is, there is a hierarchy of priorities in the retry.

During normal operation, the CSMA/DCR follows the standard IEEE 802.3 protocol (*Random Access mode*). However, whenever a collision is detected, the protocol switches to the *Epoch mode*. In this mode, lower priority message sources voluntarily cease contending for the bus, and higher priority ones try again. This process in repeated until a successful transmission occurs (Figure 48.2). After all frames involved in the collision are transmitted, the protocol switches back to random access mode.

Figure 48.2, together with Table 48.1, depicts the CSMA/DCR operation in a situation where six messages collide. Considering that lower indexes correspond to higher priorities, after the initial collision the right branch of the tree (messages 12, 14, and 15) ceases contending for the bus. Since there are still three messages on the left branch, a new collision appears, between messages 2, 3, and 5. Thus, the left subbranch is selected again, leaving message 5 out. In the following slot, messages 2 and 3 will collide again. The subbranch selected after this collision has no active message sources, and thus in the following time slot the bus will be idle (step 4). This causes a move to the right subbranch, where messages 3 and 5 reside, resulting in a new collision. Finally, in step 6 the branch containing only the message with index 5 is selected, resulting in a successful transmission. The algorithm continues this way until all messages are successfully transmitted.

Despite assuring a bounded access time to the transmission medium, this approach exhibits two main drawbacks:

- In some cases (e.g., [11]), the firmware must be modified; therefore, the economy of scale obtained when using standard Ethernet hardware is lost.
- The worst-case transmission time, which is the main factor considered when designing RT systems, can be orders of magnitude greater than the average transmission time. This forces any kind of analysis to be very pessimistic, and therefore leads to low bandwidth utilization, at least with respect to RT traffic.

Addition of a Transmission Control Layer Over Ethernet

Another way to achieve time-constrained communication over Ethernet consists of adding an interface layer above the native medium access control, intended to control the instants of message transmissions, eliminating collisions or, at least, bounding their number. The major advantage of this kind of approach when compared to the modification of the MAC layer is that standard Ethernet hardware can be used.

Virtual Time Protocol

One of the approaches present in the literature is known as Virtual Time Protocol and addresses CSMA/CD networks [19, 20]. The protocol allows implementing different scheduling policies (e.g., Minimum-Laxity First [MLF]), and bases its decisions on the assessment of the communication channel status. When the bus becomes idle and a node has a message to transmit, it waits for a given amount of time, related to the scheduling policy implemented. For example, if MLF scheduling is used, the waiting time is derived directly from the laxity using a proportional constant. When this amount of time expires, and if the bus is still idle, the node tries to transmit the message. If a collision occurs, then the scheduler outcome resulted in more than one message having permission to be transmitted at the same time (e.g., when two messages have the same laxity in MLF). In this case, the protocol can either recalculate the waiting time using the same rule or use a probabilistic approach according to which the messages involved in a collision are retransmitted with

© 2005 by CRC Press LLC

probability *p* (p-persistent). This last option is important to sort out situations in which the scheduler cannot differentiate messages, for example, messages with the same laxity would always collide.

Figure 48.3 shows the operation of the Virtual-Time protocol, with MLF scheduling. During the transmission of message *m*, messages *a* and *b* become ready. Since the laxity of message *a* (i.e., deadline minus message transmission time) is shorter than the laxity of message *b*, message *a* is transmitted first. During the transmission of message *a*, message *c* arrives. Messages *b* and *c* have the same deadline and the same laxity. Therefore, an attempt will be made to transmit them at the same time, causing a collision. Then, the algorithm uses the probabilistic approach, with message *b* having a lower waiting time than message *c*, and thus being transmitted next. Finally, message *c* is transmitted on the bus. Since the only global information is the channel status, there is no way to know that there is only a single message pending. For this reason, after the transmission of message *b* the waiting time corresponding to message *c* is computed, and only after the expiration of this interval message is *c* finally transmitted.

Beyond the advantage of using standard Ethernet hardware, this approach also has the advantage of not requiring any other global information but the channel status, which is readily available at all NICs. Thus, a fully distributed and symmetric implementation is possible, which, in this case, also incurs a relatively low computational overhead. Nevertheless, this approach presents some important drawbacks:

- Performance highly dependent on the proportional constant value used to relate the waiting time with the scheduling policy in use, leading to:
  - Collisions if it is too short.
  - Large amount of idle time if it is too long.
- Proportional constant depends on the properties of the message set; therefore, on-line changes to that set can lead to poor performance.
- The waiting times are computed locally using relative parameters only. There is no global time base and thus, relative phasing is harder to implement.
- Due to possible collisions, worst-case transmission time is much higher than the average transmission time and only probabilistic timeliness guarantees can be given (soft RT systems).

Windows Protocols

Another possible approach is to use the *Windows protocols*. These protocols have been proposed both for CSMA/CD and token ring networks [19]. With respect to the CSMA/CD implementation, the operation is as follows. The nodes on a network agree on a common time interval (referred to as *window*). All nodes synchronize upon a successful transmission, restarting the respective window. The bus state is used to assess the number of nodes with messages to be transmitted within the window:

- if the bus remains idle, there are no messages to be transmitted in the window;
- if only one message is in the window, it will be transmitted; and
- if two or more messages are within the window, a collision occurs.

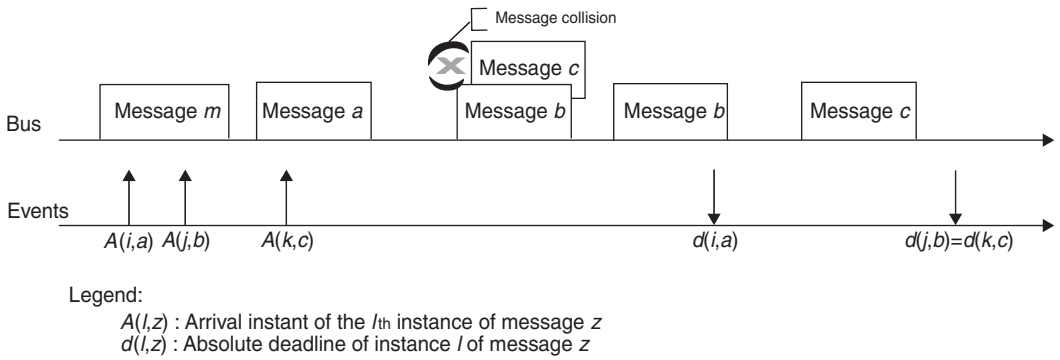

FIGURE 48.3 Example of Virtual-Time protocol (with MLF).

© 2005 by CRC Press LLC

Depending on the bus state, several actions can be performed:

- if the bus remains idle, the window duration is increased in all nodes;
- in the case of a collision, the time window is shortened in all nodes; and
- in case of a successful transmission, the window is restarted and its duration is kept as it is.

In the first two cases, the window duration is changed but the window is not restarted. Moreover, the window duration varies between a maximum (initial) and minimum value. Whenever there is a sufficiently long idle period in the bus, the window will return to its original maximum length. If a new node enters dynamically in the system, it may have an instantaneous window duration different from the remaining nodes. This may cause some perturbation during an initial period, with more collisions than expected. However, as soon as an idle period occurs, all windows will converge to the initial length. A probabilistic retry mechanism may also be necessary when the windows are shrunk to their minimum and collisions still occur (e.g., when two messages have the same transmission time).

Figure 48.4 shows an example of the operation of the windows protocol used to implement MLF message scheduling. The top axis represents the latest send times (*lst*) of messages A, B, and C. The *lst* of a message is the latest time instant by which the message transmission must start so that the respective deadline is met. The first window (Step 1) includes the *lst* of three messages, thus leading to a collision. The intervenient nodes feel the collision, and the window is shrunk (Step 2). However, the *lst* of messages A and B are still inside the window, causing another collision. In response to this event, the window size is shrunk again (Step 3). In this case, only message A has its *lst* within the window, leading to a successful transmission.

This method exhibits properties that are very similar to those of the previous method (virtual time protocol). However, it is somewhat more efficient due to its adaptive behavior. In general, it also aims at soft RT systems and uses a fully distributed symmetrical approach with a relatively low computational overhead. Notice that all message parameters are relative and that there is no global time base again. Moreover, the protocol efficiency is substantially influenced by the magnitude of variations in the window duration, either when increasing or decreasing it.

Traffic Shaping

It is a known fact that, if the bus utilization is kept low, the probability of collisions is also low (although not zero). Therefore, if the network average load is kept below a given threshold and bursts of traffic are avoided, a given probability of collisions can be obtained, as an estimation of the network-induced delay.

An implementation of this paradigm is presented in [21]. An interface layer, called traffic smoother (Figure 48.5), is placed between the IP network layer and the Ethernet data link layer (for this reason, traffic shaping

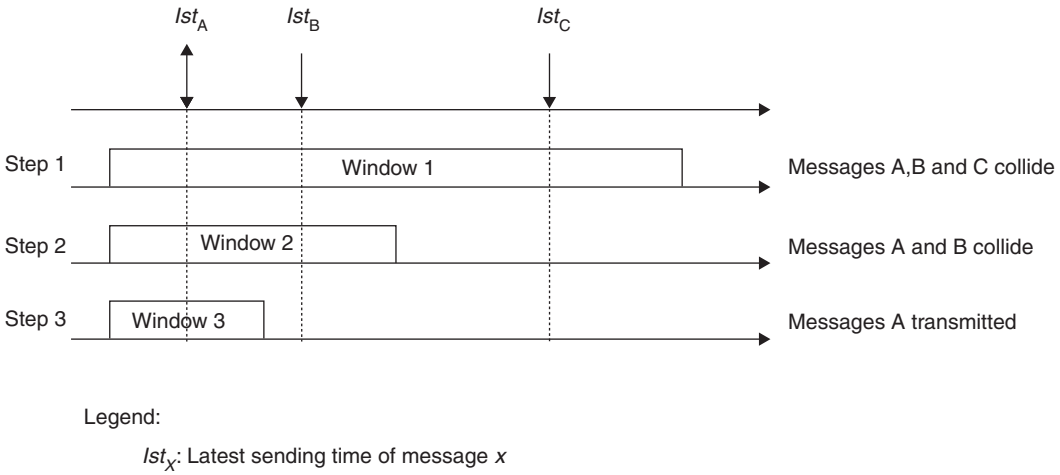

FIGURE 48.4 Windows protocol example.

© 2005 by CRC Press LLC

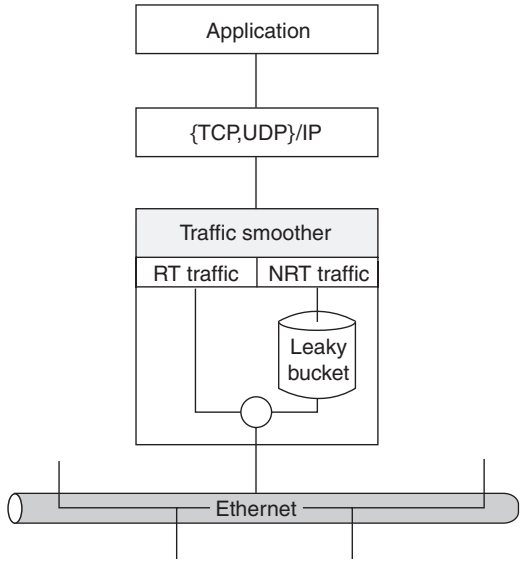

FIGURE 48.5 Software architecture of traffic smoothing.

is also commonly referred to as traffic smoothing). To avoid additional delays, RT traffic is transmitted on demand and it is not handled by the traffic smoother. Notice that real-time (RT) traffic is normally composed of periodic or sporadic message streams with a single packet per message instance, and thus the probability of collisions it induces is low. On the other hand, the Non-Real-Time (NRT) traffic is captured by the traffic smoother, which keeps track of previous message transmissions performed by the node. According to this historical record, it releases NRT messages in a controlled manner to achieve a desired node's traffic generation rate commonly referred to as *station input limit*. Moreover, inside each node, RT messages get higher priority than NRT ones. At the network level, the interference due to NRT traffic is kept under a probabilistic bound.

The station input limit, that is, the parameters of the leaky bucket, can either be static or they can be dynamic, being adjusted to the current network load in an adaptive way. A recent evolution of this latter approach has been presented in [13] in which the network load is estimated using two parameters, the number of collisions and the throughput, both observed in a given interval. These parameters are then used by a fuzzy controller that sets the instantaneous station input limit. The resulting efficiency is substantially higher than with other approaches to traffic shaping, allowing stations (nodes) to take advantage of periods of low throughput to transmit more data over the bus.

In any case, traffic shaping supports probabilistic timing guarantees only being suited to soft RT systems. Typical applications can be either multimedia applications or even some robust control applications, which can cope with a few sample losses.

Token Passing

Another approach to achieve RT behavior in Ethernet consists in explicitly assigning time slots for exclusive use of a given node. This way, collisions are completely avoided. One possible way of implementing this concept in any shared bus network is by means of a timed-token mechanism [14].

In [12], Venkatramani and Chiueh present an implementation of this concept called RETHER. This protocol operates in normal CSMA/CD mode until the arrival of RT requests, upon which it switches to token-bus mode.

In the token-bus mode, RT data are considered to be periodic and the time is divided into cycles. During the cycle duration, access to the bus is regulated by a token, both for RT and NRT traffic. First, the token visits all nodes that are sources of RT messages. Afterwards, if there is enough time until the end of the cycle, the token visits the sources of NRT data. An on-line admission control policy assures that all accepted RT requests can always be served and that new RT requests cannot jeopardize the guarantees

© 2005 by CRC Press LLC

of existing RT messages. Therefore, in each cycle, all RT nodes can send their RT messages. However, with respect to the NRT traffic, no timeliness guarantees are granted.

Figure 48.6 illustrates a possible network configuration with six nodes. Nodes 1 and 4 are sources of RT messages, forming the RT set. The remaining nodes have no such RT requirements and constitute the NRT set. The token first visits all the members of the RT set and after, if possible, the members of the NRT set. A possible token visit sequence could be: cycle i {1 – 4 – 1 – 2 – 3 – 4 – 5 – 6}, cycle i+1 {1 – 4 – 1 – 2}, cycle i+2 {1 – 4 – 1 – 2 – 3 – 4}… . In the ith cycle, the load is low enough so that the token has time to visit the RT set plus all nodes in the NRT set, too. In the following cycle, besides the RT set, the token only visits nodes 1 and 2 of the NRT set and, in the next cycle, only nodes 1 through 4 of the NRT set are visited.

Due to the complete elimination of collisions, this approach supports deterministic analysis of the worst-case network access delay, particularly for the RT traffic. Furthermore, if the NRT traffic is known *a priori,* it is also possible to bound the respective network access delay, which can be important, for example, for sporadic RT messages. However, since the bandwidth available for NRT messages is distributed according to the nodes order established in the token circulation list, the first nodes always get precedence over the following ones, which end up with very long worst-case network delays. Moreover, this method involves a considerable communication overhead caused by the circulation of the token.

Master/Slave Techniques

One of the simplest ways of enforcing RT communication over Ethernet consists in using a master/slave approach in which a special node, the master, controls the access to the medium of all other nodes, the slaves. The traffic timeliness is then reduced to a problem of scheduling that is local to the master. However, this approach typically leads to a considerable underexploitation of the network bandwidth because every data message must be preceded by a control message issued by the master resulting in a substantial communication overhead. Moreover, there is some extra overhead related to the turnaround time, that is, the time that must elapse between consecutive messages, since every node must fully receive and decode the control message before transmitting the respective data message. Nevertheless, it is a rugged transmission control strategy that has been used in many protocols. It is also the basis for the current Ethernet Powerlink protocol [15], a recently proposed industrial solution for RT communication over Ethernet.

A variant mechanism has also been proposed recently, which allows reducing the referred communication overhead. It is called the master/multislave approach [30] according to which the bus time is split into cycles and the master issues one control message for the whole cycle only indicating which data messages must be produced therein. This mechanism has been developed within the FTT framework, Flexible Time-Triggered communication, which has been implemented over different network protocols. One such implementation has been over Ethernet, leading to the FTT-Ethernet protocol [23]. This protocol combines the master/multislave transmission control technique with centralized scheduling, maintaining both the communication requirements and the message scheduling policy localized in one single node, the Master, and facilitating on-line changes to both, thus supporting a high level of operational flexibility.

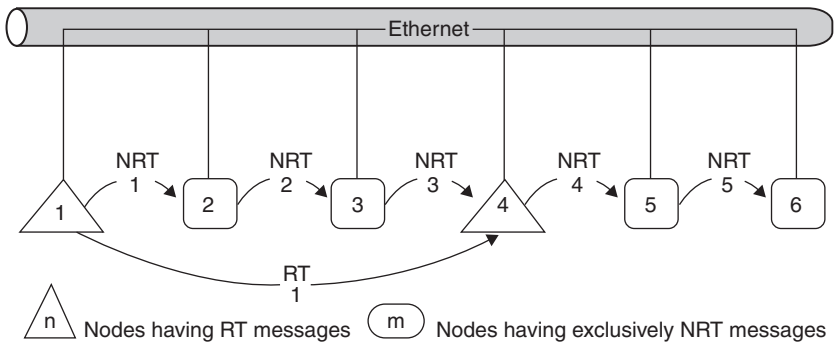

FIGURE 48.6 Sample network configuration for RETHER.

© 2005 by CRC Press LLC

The bus time is divided into fixed-duration time-slots called Elementary Cycles (ECs) that are further decomposed into two phases, the synchronous and asynchronous windows (Figure 48.7), which have very different characteristics. The synchronous window carries the periodic time-triggered traffic that is also scheduled by the master node. The expression time-triggered implies that this traffic is synchronized to a common time reference, which in this case is imposed by the master. The asynchronous window carries the sporadic traffic either related to protocol control messages, such as those conveying change requests for the time-triggered traffic, event-triggered messages, such as those related to alarms, and other NRT traffic. There is a strict temporal isolation between both phase so that the sporadic traffic does not interfere with the time-triggered one.

Despite allowing on-line changes to the attributes of the time-triggered traffic, global timeliness is enforced by the FTT–Ethernet protocol by means of on-line admission control. Due to the global knowledge and centralized control of the time-triggered traffic, the protocol may easily support dynamic QoS management as a complement to admission control.

Beyond the flexibility and timeliness properties that this protocol exhibits, there are also some drawbacks that concern the computational overhead required in the master to execute both the message scheduling and the schedulability analysis on-line. This is, however, confined to one node. Nevertheless, slaves also need some computational power to decode the trigger message in time and start the due transmissions at the right moments. Finally, in safety-critical applications, the master must be replicated, requiring further mechanisms to ensure coherency between their internal databases holding the system communication requirements.

Switched Ethernet

Since roughly one decade ago, the interest in using Ethernet switches has been growing as a means to improve global throughput, traffic isolation, and reduce the impact of the nondeterministic features of the original CSMA/CD arbitration mechanism. Switches, unlike hubs, provide a private collision domain for each of its ports, that is, there is no "direct" connection between its ports. When a message arrives at a switch port, it is buffered, analyzed with respect to its destination, and moved to the buffer of the destination port (Figure 48.8). The "packet handling" block in the figure includes the switch fabrics, which transfers messages from input to output ports, the switch controller or CPU, which controls the switch fabric and manages the internal traffic, and the switch memory, which is used to hold the port queues.

When the arrival rate of messages at each port, either input or output, is greater than the rate of departure, the messages are queued. Currently, most switches are fast enough in handling message arrivals so that queues do not build up at the input ports (these are commonly referred to as nonblocking switches). However, queues may always build up at the output ports whenever several messages arrive in a short interval and are routed to the same port. In such case, queued messages are transmitted sequentially, normally in FCFS order. This queue handling policy may, however, lead to substantial network-induced delays because higher priority or more important messages may be blocked in the queue while lower priority or less important ones are being transmitted. Therefore, the use of several parallel queues for different priority levels has been proposed (IEEE 802.1p). The number of distinct priority levels is limited to eight, but many current

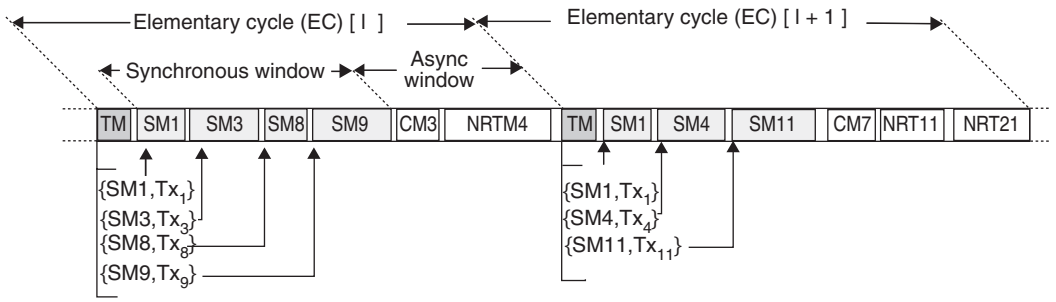

FIGURE 48.7 FTT–Ethernet traffic structure.

© 2005 by CRC Press LLC

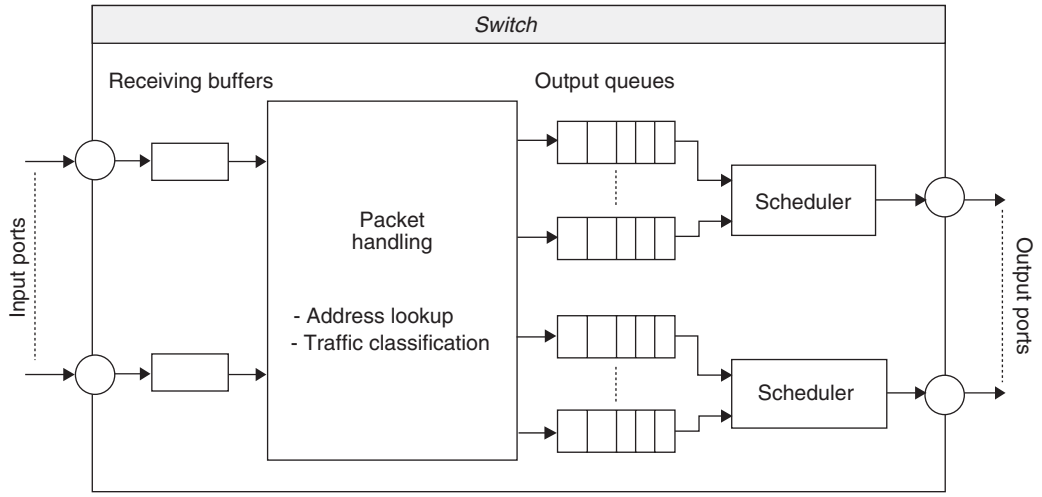

FIGURE 48.8 Switch internal architecture.

switches that support traffic prioritization offer even a further limited number. The scheduling policy used to handle the messages queued at each port also has a strong impact on the network timing behavior [22].

A common misconception is that the use of switches, due to the elimination of collisions, is enough to enforce RT behavior in Ethernet. However, this is not true in the general case. For instance, if a burst of messages destined to the same port arrives at the switch, output queues can overflow, thus leading to a loss of messages. This situation, despite seeming somewhat unrealistic, can occur with a nonnegligible probability in certain communication protocols based on the producer–consumer model, for example, Control Information Protocol (CIP) and its lower level protocols such as Ethernet/Industrial Protocol (IP) [24], or based on the publisher–subscriber model such as RTPS [25] used within Interface for Distributed Automation (IDA). In fact, according to these models, each node that produces a given datum (producer or publisher) transmits it to potentially several nodes (consumers or subscribers) that need it. This model is efficiently supported in Ethernet by means of special addresses, called multicast addresses. Each network interface card can define the multicast addresses related to the information that it should receive. However, the switch has no knowledge about such addresses and thus treats all the multicast traffic as broadcasts, that is, messages with multicast destination addresses are transmitted to all ports (*flooding*).

Therefore, when the predominant type of traffic is multicast/broadcast instead of unicast, one can expect a substantial increase of peak traffic at each output port that increases the probability of queue overflow, causing degradation in network performance. Furthermore, in these circumstances, one of the main benefits of using switched Ethernet, that is, multiple simultaneous transmission paths, can be compromised. A possible way to limit the impact of multicasts is using virtual LANs (VLANs) so that flooding affects only the ports of the respective VLAN [16].

Other problems concerning the use of switched Ethernet are referred in [9] such as the additional latency introduced by the switch in the absence of collisions as well as the low number of available priority levels that hardly supports the implementation of efficient priority-based scheduling.

These problems are, however, essentially technological and are expected to be attenuated in the near future. Moreover, switched Ethernet does alleviate the nondeterminism inherent to CSMA/CD medium access control and paves the way for efficient implementations of RT communication over Ethernet.

48.5 Recent Advances

Most of the recent work performed on RT Ethernet targets switch-based implementations. However, as discussed in Section Switched Ethernet, just replacing a hub by a switch is not enough to make an

© 2005 by CRC Press LLC

Ethernet network exhibit RT behavior. One of the issues recently addressed in the literature concerns the way packets are handled by the protocol software (protocol stack) within the system nodes. Most of the operating systems implement a single queue, usually working according to a First-Come First-Served policy, for both RT and NRT traffic. This approach induces important delays and priority inversions. A methodology that has been proposed to solve this problem is the implementation of multiple transmit/receive queues [27]. With this approach, the RT traffic is intrinsically separated from the NRT traffic. NRT traffic is only sent/processed when the RT queues are empty. It is also possible to build separate queues for each traffic class, providing internal priority-aware scheduling.

An other important issue concerns the degree of freedom in the network topology (e.g., bus, star). The topology impacts the number of switches that messages have to cross before reaching the target, which impacts the temporal properties of the traffic [28, 29]. For instance, the bus (or line) topology, in which each device integrates a simplified switch eases the cabling, but is the most unfavorable topology for RT behavior.

Another aspect concerning switch-based Ethernet networks respects the scheduling policy within the switch itself. Switches support up to eight distinct statically prioritized traffic classes. Different message scheduling strategies have a strong impact on the RT behavior of the switch [28]. Particularly, strategies oriented toward average performance and fairness, which are relevant for general-purpose networks, may negatively impact the switch RT performance.

Finally, the interest in shared Ethernet is not over yet, either for applications requiring frequent multicasting, in which case the benefits of using switches are substantially reduced, as well as for applications requiring precise control of transmission timing, such as high-speed servoing. In fact, switches tend to induce a higher delay and jitter in message forwarding than hubs, caused by internal mechanisms such as MAC address to port translation in forwarding and spanning-tree management protocol. In the previous sections, several examples of this interest were discussed, such as the recent work around adaptive traffic smoothing [13] and master/slave techniques including both the Ethernet Powerlink [15] as well as FTT–Ethernet [23] protocols. This last protocol is also being analyzed for implementation on switched Ethernet, taking advantage of the message queuing in the switch ports and thus simplifying the transmission control. This has the potential to ease the implementation of slave nodes since then it would not be necessary to enforce fine control of the transmission instants of both synchronous and asynchronous messages, strongly reducing the computational overhead. Several existing Ethernet-based industrial protocols, such as Ethernet/IP, are also taking advantage of switches to improve their RT capabilities [16]. Particularly, this protocol is now receiving unprecedented support from major international associations of industrial automation suppliers, such as Open DeviceNet Vendor Association (ODVA), ControlNet International (CNI), Industrial Ethernet Association (IEA), and Industrial Automation Open Networking Alliance (IAONA).

48.6 Conclusion

Due to several reasons, Ethernet became the most popular technology for LANs today. This makes it very attractive even in application domains for which it was not originally designed, in order to benefit from its low cost, high availability, and easy integration with other networks, just to name a few arguments. Some of such application domains, for example, industrial automation, impose RT constraints on the communication services that must be delivered to the applications. This conflicts with the original medium access control technique embedded in the protocol, CSMA/CD, which is nondeterministic and behaves very poorly with medium to high network loads. Therefore, in its nearly 30 years of existence, many adaptations and technologies for Ethernet have been proposed in order to support the desired real-time behavior.

This chapter has presented an overview of those techniques, ranging from changes to the bus arbitration, to the addition of transmission control layers, and also to the use of special networking equipment, such as switches. Such techniques have been described and briefly analyzed in what concerned their pros and cons for different types of application. This chapter concludes with a reference to recent trends, where the growing impact of switches is clear, despite a few specific situations in which shared Ethernet might still be preferable, such as when the traffic is mainly of a multicast nature or a precise transmission timing control is required.

© 2005 by CRC Press LLC

With the current high pressure to bring Ethernet more and more into the world of distributed automation systems, it is likely that such technology will end up taking the place of existing fieldbuses and establishing itself as the *de facto* communication standard for this area. Although its efficiency in terms of bandwidth utilization is still low when considering short messages, particularly lower than with several fieldbuses, its high and still growing bandwidth seems more than enough to supplant such an aspect. Ethernet will then become the long-awaited single networking technology within automation systems, which will support the integration of all levels, from the plant floor to the management, maintenance, supply-chain, etc.

49.1 Introduction

In recent years, the Ethernet technology has taken several giant evolution steps. From the 10 Mbit/sec shared cable in 1990, the state of the art is now a switch-based communication technology running at 100 or 1000 Mbit/sec. The network switches are also becoming more sophisticated in that they have started including support for packet priority and virtual networks. Since all this power comes at a steadily decreasing cost, it is steadily invading other cost-sensitive areas, most notably automation networks. This chapter will look at some critical aspects of switched Fast Ethernet as an automation network.

49.2 The Switches are Not the Complete Network

Exchanging the classic Ethernet infrastructure for a switched infrastructure does wonders for the infrastructure but not necessarily for our automation network. The reason for this fact is illustrated in Figure 49.1, which shows all the stages in an information transfer between an automation controller and an I/O node.

© 2005 by CRC Press LLC

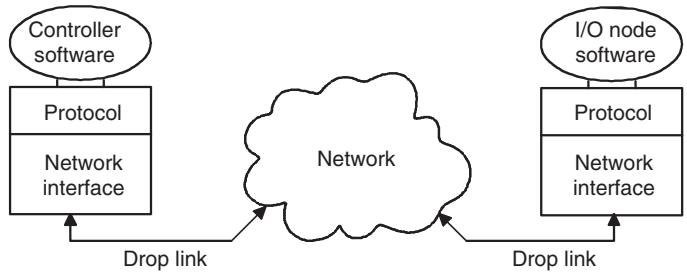

FIGURE 49.1 The complete end-to-end network.

The purpose of this chapter is to

- analyze the advantages, disadvantages, and peculiarities of a switched Ethernet automation network,
- point out the remaining bottlenecks between the controller software and the I/O node software, and
- discuss how the characteristics of the switched network affects some specialized automation network tasks.

49.3 Analyzing Switched Fast Ethernet

Let us start by recapitulating some basic facts about switched Ethernet automation networks.

1. Just as in a hub, an Ethernet switch contains a number of *ports*. Each port is either active (connected to an active Ethernet node) or passive (disconnected or connected to an inactive Ethernet node).
2. The connection between an active port and its associated Ethernet node is point-to-point. The connection may be full duplex (send and receive simultaneously) if the associated node supports it; otherwise, it is half duplex.
3. Each port in an Ethernet switch has a table of network addresses associated with that port. These tables are created by inspecting network packets sent from the node and extracting the source address from the packets.
4. Ethernet switches use a store-and-forward approach, which means that the complete network packet is received and verified by the switch before it is transferred to the output port.
5. The transfer of a network packet from one port to another inside the Ethernet switch is done by memory-to-memory copy at a very high speed.
6. An Ethernet switch does not use the collision mechanism of classic Ethernet.
7. Several transfers between different ports may take place more or less simultaneously. If an Ethernet switch has N ports, it should also be capable of handling N simultaneous connections running at full link speed (assuming that none of them request the same output port). This means that an Ethernet switch has a potentially much greater data transfer capability than a hub.

The Learning Process Inside the Switch

Item (3) above gave the algorithm the switch uses for the internal transfer of network packets. What happens if the switch does not have the destination node address in any port table? In this case, the switch plays it safe and transfers the packet to every output port in the switch. It reduces the switch performance to that of a hub; but it ensures that if the destination node is anywhere on the network, the packet will get through. In the meantime, the switch has learnt the location of the source node and has stored it in the correct table.

This learning process is usually very fast, since each node only has to answer once in order for it to be associated with the correct port. There are, however, some cases when the learning process fails, the most important being:

- Ethernet broadcast and
- Ethernet multicast.

© 2005 by CRC Press LLC

Broadcast: Use with Care

Ethernet inherited the concept of *broadcast* (an address that is accepted by every node on the network) from HDLC. This functionality turned out to be very useful in several network protocols:

- Name announcing in *NetBIOS* ("Hi, everybody, my name is…").
- The Service Advertising Protocol (SAP) in *IPX/SPX*.
- Network address inquiry in *ARP* ("Hello everybody, who has got this IP address?").
- IP address deployment in *BOOTP* and *DHCP* ("I just woke up and I want an IP address!").

The drawbacks inherent in excessive usage of broadcast messages are:

- Broadcast messages cannot be filtered by hardware and must perforce be handled by software, thus consuming CPU resources.
- If broadcast messages are allowed to pass through bridges and routers unchecked, they may create a *broadcast storm* (broadcast messages propagated in circles and thereby clogging the whole network).
- If a broadcast address is used as a *source address*, it may create several network problems (this is a well-known way of creating *network meltdown*).
- Of course, it reduces the performance of a switched network to that of a hub-based network.

Multicast: A Useful, but Dangerous Concept

A huge number of Ethernet addresses are reserved for *multicast* usage. The Multicast concept addresses the need for creating network *groups* of some kind. Traditionally, the multicast concept has been popular in some automation contexts, usually associated with a philosophy called publish-and-subscribe.

This philosophy allows independently developed distributed applications to be able to exchange information in an event-driven manner without needing to know the source of the data or the network topology. Information producers publish information anonymously. Subscribers anonymously receive messages without requesting them.

Like other broadcast-based models, publish-and-subscribe is efficient when used on a classic network. For example, if the cost of energy changes in a distribution system, only a single transmission is required to update all of the devices dependent on the energy price (this is, of course, in the best or most optimistic case).

On a switched Ethernet network, the situation changes drastically. For a standard (unmanaged) switch, multicasting actually uses *more* bandwidth than sending the same message to one recipient after another. This surprising fact is best illustrated with an example.

> If we have a 16-port switch and send the same message to four nodes, the message will occupy the sending port 4 times and the four receiving ports one time each, for a total of eight message times. Sending it as a multicast means that the message will occupy all 16 port for one message time — a total of 16 message times.

The moral in this case is: know your protocols and your infrastructure — and make sure they work together, not against one another.

49.4 There are Always Bottlenecks

Referring again to Figure 49.1, we observe that the network infrastructure is just one part of the communication path from the controller application to the I/O node application. The drop links are unchanged from the hub-based network and the end nodes (the controller and the I/O station) may well be unchanged from the days of the 10 Mbit network, or even older. We shall now proceed to look at the most important bottlenecks in our switched network.

Even Highways have Queues

Queues in the Switches

The nondeterministic behavior of traditional switched Ethernet is caused by unpredictable traffic patterns. At times, packets from several input ports will be destined for the same output port and some of them

© 2005 by CRC Press LLC

must perforce be queued up waiting for the output port to be free. The reason is that at times, there will be considerable low-priority traffic in the system (node status reports, node firmware update, etc.). If we do not introduce some sort of traffic rules, such a situation will give an unpredictable buffering delay depending on the number of involved packets and their length. In the worst case, packets can be lost when the amount of packets sent to an output port exceeds the bandwidth of this port for a time period that is longer than the output buffer is able to handle.

An automation network will have such coexisting real-time traffic (raw data, time sync data, commands, etc.) and noncritical data (TCP/IP — file transfer, etc.). A maximum size packet (1518 bytes) represents an extra delay of 122 μsec for any following queued packets in case of a 100 Mbps network.

Queues on the Drop Links

Even if we manage to introduce some sort of priority mechanism in our system, we have one queue mechanism left. Since some standards (IEC 61850-9 springs to mind) propose to transfer real-time data by using a "publish-and-subscribe" approach (which is again based on the use of multicast groups), a standard unmanaged Ethernet switch has to route these data packets on to every drop link in the system adhering to the broadcast paradigm. Since all those real-time packets might have the same priority, they will be put in the same switch queue on all output ports. The processing rate for these queues is equal to the bandwidth of the drop link between the switch and the nodes, and is therefore effectively a drop link queue. This way, important data packets destined for one node may be delayed by multicast traffic destined for another node. Obviously, we need to introduce some traffic rules/mechanisms for multicast data packets as well in order to reduce the worst-case transfer time.

Queues in the Nodes

Introducing traffic rules in the Ethernet switches will improve the worst-case latency across the network (from the Ethernet controller in the source node to the Ethernet controller in the destination node). Inside the node, however, there is usually only one single network task, and just a single hardware queue associated with the Ethernet controller. Since a network packet spends a large percentage of its total end-to-end time inside a node, internal packet prioritization is needed in order to have maximal control over the total packet transfer time (80–90% of the end-to-end message latency is spent within the end nodes, at least when adhering to the IETF protocols UDP/TCP/IP).

- For the transmit operation, one typically could have a situation where multiple max size Ethernet packets, for example, fragments of an FTP transfer, queued up at the Ethernet driver level. In a standard implementation, real-time packets will be added to the end of the queue. Such behavior will cause a nonpredictable delay in transmission.
- For the receive operation, the protocol stack implementation represents a possible bottleneck in the system. This is mainly due to the first-come first-served queue at the protocol multiplexer level (the level where the network packets are routed to the appropriate protocol handler software).

Introducing a Standard for Priority and Delivery

High-Priority Packets Jump Ahead in Switch Queues

IEEE 802.1D (see [3]) has been introduced to alleviate the switch queue problem; moreover, the standard specifies a layer 2 mechanism for giving mission-critical data preferential treatment over noncritical data. The concept has primarily been driven by the multimedia industry and is based on priority tagging of packets and implementation of multiple queues within the network elements in order to discriminate packets [1]. For tagging purposes, IEEE 802.1Q [4] defines an extra field for the Ethernet MAC header. This field is called *Tag Control Info* (TCI) field and is inserted as indicated by Figure 49.2. This field contains three priority bits; thus the standard defines eight different levels of priority.

Multicast Distribution Rules Reduce Drop Link Traffic

Figure 49.2 defines more than some priority bits. If you observe closely, you can see something called a "12 bit 802.1Q VLAN identifier." This Virtual Local Area Network (VLAN) identifier is a mandatory part of

© 2005 by CRC Press LLC

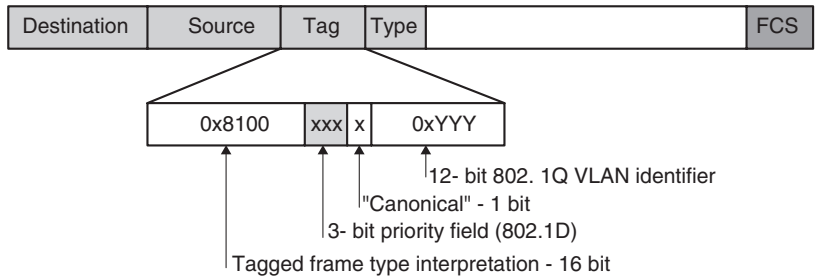

FIGURE 49.2 MAC header (layer 2) with tag.

each TCI field and can, when properly used, remove all unnecessary drop link traffic in an automation network based on publish-and-subscribe. We will discuss the handling and usage of this field in the section on Virtual LANs.

High-Priority Packets Get High-Priority Treatment

A network data packet spends a relatively small percentage of its application-to-application transfer time on the physical network. The actual percentage varies with the speed of the network and the performance of the node, but for a 100 Mbit/sec Fast Ethernet, the average percentage is between 20 and 0.1%. For this reason, implementing network priority will have little influence on the average application-to-application transfer time (it will, however, have a large influence on the worst-case transfer time). In order to improve the average application-to-application transfer time, the concept of priority must be extended to include the protocol layers in both the sending and receiving end. In order to accomplish this, we must consider:

- Adjustable process priority for the protocol stack software.
- Several instances of the protocol stack software running at different priority levels.
- Multiple transmit queues at the Ethernet driver level.

Matching Network Process Priority to Packet Priority

In most real-time operating systems, the protocol stack runs as a single thread in the context of some networking task. If we want the task priority to depend on the packet priority, we can implement it in a very simple way:

1. At compile time, decide on the task priority that should correspond to each packet priority and to an untagged packet. Put those priorities in a table.
2. Set a high basic networking task priority (the priority it uses when no packet is being processed).
3. When the networking task starts to process a packet, it should extract the packet priority and use it with the priority table described above to find the appropriate task priority.
4. Change the task priority by executing a system call.

Multiple Instances of the Protocol Stack Software

There is, however, a problem with the previous solution. Adjusting to correspond to the packet priority ensures that the processing of high-priority network packets does not get interrupted by less important administrative tasks. Still, networking tasks process incoming messages one at a time in a linear manner. What we really want is to process high-priority messages before low-priority ones. In fact, if we could suspend the processing of low-priority network packets when a high-priority message arrives, we would have the perfect solution.

At first glance, there exist an ideal solution. It goes like this:

1. At compile time, decide on the task priority that should correspond to each packet priority and to an untagged packet. Create one task for each priority and put the task IDs in a table.
2. When a packet arrives, extract the packet priority, use it with the task table described above, send the packet to that task, and send a signal to the task in order for it to start processing.

© 2005 by CRC Press LLC

The problem with this solution is that it supposes that the network software is *reentrant*, a condition that is seldom fulfilled. Rewriting the stack software to make it reentrant is not hard, just tedious and time-consuming. Of course, it also means that you have to support the rewritten software in the future.

Running multiple instances of the protocol software may be the most elegant and efficient solution, but one must be prepared to spend some time and resources on it.

Multiple Receive Queues and Adjustable Priority

If we do not want to spend time and money on making the network software reentrant; there is an alternative solution available. This solution does not suspend the processing of lower priority packets, but selects the next packet to be processed from a set of criteria based on the packet priority. One possible implementation goes like this:

5. At compile time, decide on the task priority that should correspond to each packet priority and to an untagged packet. Create one queue for each priority and put a pointer to the queue in a table.
6. Whenever the network software is ready to process the next packet, it pulls all packets from the input queue and distributes them to the priority queues.
7. When the input queue is empty, the priority selection algorithm is run. This algorithm may be implemented in several different ways, for example:
   - Always pick the packet from the highest priority nonempty queue.
   - Pick the packet from the highest priority nonempty queue a certain number of times. Then, move the first packet from each nonempty queue to the next higher priority queue before picking the packet from the highest priority nonempty queue again.
   - Introduce a LOW flag. Wait for a packet to appear in the highest priority queue or for the LOW flag to be set. If the packet appeared in the highest priority queue, set the LOW flag and process that packet. If the LOW flag was set, reset it and process the packet from the highest priority nonempty queue.

Implementing Multiple Transmit Queues

On a transmit request, a standard Ethernet driver takes a buffer, does some housekeeping, and transfers it to the Ethernet controller hardware. Such a driver is simple and "fair" (first come, first served), but may be unsuitable for an efficient priority implementation. One or more large low-priority packets, once they are scheduled for transmission, will delay high-priority packets for the time it takes to transfer the low-priority ones. If we want high-priority packets to go to the head of the transmission queue, and the hardware does not support multiple queues, we must do some priority handling at the driver level.

The simplest solution is to use two queues: the hardware queue and a software queue. Low-priority packets go into the software queue; high-priority packets go straight into the hardware queue. From this point onward, there exist several algorithms addressing different needs.

- If the real-time requirements are moderate, move the first packet in the software queue to the hardware queue whenever the hardware queue is empty.
- If the real-time requirements are strict, move the first packet in the software queue to the hardware queue whenever a high-priority packet has been placed in the hardware queue.

Bottleneck Conclusions

The conclusion, based on a large set of real-world measurements (see [2]), is that:

1. At 100 Mbit/sec, the Ethernet switch and the drop links do not constitute a bottleneck under FTP load.
2. If several switches are interconnected by standard drop link cables, these cables might represent bottlenecks. Most switches have provisions for Gigabit Ethernet (1000 Mbit/sec) interconnections, however, thereby removing this possibility.
3. The main communication delays are inside the nodes. A suitable queue strategy for high-priority packets assures that those will be processed before low-priority packets.

© 2005 by CRC Press LLC

4. For a high-performance node processor, implementing prioritized transmit queues has a greater overall impact on high-priority packet delays than implementing prioritized receive queues.
5. If you want to implement internal receive priority queuing, ensure that it is possible to configure the chosen switch not to remove the priority tagging information.

49.5 Time Synchronization Across Switched Ethernet

Now and then you come across measurement problems that are tightly associated with the notion of *synchronicity*, meaning that things need to happen simultaneously. The usual things that need such *synchronicity* are data sampling and motion control. In the case of data sampling, you need to know the value of two different quantities measured at the same time (within a narrow tolerance). If the measurement sources are close together, this is fairly easy to accomplish, but if they are far apart and connected to different measurement nodes, it suddenly becomes harder. The usual choices are:

1. Use a *special hardware signal* on a separate cable between the controller and all nodes that need synchronization. If the nodes are far apart and the tolerances are tight, make sure that all cables that carry the synchronization signal have the same length.
2. Add a local clock to each node and use the present automation network to keep them in synchronization. Tell each node how often the measurement sources should be sampled and require the node to *time stamp* each measurement.

We shall now take a look at the hardest synchronization requirements for automation purposes and discuss the possibility of implementing class T5 (1-μsec) and class T3 (25-μsec) synchronization in a multitraffic switched Ethernet environment. Common for both solutions is that they adhere to the same standardized time protocol. Such a step would significantly reduce the cabling and transceiver cost, since costly dedicated (separate) links are used for this purpose today.

The Concept of Time Stamping

Let us start at the very beginning — the concept of time stamping:

> Time stamping is the association of a data set with a time value. In this context, "time" may also include "date."

Why would anybody want to time stamp anything? The closest example may be on your own PC — whenever you create a document and save it, the document is automatically assigned a data-and-time value. This value enables you to look for

- Documents created on a certain date (e.g., last Monday).
- Documents created within a certain time span (e.g., last half of 1998).
- The order in which a set of documents were created (e.g., the e-mails in your inbox).

If we just look at the examples above, we see that the accuracy we need for the time stamping is about the same as we expect from our trusty old wristwatch. This again means "within a couple of minutes," but as long as the clock does not stop it does not really matter much how precise it is.

Let Us Synchronize Our Watches!

Now we know about time stamping on our own PC. The next step is to connect the PC to a network, maybe even to the Internet and start exchanging documents and e-mails. What happens if the clock in your PC (the clock that is used for time stamping) is wrong by a significant amount?

- If you have an e-mail correspondence with someone, a reply (which is time stamped at the other end) might appear to be written before the question (which is time stamped at your end).
- If you collaborate on some documents, getting the latest version might be problematic.

Therefore, when several PCs are connected together in any kind of network, the PC clocks are still accurate enough, but a new requirement is that they should be *synchronized* (show the same time at one

© 2005 by CRC Press LLC

point in time). Now, we could go around to each PC, look at our wristwatch, and set the PC clock to agree with it. The trouble is that this is a boring and time-consuming job and we should look for a better solution.

One solution is to elect one PC to be the "time reference," which means that every other PC should get the current time from it at least once a day and set its own clock to agree with that time. This solution works satisfactorily on a Local Area Network (LAN), but all PC clocks will lag the time reference by the time it takes a clock value to travel from the time reference to the synchronizing PC. Except for very unusual cases, this lag is less than 1 sec and thus good enough for office purposes.

Enter the Internet. Suddenly the synchronization problem escalates, since two collaborating PCs may be located in different time zones (remember to compensate for that) and a synchronization message may take a long time from one PC to the other. Fortunately, the Internet Network Time Protocol has a solution to both problems. This protocol involves sending a time-stamped time request message to a "timeserver." This timeserver adds an arrival time stamp and a retransmit time stamp before returning the request message to the requesting PC. The requesting PC time stamps the message when it returns and uses all the time stamps in calculating the correct time. This protocol and it little brother, the Simple Network Time Protocol, are able to synchronize computers across the Internet with a precision in the low milliseconds.

Synchronization Requirements in Substation Automation

In the energy distribution world, a *substation* is an installation where the energy is combined, split, or transformed. A Substation Automation (SA) system refers to tasks that must be performed in order to control, monitor, and protect the primary equipment of such a substation and its associated feeders. In addition, the SA system has administrative duties such as configuration, communication management, and software management.

The communication within SA systems is crucial from the point that the functionality demands for very time-critical data exchange. These requirements are substantially harder than the corresponding requirements in general automation. This is also true for the required synchronization accuracy of the Intelligent Electrical Device's (IED's) internal clock in order to guarantee precise time stamping of current and voltage samples. Various SA protection functions require different levels of synchronization accuracy. IEC has provisionally defined five levels — IEC classes T1 – T5 (IEC 61850-5, Secs 12.6.6.1 and 12.6.6.2):

- IEC class T1: 1 msec
- IEC class T2: 0.1 msec
- IEC class T3: ±25 μsec
- IEC class T4: ±4 μsec
- IEC class T5: ±1 μsec

Since these definitions and classes are not frozen as yet, we will refer to them as class T1, class T2, etc. (without IEC) here.

At this point in time, the SA field is also on the edge of migrating toward the usage of Switched Fast Ethernet as the automation network infrastructure. The ultimate vision is to achieve interoperability between products from different vendors on all levels within the substation automation field. A proof of this new trend is the upcoming IEC 61850 standard on *Communication networks and systems in substations* issued by Technical Committee. Inventions of de facto standard concepts, and adoption of off-the-shelf technologies are the key instruments to reach the interoperability goal. Figure 49.3 illustrates the communication structure of a future substation adhering to switched Ethernet as a common network concept holding multiple coexisting traffic types [5].

We already know that Switched Fast Ethernet has sufficient real-time characteristics to meet very demanding automation requirements. What is left to show is that it is possible to implement the various IEC classes of synchronization accuracy over such a network. This is considered to be the final obstacle of fully migrating to Ethernet in SA.

© 2005 by CRC Press LLC

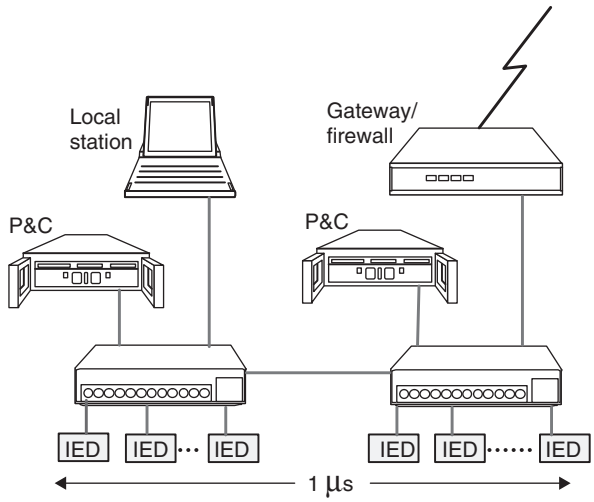

FIGURE 49.3 The communication network in a future SA system using Ethernet as a common network infrastructure.

Time Synchronization Status

There is a plethora of proposed theory and methods for synchronizing clocks in distributed systems. The most prominent public domain synchronization method is the Network Time Protocol (NTP), which is standardized by the Internet Engineering Task Force in RFC1305. A subset of NTP (SNTP — Simple Network Time Protocol) is also defined, and is protocol-compatible with NTP.

The intended use of NTP is to synchronize computer clocks in the global Internet. For this purpose, it relies on sophisticated mechanisms to access national time, organize time synchronization subnets possibly implemented over various media, and adjustment of local clock in each participating peer. SNTP, on the other hand, does not implement the full set of NTP algorithms and is targeting simpler synchronization purposes. Common for this body of work is that it does not present solutions for low microsecond accuracy, instead targeting synchronization of LANs and WANs in the general sense where a precision of some milliseconds is sufficient.

Looking at the automation field in general and especially at the SA world, we find a diversity of proprietary and patented solutions in order to achieve highly accurate time synchronization over Ethernet. Interoperability concerns are, however, present.

Stating the Problem — Why Network Synchronization is Difficult

The delays from the time stamping of a time synchronization message in the message source node until it is time stamped in the message destination node are:

- Message preparation delay
- Communication stack traversal delay (transmission)
- Network access delay
- Network traversal delay
- Communication stack traversal delay (reception)
- Message handling delay

Variations in the delays are due to:

- Real-Time Operating System (RTOS) scheduling unpredictability
- Network access unpredictability
- Network transversal time variations

Time stamping at the lowest stack level helps eliminate the stack delay variations and real-time OS scheduling unpredictability but introduces some complications in the implementation.

© 2005 by CRC Press LLC

How to be Extremely Accurate — IEC Class T3

We have mentioned that the precision that may be achieved by the traditional NTP/SNTP implementations is one millisecond at best. Basically, this stems from the time stamping of incoming and outgoing NTP/SNTP packets at the NTP/SNTP application layer. As stated in the previous paragraph, this makes time stamping a victim of real-time OS scheduling unpredictability.

In this section, we describe how a high degree of accuracy can be achieved using a tuned SNTP implementation and standard Ethernet switches.

A Tuned SNTP Time Protocol Implementation

The NTP/SNTP time synchronization algorithm presented has definite limits to the level of attainable accuracy. Let us recapitulate:

The NTP/SNTP algorithm is based on a network packet containing three time stamps:

- t_1: The (client) time the packet was generated in the client asking for the current time.
- t_2: The (server) time the packet arrived at the timeserver.
- t_3: The (server) time the packet was updated and put into the transmission queue at the server. In addition, the calculations require:
- t_4: The (client) time the packet arrived back at the client.

Now, t_2 and t_4 can easily be determined down to microseconds (and perhaps even better) using hardware or software time stamps based on packet arrival interrupts. The other two have definite problems, however.

For full accuracy, t_1 and t_3 should have been *the time when the packet left* the time client or timeserver, respectively. The problem is that this time stamp is not available until the packet has really left the timeserver or client and then it is, of course, too late to incorporate it into the packet. Therefore, the time synchronization inaccuracy for an NTP/SNTP setup is the variation in the delay between t_1 and the time the packet leaves the time client plus is the variation in the delay between t_3 and the time the packet leaves the timeserver.

It turns out that there are several ways of determining the time when the synchronization packet actually leaves the time client. One algorithm runs like this:

1. Create the NTP packet and fill in the t_1 (Originate Timestamp) as usual. Transmit the package to the timeserver.
2. Get hold of the time stamp when the packet leaves the time client, using any appropriate mechanism. Store this time stamp (t_{11}) in a data structure together with t_1.
3. When the packet returns from the timeserver, extract t_2 from the packet and use t_1 to look up the corresponding value of t_{11}. Since t_{11} and t_1 are stored together, there is no chance of confusion here.
4. Substitute t_{11} for t_1 in the packet.

Achieving Precise Time Stamping Within a Node

The nature of real-time operating systems (they guarantee a maximum response time for an event but allow for a wide variation below that) introduces a substantial variation in the time spent in the communication stacks. This fact has necessitated an interrupt-level time stamping both in the time client and timeserver. The IEC class T3 solution described here adheres to the principle of *interrupt-level time stamping of the SNTP request packet when sent from the time client and when received at the timeserver*. Moreover, we propose that the synchronization is based on the (corrected) *transmit time stamp* set by the client (referred to as t_1 in SNTP terminology) and the *receive time stamp* set by the server (referred to as t_2). Usage of a possible low-level transmit time stamping of the corresponding SNTP reply packet (referred to as t_3) necessitates novel techniques for controlling the nondeterministic access of an Ethernet packet to an Ethernet bus.

A side effect of using $t_1 - t_2$ only is that no mechanism for automatic calibration of the network latency will be available and therefore a manual calibration of the propagation delays of the drop links and the minimum switch latency[1] must be performed.

[1]The minimum Ethernet switch delay is usually given in the switch data sheet.

© 2005 by CRC Press LLC

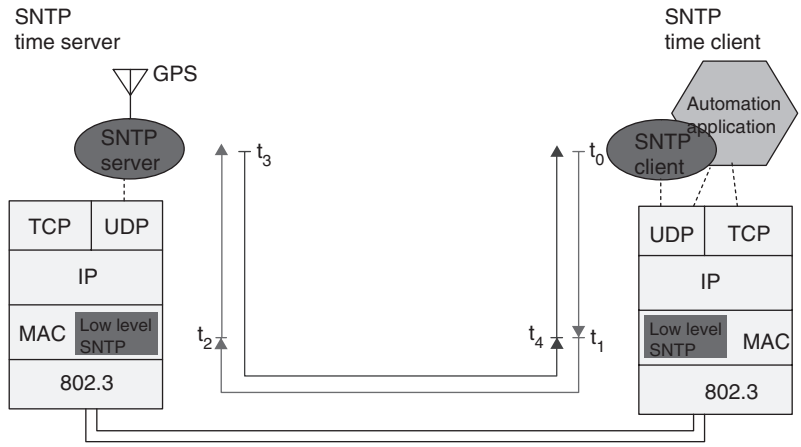

FIGURE 49. 4 The SNTP time client – server relation using low-level time stamping.

Figure 49.4 illustrates the setup of an SNTP time client and timeserver adhering to interrupt-level time stamping.

Time Client Implementation Issues

There are several ways of time stamping a network packet. We shall look at three of them and show that only the first two are suitable for accurate time synchronization:

1. Hardware time stamping in the Ethernet controller.
2. Software time stamping in an Interrupt Service Routine (ISR) outide the RTOS. This ISR should be connected to the Ethernet Interrupt Request signal and have a top hardware priority.
3. Software time stamping in an ISR controlled by the RTOS (Ethernet driver). This ISR is connected to the Ethernet Interrupt Request signal with a normal hardware priority.

Use of any of this low-level time stamping methods is considered an implementation issue and will not cause any incompatibly between a low-level time stamping client and a standard high-level time stamping server. In addition to low-level time stamping, the time client must consider the following aspects:

- The interval between time updates.
- The specifications of the local time-of-day clock with respect to resolution, accuracy/stability, and the availability of drift and offset correction mechanisms.
- The usage of adaptive filtering and time stamp validation methods in order to remove network delay variations.

Timeserver Implementation Issues

In order to achieve class T3 accuracy, the timeserver should be able to time stamp an incoming message with an accuracy of better than 2 μsec independent of network load. The exact time should be taken from a GPS receiver, and the time parameters distributed from the timeserver should be based on Global Positioning System (GPS) time representation instead of absolute time (i.e., UTC timing) in order to cope with the leap second problem. It is also convenient if the timeserver supports full duplex connectivity in order to avoid a situation where upstream data introduce extra switch latency in downstream data (i.e., time requests).

Ethernet Infrastructure Implementation Issues

Only one switch should preferably be allowed between a time client and a timeserver. Having multiple switch levels will impose increased jitter[2] through the infrastructure, which again might call for more

[2]Jitter: variations in the delay.

© 2005 by CRC Press LLC

complex filtering at the time client side. The Ethernet switch must also have good switch latency characteristics. The switch latency from the client drop link to the server drop link depends on several parameters:

- *General switch load*. This means all the network load on the switch except for the packets sent to the timeserver. The variations in the switch latency from the client drop link to the server drop link should be less than 2 μsec.
- *Timeserver load*. This parameter means other packet sent to the timeserver that may introduce extra delay in the transmission of a given SNTP request packet. This delay can be handled at the time client side using various filtering techniques (see time client requirements).

Measurements on an Actual Network

Extensive tests and measurements regarding time synchronization accuracy on a switched Ethernet network have been undertaken [6]. The conclusions from this body of work are:

- Traffic not destined for the timeserver does not interfere with traffic to the timeserver.
- The switch latency for Ethernet packets to the timeserver depends to a great extent on other traffic to the timeserver.

The full network measurements conclusions are:

- Software time stamping using a sufficiently high-priority interrupt (preferably nonmaskable) is for all practical purposes indistinguishable from time stamping using special-purpose hardware.
- Software time stamping using an interrupt under RTOS control needs sophisticated filtering and statistical techniques before it can be used for time synchronization purposes. In this respect, this time stamping method is not suitable for IEC class T3 synchronization.
- IEC class T3 time synchronization using tuned SNTP over a switched Ethernet has shown to be eminently feasible.

Beyond the Speed of Light — Class T5

It is now possible to procure industrial-class Fast Ethernet switches fulfilling an extensive list of environment requirements relevant for substation automation applications. Some of these switches can even be delivered with an integrated SNTP timeserver.

Since the internal switch logic has full control over input and output ports, time stamping an SNTP request packet on arrival is no problem. In addition, the switch logic can insert the transmit time stamp whenever the output port is ready for the reply packet (and even adjust the time stamp for the delay between time stamping and actual transmission). Thus, the traditional problem related to the nondeterministic access to the Ethernet is not a problem here due to the tight interaction between the SNTP timeserver and the switch architecture.

This time synchronization scheme provides the following:

- Timing synchronization accuracy better than one microsecond if time stamping in the time client is performed in hardware; see Time client implementation issues.
- Both server time stamps — t_2 (receive) and t_3 (transmit) — may be used at the time client for synchronization purposes, and the drop link propagation delay can easily be removed based on the calculated round-trip delay.
- The timing accuracy is independent of the network load.
- No clever filtering/erasure techniques are needed in the time client.

Summary and conclusions

We have presented general solutions for achieving class T5 (1 μsec) and class T3 (25 μsec) time synchronization over switched Ethernet. The former is based on a dedicated Ethernet switch/Time Server

© 2005 by CRC Press LLC

combination, while the latter relies on standard switches. Common for both solutions is that they adhere to the low-level time stamp implementation of the SNTP.

Hardware time stamping or low-level software time stamping outide the real-time operating system eliminates the client inaccuracy from the error budget of the SNTP time synchronization loop. If the SNTP timeserver relies on the same time stamping techniques, the only remaining factor to be handled in the error budget is possible time delay variations within the infrastructure. In these settings, class T3 synchronization is possible over switched Ethernet.

49.6 Introducing Virtual Subnetworks

What are VLANs? A concept made possible by Ethernet switches, the multitude of vendor-specific VLAN solutions and implementation strategies has made it very difficult indeed to define precisely what a VLAN is. Nevertheless, most people would agree that a VLAN might be roughly equated to a broadcast domain[3]. More specifically, VLANs can be seen as analogous to a group of end-stations, perhaps on multiple physical LAN segments, which are not constrained by their physical location and can communicate as if they were on a common LAN.

Currently, three types of VLANs are of interest:

- Port Group VLANs
- Layer 2 — Multicast Group-based VLANs
- Layer 3-Based VLANs

Here, we will only give a brief overview of these different types of VLANs. An important aspect to note in this context is the fact that it is now possible to define dynamic VLANs that correspond exactly to a multicast group. This means that multicast frames will only propagate to members of the indicated VLAN and not to anyone else. In particular, the frames will not occupy drop links or CPU resources in nodes that do not belong to the multicast group.

Port Group VLANs

Port-based VLAN is a concept relying on a pure manual configuration of Ethernet switches (bridges) to set up VLAN membership. Many initial VLAN implementations defined VLAN membership by groups of switch ports (e.g., ports 1, 2, 3, 7, and 8 on a switch make up VLAN A, while ports 4, 5, and 6 make up VLAN B). Furthermore, in most initial implementations, VLANs could only be supported on a single switch.

Second-generation implementations support VLANs that span multiple switches (e.g., ports 1 and 2 of switch #1 and ports 4, 5, 6, and 7 of switch #2 make up VLAN A, while ports 3, 4, 5, 6, 7, and 8 of switch #1 combined with ports 1, 2, 3, and 8 of switch #2 make up VLAN B).

Port grouping is still the most common method of defining VLAN membership, and configuration is fairly straightforward. Defining VLANs purely by port group does not allow multiple VLANs to include the same physical segment (or switch port). However, the primary limitation of defining VLANs by port is that the network manager must reconfigure the VLAN membership when a node is moved from one port to another.

Group-Based VLANs: GARP VLAN Registration Protocol

In the 802.1D standard (see [3]), the Generic Attribute Registration Protocol (GARP) is introduced. This is a general protocol that allows network nodes to control selected switch properties. The first two implementations of this protocol are the GARP Multicast Registration Protocol and the GARP VLAN Registration Protocol (GVRP).

GVRP provides a mechanism that allows switches and end stations to dynamically register (and subsequently, deregister) VLAN membership information with the Ethernet switches attached to the same LAN segment, and for that information to be disseminated across all switched in the LAN that support Extended Filtering Services. Moreover, no manual configuration of the switches is required opposed to

[3]Broadcast Domain: A collection of all nodes that can be reached by a broadcast message from one of them.

© 2005 by CRC Press LLC

the port-based solution — on the other hand, the switches must implement extra software as specified by the IEEE 802.1D standard [3].

The operation of GVRP relies upon the services provided by GARP. The information registered, deregistered, and disseminated via GVRP is of the following forms:

1. VLAN membership information. This indicates that one or more GVRP participants that are members of a particular VLAN (or VLANs) exist, and the Ethernet frames carry a 12-bit VLAN Identifier (VID) (see Figure 49.2) that state the membership. The act of registering/deregistering a VID affects the contents of Dynamic VLAN Registration Entries to indicate the Port(s) on which members of the VLAN(s) have been registered.
2. Registration of VLAN membership information allows the Ethernet switches in a LAN to be made aware that frames associated with a particular VID should only be forwarded in the direction of the registered members of that VLAN. In this way, the VLAN membership is propagated through the Ethernet infrastructure, and forwarding of frames associated with the VID therefore occurs only on Ports on which such membership registration has been received.

GVRP is a very new protocol concept and is not yet widely supported by Industrial Ethernet switches, but is foreseen to be one of the future technologies for handling the publish-and-subscribe automation network philosophy. One such handling algorithm consist of three steps:

1. Map every multicast group to one specific VLAN identifier. This is, of course, an off-line activity.
2. At system start-up time, all nodes send out one small packet for each VLAN (and thereby multicast group) it wants to join. This packet, which is not a part of any complicated protocol stack, gives the network infrastructure the information it needs in order to map VLAN identifiers to physical drop links. For simple data source nodes, these packets can be precompiled.
3. Whenever a multicast packet is to be transmitted, it should be tagged with "real-time priority" and the VLAN identifier corresponding to the multicast group.

These simple steps ensure that multicast packets do not block any unnecessary drop links. Below, we discuss the possible solutions for taking control of the latency within the end-nodes.

Layer-3 Based VLANs

VLANs based on layer 3 information take into account protocol type (if multiple protocols are supported) or network-layer address (e.g., subnet address for TCP/IP networks) in determining VLAN membership. Although these VLANs are based on layer-3 information, this does not constitute a "routing" function and should not be confused with network-layer routing.

Even though a switch inspects a packet's IP address to determine VLAN membership, no route calculation is undertaken, and frames traversing the switch are usually bridged according to implementation of the Spanning Tree Algorithm (the purpose of this algorithm is to make sure that no network packet is caught in an endless loop between switches).

There are several advantages to defining VLANs at layer 3. First, it enables partitioning by protocol type. This may be an attractive option for network managers who are dedicated to a service-or application-based VLAN strategy. Second, nodes can physically move their workstations without having to reconfigure each workstation's network address — a benefit primarily for TCP/IP nodes. Third, defining VLANs at layer 3 can eliminate the need for frame tagging in order to communicate VLAN membership between switches, reducing transport overhead.

One of the disadvantages of defining VLANs at layer 3 (vs. MAC- or port-based VLANs) can be performance. Inspecting layer 3 addresses in packets is more time consuming than looking at MAC addresses in frames. For this reason, switches that use layer 3 information for VLAN definition are generally slower than those that use layer 2 information. It should be noted that this performance difference is true for most, but not all, vendor implementations.

50.1 Introduction

Wireless communication systems diffuse into an ever-increasing number of application areas and achieved wide popularity. Wireles telephony and cellular systems have entered our daily lives, and wireless local area network (WLAN) technologies serve more and more as a primary means to access business and personal data. Two important benefits of wireless technology are key to this success: the need for cabling is greatly reduced, and computers as well as users can be truly mobile. These properties not only save costs but also enable new applications. This also holds true for factory plants, where wireless technology can be used in many different ways [18, chap. 2]:

- Applications with mobile subsystems, for example, autonomous transport vehicles, robots, and turntables.
- Implementation of distributed control systems in explosible areas, in the presence of aggressive chemicals or heat.

© 2005 by CRC Press LLC

- Rapid prototyping of industrial plants without putting much effort into cabling.
- Mobile plant diagnose systems, and wireless stations for programming and on-site configuration.

However, adopting WLAN technologies for the factory floor must take two things into account: on the one hand, the special requirements of industrial applications, most notably the reliability and hard real-time constraints for communications, and on the other the properties of wireless transmission channels, which often exhibit a substantial and time-varying amount of transmission errors, potentially harming safety-critical data packets. Therefore, an important challenge for wireless industrial LANs is to find transmission schemes and protocols that give optimum performance in terms of real-time and reliability despite channel errors and certain other specific properties of wireless channels. Protocols should be specifically tailored for wireless media and thus they may well be different from the protocols used in wired industrial communication systems.

In this article, we survey some issues in designing and investigating protocols for wireless industrial LANs and provide an overview on the state of the art. The focus is on aspects influencing the time and reliability behavior of wireless transmission, and how these are addressed on the physical layer, the medium access control (MAC), and the link layer. These layers play a key role in delivering reliable and timely service to upper layers and to applications, and they are exposed most to the wireless link characteristics on the other hand. Furthermore, we provide an overview on current wireless field-bus systems and on the IEEE 802.11 WLAN standard, which might play an important role in industrial applications as well.

This chapter is structured as follows: in Section 50.2 important general considerations for wireless industrial communications and wireless field-bus systems are presented. In Section 50.3, we discuss some basic properties of wireless LAN technology and wireless wave propagation effects. The transmission impairments resulting from these effects and some approaches to target them on the physical layer are presented in Section 50.4. For the MAC and link layers, some specific problems as well as solution approaches are discussed in Section 50.5. The following two sections 50.6 and 50.7 adopt a more technology-oriented perspective. Specifically, in Section 50.6, we survey the state of the art regarding wireless industrial communication systems and wireless field-bus systems, and in Section 50.7 we present the important aspects of the IEEE 802.11 WLAN standard w.r.t. transmission of real-time data. Finally, in Section 50.8, we provide a brief summary.

This chapter is restricted to protocol-related aspects of wireless transmission, other aspects like signal processing, analog and digital circuitry, energy aspects, management, etc. are not considered. There are many introductory and advanced books on wireless networking, for example, [48, 1, 9, 26, 45, 50,–52] and several separate topics in wireless communications are treated in [19].

50.2 Wireless Industrial Communications and Wireless Field-Bus

In industrial applications, often *hard real-time* requirements play a key role. In accordance with [46], we assume the following important characteristics of hard real-time communications: (a) safety-critical messages must be transmitted reliably within an application-dependent deadline; (b) there should be support for message priorities; and (c) messages with stringent timing constraints typically have a small size. The qualifier "hard" stems from the fact that losses or deadline misses of safety-critical packets can lead to damage for life or equipment. Often, so-called *field-bus systems* are used in industrial communications. These systems are explicitly designed to meet hard timing and reliability requirements in harsh environments.

To date, the error properties of wireless links as experienced in different measurements (see the section Effects on transmission) suggest that wireless technology is not a candidate for systems where lost messages or deadline misses lead to catastrophes. As an example, the measurements presented in [64] have shown that in a certain industrial environment for several seconds no packet could be transmitted. Therefore, instead of seeking absolute guarantees, it is appropriate to formulate another optimization criterion: the percentage of safety-critical messages that can be transmitted reliably within a prespecified time-bound should be as high as possible (e.g., $> 99.x\%$), even at the cost of other

© 2005 by CRC Press LLC

performance measures like throughput or mean delay. We call this approach *stochastic hard real-time*. Of course, this limits the application areas of a wireless industrial LAN: when deterministic guarantees in the range of 10 to 100 msec are essential, wireless transmission is ruled out. However, in applications, where occasionally emergency stop conditions due to message loss or missing deadlines are tolerable, wireless technology can offer its potential. The goal is then to reduce the frequency of losses and deadline misses.

It depends on the communication model how reliability can be implemented. Many field-bus systems (e.g., PROFIBUS), address *stations*, and packets are transmitted from a sender to a receiver station without involving other stations. Reliability can be ensured using different mechanisms, for example, retransmissions, packet duplications, or error-correcting codes, which can all be implemented on wireless media. On the other hand, systems like factory instrumentation protocol (FIP) and controller area network (CAN) implement the model of a real-time database, where not stations but data are identified. A piece of data has one one producer and potentially many consumers. The producer broadcasts the data and all interested consumers copy the packet into an internal buffer. Typically, in these systems, there are no retransmissions, but reliability can be increased by other mechanisms, for example, by using error-correcting codes.

A *wireless field-bus system* aims at providing as stringent time and reliability properties as could be achieved on wireless media [10]. The vast number of already deployed wired field-bus installations and the desire to continue operation of these running systems is an incentive to focus research on *wireless extensions* of already existing field-bus systems instead of creating a new system from scratch. Having a wireless extension allows to integrate wireless and wired stations into a single field-bus LAN.

From a protocol architecture perspective, the different approaches to integrate wireless stations into wired field-bus LANs can be classified according to the layer of the OSI reference model, where the integration actually occurs [63, 10]. This classification reflects the generic architecture of many field-bus systems, where only the layers 1, 2, and 7 of the OSI reference model are used [11]. We use the term *wired station* for a station with a wired transceiver; consequently, a *wireless station* has a wireless transceiver.

Wireless repeater approach: All stations are attached to a cable (hence are wired stations), and just a piece of cable is replaced by a wireless link, using bridge-like devices translating the framing rules of the wireless and wired stations but without modifying the MAC- and link-layer-related fields of the packet. We call this type of bridge a *MAC-unaware bridge.* In this approach, no station is aware of the wireless link. A typical application scenario is the wireless interconnection of two field-bus segments.

Wireless MAC-unaware bridging approach: The LAN comprises both wired and wireless stations, and integration occurs solely at the physical layer. A MAC-unaware bridge translates the different framing rules used by wired stations and wireless stations. The wireless stations use "only" another physical layer (PHY), while MAC and link layer protocols are not modified. Hence, wired and wireless stations run the same set of protocol.

Wireless MAC-Aware bridging opproach: The LAN comprises both wired and wireless stations, and integration occurs at the MAC- and data link-layers. There are two different MAC- and link-layer protocol stacks for wired and wireless stations, but both offer the same link-layer interface. The wireless MAC- and link-layer protocol should be: (a) specifically tailored to the wireless medium and (b) easily integrable with the wired MAC and link-layer protocol. An intelligent bridge-like device is responsible for both translating the different framing rules as well as interoperation of the different MAC protocols.

Wireless gateway approach: Integration at the application layer. In these systems, the PHY, MAC-, and link-layer protocol as well as application support services can be different for wireless and wired stations.

Clearly, these scenarios can be mixed.

50.3 Wireless LAN Technology and Wave Propagation

In this section, we discuss some basic notions of WLANs and present fundamental wave propagation effects. The wave propagation effects result in certain transmission problems, which are discussed in Section 50.4.

© 2005 by CRC Press LLC

Wireless LANs

Wireless LANs are targeted for packet-switched communications over short distances (up to a few hundred meters) and with moderate bit rates. Typical values for the bit rate range between 1 and 54 Mb/sec in IEEE 802.11a [43]. They work with infrared or radio frequencies; in the latter case often license-free bands are used, for example, the 2.4 GHz Industrial, Scientific, and Medical band (ISM band). In these bands, the transmit power is legally restricted. Radio waves below 6 GHz propagate through walls and can be reflected on several types of surfaces, depending on both frequency and material. Thus, with radio frequency non-line of sight (NLOS) communications are possible. In contrast, systems based on infrared only allow for line of sight (LOS) communications over a short distance (e.g., IrDA [62]).

Wireless LANs can be roughly subdivided into *ad hoc networks* [56] and *infrastructure-based networks.* In the latter case, some centralized facility, often administered by the network provider, is responsible for tasks like radio resource management, data forwarding to distant stations, mobility management, etc. In general, stations cannot communicate without using the infrastructure. Infrastructure-based WLANs offer some advantages for industrial applications. Many industrial communication systems already have an asymmetric structure, which can be naturally accommodated in infrastructure-based systems. The often used master–slave communication scheme serves as an example. Furthermore, the opportunity to offload certain protocol processing tasks to the infrastructure allows to keep mobile stations more simple and to make efficient centralized decisions.

As compared to other wireless technologies like cellular systems and cordless telephony, WLAN technologies seem most suitable for industrial applications due to the offered compromise between data rate, geographical coverage, and license-free and independent operation.

Wave Propagation Effects

In the wireless channel, waves propagate through the air, which is an unguided medium. The wireless channel characteristics are significantly different from those of guided media like cables and fibers, and create unique challenges for communication protocols.

A transmitted waveform experiences several phenomena: path loss, attenuation, reflection, diffraction, scattering, adjacent- and co-channel interference, thermal or man-made noise, and finally imperfections in the transmitter and the receiver [48, 7].

The path loss/attenuation characterizes the loss in signal power when increasing the distance between a transmitter T and a receiver R. In general, the mean received power level $\widehat{P_{Rx}}$ can be represented as the product of the transmit power P_{Tx} and the mean path loss $\widehat{PL}$:

$$\widehat{P_{Rx}} = P_{Tx} \cdot \widehat{PL}$$

A typical path loss model for omnidirectional antennas is given by [48, chap. 4.9]

$$\widehat{PL}(d) = C \cdot \left(\frac{d}{d_0}\right)^n \; (d \geq d_0)$$

where d is the distance between T and R, $\widehat{PL}(d)$ is the mean path loss, d_0 is a reference distance that depends on the antenna technology, C is a technology- and frequency-dependent scaling factor, and n is the so-called path-loss exponent. Some typical values for n are given in Table 50.1. A second source of signal attenuation are obstacles in the LOS path.

A waveform is reflected on smooth surfaces having a much larger dimension than the actual wavelength. Not all signal energy is reflected; but a fraction of it is absorbed and the amount of absorption depends on the material. The diffraction mechanism can be explained by Huygens principle and allows a wave to propagate into a shadowed region, provided that some sharp edge exists. Scattering is produced when a wavefront hits a rough surface having structures smaller than the wavelength. Then, the signal diffuses.

The most important types of interference are cochannel interference and adjacent-channel interference. In cochannel interference, a signal transmitted from T to R on channel c_1 is distorted by another

© 2005 by CRC Press LLC

TABLE 50.1 Path-Loss Exponents for Different Environments (taken from [48, chap. 4.9])

Environment	n
Free-space	2
Urban area cellular radio	2.7–3.5
Shadowed urban cellular radio	3–5
In-building LOS	1.6–1.8
Obstructed in-building	4–6
Obstructed in factories	2–3

transmission on the same channel c_1. In the case of adjacent channel interference, the interferer I transmits on an adjacent channel c_2, but due to imperfect filters R captures frequency components from c_2, or the interferer I leaks some signal energy into channel c_1 due to nonperfect transmit circuitry (amplifier).

The notion of noise refers to any unwanted signal energy that occurs in the interesting frequency band and that is not generated by any communication system. Thermal noise is present in almost any communications channel. Man-made noise in industrial environments can have several sources, for example, remote controls, motors, or microwave ovens.

50.4 Physical Layer: Transmission Problems and Solution Approaches

The previously discussed wave propagation effects can lead to channel errors. In general, their impact depends on a multitude of factors, for example, frequency, modulation scheme, and the current environment, which comprises the distance between stations, interferers, number of different paths, and their respective loss, etc. These factors can change with time, for example, the number of paths and their attenuation change if the transmitter, receiver, or something in the environment moves. Consequently, the transmission quality is time-variable.

Effects on Transmission

The notion of *slow fading* refers to significant variations in the mean path loss, as they occur due to changes in distance between transmitter T and receiver R, or by moving through tunnels or beyond large obstacles. Slow fading phenomena usually occur on longer timescales, and they often coincide with human activity (e.g., mobility). For short durations in the range of a few seconds, the channel can often be assumed to have constant path loss.

An immediate result of reflection, diffraction, and scattering is that multiple copies of a signal may travel on different paths from T to R (see Figure 50.1). Since these paths usually have different lengths, the copies arrive at different times (delay spread) and with different phase angles at the receiver and overlap. This has two consequences:

- The resulting signal can be amplified or attenuated (constructive or destructive interference), depending on the relative phase shift. This may lead to loss of received power of up to 40 dB.
- The delay spread leads to intersymbol interference, since signals belonging to neighbored information symbols may arrive at the same time.

If the stations move relative to each other or to parts of the environment, the number of paths and their phase shifts vary in time, thus giving a fast fluctuating signal strength at the receiver (*fast fading* or *multipath fading*), however, with nearly constant mean value on short timescales. If the delay spread is small relative to the duration of a channel symbol, the channel is called *nonfrequency selective* or *flat*; otherwise, it is called *frequency-selective.*

These problems translate into bit errors or packet losses. Packet losses occur when the receiver fails to acquire bit synchronization [64], while for bit errors synchronization is successfully acquired, but a number

© 2005 by CRC Press LLC

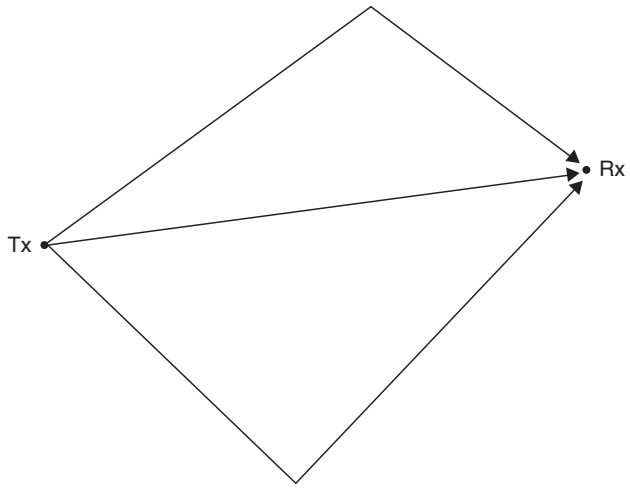

FIGURE 50.1 Multipath fading.

of channel symbols is decoded incorrectly. Bit errors can be combatted with forward error correction (FEC) techniques, packet losses cannot. The characteristics of bit errors and packet losses were investigated in a number of studies [13, 40, 64]. While the results are not immediately comparable, certain trends show up in almost every study:

- Both bit errors and packet losses are "bursty," that is, they occur in clusters with error-free periods between the clusters. The distributions of the cluster lengths and the lengths of error-free periods often have a large coefficient of variation or even seem to be heavy-tailed. Bit errors and packet losses appear to be instationary and time-variable on several time scales.
- The bit error rates depend on the modulation scheme; typically, schemes with higher bit rates exhibit higher error rates.
- Often, bit error rates of 10^{-3}–10^{-6} were observed; hence, the wireless channel is much worse than wired channels. Furthermore, the bit error rate can vary over several orders of magnitude within minutes.

The knowledge about error generation patterns and error characteristics can be helpful in designing more robust protocols.

Wireless Transmission Techniques

A number of different transmission techniques have been developed to combat the impairments of the wireless channel and to increase the reliability of data transmission.

Many types of WLANs (including IEEE 802.11) rely on *spread spectrum* techniques [20], where a narrowband information signal is spread to a wideband signal at the transmitter and despread back to a narrowband signal at the receiver. By using a wideband signal, the effects of narrowband noise or narrowband interference are reduced, since by the despreading operation their bandwidth shrinks, too. The two most important spread spectrum techniques are *direct sequence spread spectrum (DSSS)* and *frequency hopping spread spectrum (FHSS)*. In DSSS systems, an information bit is multiplied (XORed) with a finite digital *chip seqence* such that transmission takes place at the *chip rate* instead of the information bit rate. The chip rate is much higher than the information rate and consequently requires a much larger bandwidth. The channel is assumed to be frequency-selective with respect to the chip rate. This can be explored in two ways. To explain the first one, let us assume that the receiver receives a signal S from an LOS path and a delayed signal S_d from another path, such that the lag between S and S_d is

© 2005 by CRC Press LLC

k chips. The chip sequences are designed such that the autocorrelation between the sequence and a shifted version of it is low for all nonzero lags. If the receiver is synchronized on the direct signal S, the delayed signal S_d appears as white noise and produces only a minor distortion for the receiver. The IEEE 802.11 WLAN specifies a DSSS physical layer with a receiver of this type. In the second approach, the information contained in delayed copies of the signal is explicitly explored by using *RAKE receivers* [51, Sec. 10.4]. Put briefly, a RAKE receiver tries to acquire the direct signal and the strongest time-delayed copies of it in order to combine them coherently. However, RAKE receivers are much more complex than simple DSSS receivers.

In FHSS, the available spectrum is divided into a number of subchannels. The transmitter hops through the subchannels according to a predetermined schedule, which is also known to the receiver. The advantage of this scheme is that a subchannel currently subjected to transmission errors is used only for a short time before the transmitter hops to the next channel. The hopping frequency is an important parameter of FHSS systems, since high frequencies require fast and accurate synchronization. As an example, the FHSS version of IEEE 802.11 hops with 2.5 Hz and many packets can be transmitted before the next hop. In Bluetooth, the hopping frequency is 1.6 kHz and at most one packet can be transmitted before the next hop. Typically, there is no hopping during transmission of a packet.

Recently, there has been considerable interest in orthogonal frequency division multiplexing (OFDM) techniques [59]. OFDM is a multicarrier technique, where blocks of N different symbols are transmitted in parallel over a number of N subcarriers. Hence, a single symbol has an increased symbol duration $N \cdot \tau$ as compared to full-rate transmission with symbol duration τ. The symbol duration $N \cdot \tau$ is usually much larger than the delay spread of the channel, thus combating intersymbol-interference and increasing channel quality. The IEEE 802.11a standard [43] as well as HIPERLAN/2 [15, 16] use an OFDM physical layer.

50.5 Problems and Solution Approaches on the MAC- and Link-Layer

It is the MAC- and the link-layers, that are exposed most to the error characteristics of wireless channels and that should do most of the work to improve the quality and reliability of the channel. Specifically for hard real-time communications, the MAC layer is a key component: if the delays on the MAC layer are not bounded, the upper layers cannot compensate this. In general, the operation of the MAC protocol is largely influenced by the properties of the physical layer. For the case of wireless transmission, there are some unique problems and solutions to these, discussed next. For a general discussion of MAC- and link-ayer protocols, we refer to references [21, 29, 58, 54, 12].

Problems for Wireless MAC Protocols

Several problems arise due to path loss in conjunction with a *threshold property*: wireless receivers require the signal to have a minimum strength, before it is recognized. This translates immediately into an upper bound on the distance between two stations wishing to communicate.[1] Therefore, if the distance between two stations exceeds some threshold distance, they cannot receive each other's transmissions. For protocols using carrier sensing (carrier sense multiple access [CSMA]), this gives rise to the *hidden terminal scenario* [55], depicted in Figure 50.2. Consider three stations A, B, and C with transmission radii as indicated by the circles. Stations A and C are in the range of B, but A is not in the range of C, and vice versa. If C starts to transmit to B, A cannot detect this by its carrier sensing mechanism and considers the medium to be free. Hence, A also starts packet transmission and a collision occurs at B.

[1]To complicate things, it is not necessarily always the case that station B hears station A given that station A hears station B. This can be the result of both stations controlling their transmit power independently.

© 2005 by CRC Press LLC

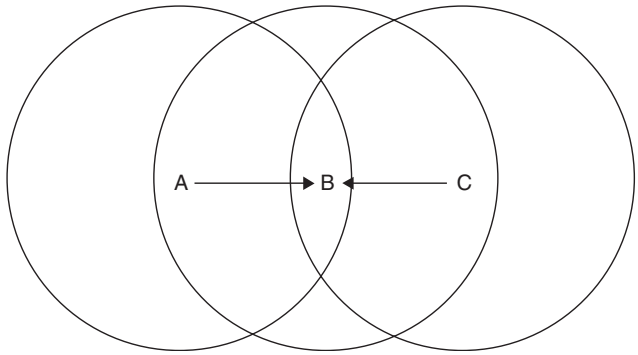

FIGURE 50.2 Hidden terminal scenario.

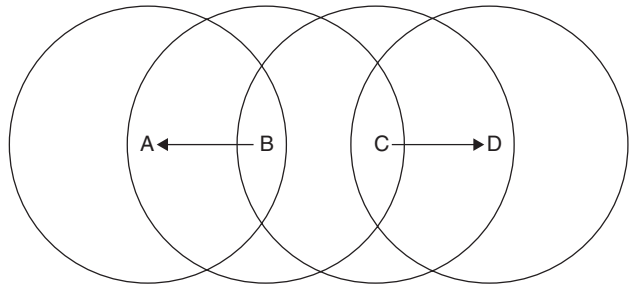

FIGURE 50.3 Exposed terminal scenario.

There is a second scenario where carrier sensing leads to false predictions about the channel state at the receiver: the so-called *exposed terminal scenario,* depicted in Figure 50.3. The four stations A, B, C, and D are placed such that the pairs A/B, B/C, and C/D can hear each other, and all remaining combinations cannot. Consider the situation where B transmits to A, and one short moment later C wants to transmit to D. Station C performs carrier sensing and senses the medium busy, due to B's transmission. As a result, C postpones its transmission. However, C could safely transmit its packet to D, without disturbing B's transmission to A. This leads to a loss of efficiency.

Two approaches to solve these problems are busy tone solutions [55] and the request to send/clear to send (RTS/CTS) protocol, as applied, for example, in the IEEE 802.11 WLAN MAC protocol. In the busy tone approach, the receiver transmits a busy tone signal on a second channel during packet reception. Carrier sensing is performed on this second channel. This solves the exposed terminal problem. The hidden terminal scenario is also solved except in the rare cases where A and C start their transmissions simultaneously.

The RTS/CTS protocol attacks the hidden terminal problem using only a single channel. Consider the case that A has a data packet for B. After A has obtained channel access, it sends a short RTS packet to B, indicating the time duration needed for the whole packet exchange sequence. If B receives the RTS packet properly, it answers with a CTS packet, which indicates the time needed for the remaining packet exchange sequence. Station A starts transmission after receiving the CTS packet. Any other station C hearing the RTS and/or the CTS packets defers its transmissions for the indicated time, thus not disturbing the ongoing packet exchange. It is a conservative choice to defer on any of these packets; but the exposed terminal problem still exists. If a station C defers only on receiving both packets, the exposed terminal problem is solved. However, there is the risk of bit errors in the CTS packet; which may lead C to start transmissions falsely. The RTS/CTS protocol does not resolve collisions of RTS packets at the receiver; furthermore, it introduces significant overhead.

© 2005 by CRC Press LLC

It is not possible to transmit and receive simultaneously on the same frequency band, due to overcharge of receive filters. Hence, the transmitter cannot detect collisions by itself, as is required by, for example, the collision detection part of a CSMA/CD MAC protocol. A possible solution would be to use feedback given by the receiver on another channel, as is done in the busy tone approach [55]. In addition, this property makes implementation of CAN-like protocols impossible.

Even when the collision detection is done at the receiver, it may not work reliably due to the *near–far effect*: consider two stations A and B transmitting packets in parallel to a station C. For simplicity, let us assume that both stations use the same transmit power. Station A is very close to C, station B is far away but still within reach of C. This means that A's signal at C is much stronger than B's. In this case, it may happen that C decodes a packet sent by A despite B's parallel transmission. This situation is advantageous for the system throughput, but disadvantageous for MAC protocols relying on collision detection or collision resolution.

Methods for Combatting Channel Errors and Channel Variation

A challenging problem is the error-prone and time-variable channel, caused by slow fading, multipath fading (delay spread, intersymbol-interference), and interference phenomena. There are many control knobs for improving the channel quality, for example, transmit power, bit rate/modulation, coding scheme/redundancy scheme, packet length, choice of retransmission scheme (automatic repeat request (ARQ)), postponing schemes/timing of transmissions, using spatial diversity, and adaptation as a meta method [17]. In general, adaptation at the transmitter requires some kind of feedback from the receiver, for example, by using immediate acknowledgment packets after every data packet.

The variation of transmit power and of the bit rate/modulation scheme are both equivalent to varying the energy per bit, which in turn influences the bit error rate [47, 48]. In order to increase the probability of successful packet reception, a higher transmit energy or a modulation scheme with a lower bit rate can be chosen [23].

A suitable way to protect data bits against bit errors is to use redundancy, either in the form of error-detecting and correcting codes [33] (forward error correction (FEC)), redundancy packets, or by transmitting multiple copies of a packet [2], which is also helpful for combating packet losses. It has been proven beneficial for the overall throughput to control the amount of redundancy according to the current channel state, such that none or only a little redundancy is added, if the channel currently shows only a few errors [8, 13].

A second standard way to deal with transmission errors are retransmissions and suitable ARQ schemes. For channels with bursty errors immediate packet retransmissions are not clever, since, if the channel is now in a bad state, likely it will still be in the bad state one packet transmission time later. As an example, consider the case of a centralized scenario with one access point (AP) and several mobile stations (MS), channel errors, and downlink traffic. It has been shown that system throughput can be increased significantly for the case of bursty errors (as opposed to "smooth" independent errors) when retransmissions from the AP to an MS are postponed for a while, and other MS are served in the meantime [3, 4, 5]. Furthermore, ARQ schemes can be integrated with FEC schemes (hybrid error control). An overview on ARQ- and FEC-based error control schemes is given in [34].

For bursty channels, the need to retransmit a packet is often taken as a sign of bad channel conditions. However, this approach is costly, since a (possibly) long data packet is wasted. To circumvent this, *channel probing* can be used. Here, the transmitter sends a short probe packet to the receiver, which the latter has to acknowledge. If the transmitter receives no ack packet, it determines the channel to be in a bad state and defers transmission.

Another possibility to reduce the probability of erroneous packet transmissions is to make packets smaller, at the expense of increased overhead. If the transmitter has estimates on the current channel conditions, it can choose the "appropriate" packet size giving the desired tradeoff between reliability and efficiency [35].

If the error behavior is dominated by multipath fading, it may happen that a signal transmitted by station A is subject to destructive interference at geographical position p_1 and strong enough to be properly received at another position p_2. This property can be exploited using transmitter or receiver diversity

© 2005 by CRC Press LLC

techniques [48]. With receiver diversity, the receiver has two or more antennas, spatially separated by at least half a wavelength. For example, a receiver can choose the strongest signal.

A second way to explore this property is the following: assume that station A transmits a packet to station B. The channel from A to B is currently in a deep fade, but another station C has successfully received the packet. If the channel from C to B is currently in a good state, the packet can be successfully transmitted from C to B. In [63], this approach is applied to retransmitting data and poll packets in a polling-based MAC protocol.

50.6 Wireless Field-Bus Systems: State of the Art

Field-bus systems are explicitly designed to deliver hard real-time communications under harsh environmental conditions. Correspondingly, a *wireless field-bus* [10] is designed to provide as stringent timing and reliability guarantees as possible over wireless links, that is, it should strive to optimize its stochastic hard real-time performance. However, in most of the literature surveyed here, this issue is not covered. Nonetheless, we discuss existing approaches for different popular field-bus systems.

CAN

A group at the university of Sussex investigated the topic of wireless CAN. Since the CAN MAC protocol cannot be implemented directly on top of a wireless medium, two different approaches were developed [31].

The distributed WMAC protocol uses a CSMA/CA scheme, where a station waits for some backoff time after the medium become idle. The backoff time is chosen according to the packet's priority. If another station starts transmission during the backoff time, the station defers. In the centralized RFMAC protocol, the base station broadcasts the identifiers of the variables to be polled, and their producers transmit them according to the given schedule. In another distributed scheme, the CAN message priority value is mapped onto the channel using an on-off-keying scheme [30]: a station transmits a short burst, if the current priority bit is a logical one, or it switches to receive mode if it is a zero. If the station receives something in the receive mode, it resumes from contention. The priority bits are handled from the most significant bit to the least significant bit. This approach requires tight synchronization and fast switching between transmit and receive mode for the radio modem, which is a problem for certain WLAN technologies. In all references neither station failures nor transmission errors were considered, and thus no statements about their stochastic hard real-time behavior can be made.

FIP/WorldFIP

A group at EPFL Lausanne worked on transparent integration of wireless stations into FIP [37]. FIP uses a polling table to implement a real-time database [57]. A main element of the approach presented in [37] is a wireless-to-wired gateway, which serves as central station for the wireless part. The wireless MAC protocol is built upon a time division multiple access (TDMA)-scheme. In [38], it is investigated how the MAP/MMS application layer protocol can be enhanced with mobility. In the proposed system, the IEEE 802.11 WLAN with distributed coordination function (DCF) is used, time-critical transmissions and channel errors are not considered. In [36], the same question was investigated with digital European cordless telephone (DECT) as underlying technology.

The goal of the European community project OLCHFA (June 92 until September 94) was to add wireless stations to FIP. A prototype system worked in the 2.4 GHz ISM band using a DSSS physical layer [25]. The available publications put emphasis on the management of configuration data and on distributed algorithms for clock synchronization. Within the project, a communications controller was developed, which can transmit over either wireless or wired media. The MAC and data link protocol of FIP was not modified. The system thus uses wireless MAC-unaware bridging. Since FIP extensively uses periodic broadcasting of data, the protocol contains no retransmission scheme for the time-critical data. Instead, the OLCHFA approach is to enhance the FIP process variable model with so-called time-critical variables,

© 2005 by CRC Press LLC

which also provide freshness information to the applications. It is thus up to the application to handle cases of repeated losses.

IEC FieldBus

For the IEC FieldBus [24] (which uses a centralized, polling-based access protocol for supporting periodic data and a token passing protocol for asynchronous data) in reference [6] an architecture that allows coupling of several fieldbus segments using a wireless backbone based on IEEE 802.11 with point coordination function (PCF) is proposed.

PROFIBUS

The R-FIELDBUS project (*www.rfieldbus.de*) within the European Union lnformation Society Technologies (IST) program evaluates how IEEE 802.11 with DSSS can be used in a PROFIBUS fieldbus system, and how such a system can be used for transmission of IP-based multimedia data [27, 49]. The system uses the given PROFIBUS MAC- and link-layer protocol on top of a wireless PHY, and hence is an incarnation of the wireless MAC-unaware bridging approach. A vital part of the project is to set up a prototype and to perform field trials. In [32], a scheme for integration of wireless nodes into a PROFIBUS-DP network (single master, many slaves, no token passing) is described. An application layer gateway is integrated with a "virtual master" station. The virtual master acts as a proxy for the wireless stations, it polls them using standard IP and IEEE 802.11 DCF protocols.

In [63], a system following the wireless MAC-aware bridging approach is proposed. More specifically, on the wireless side specifically tailored polling-based protocols are used, while wired stations run the unmodified PROFIBUS protocol stack. Special care is taken to avoid token passing on wireless segments, since the error behavior of wireless links disturbs the token passing process seriously [65] (the same is true for the similar IEEE 802.4 Token Bus protocol [28]). In fact, it is shown that for bursty channel errors, the polling-based protocols achieve a substantially better performance in terms of stochastic hard real-time behavior than the PROFIBUS token-passing protocol; for certain kind of channels, the 99% quantile of the delay needed to successfully transmit a high-priority packet is up to an order of magnitude smaller than for the PROFIBUS protocol. To combine both protocols, a special coupling device is introduced, which provides a *virtual ring extension*: the coupling element acts on the wired side like a set of PROFIBUS stations on behalf of the wireless stations. Specifically, it creates token frames and ring management frames on behalf of wireless stations.

50.7 Wireless Ethernet/IEEE 802.11

Instead of developing WLAN technology for the factory floor from scratch, existing technologies might serve as a starting point. The prime example is the lEEE 802.11 WLAN standard [41, 43, 42], since it is the most widely used WLAN and was also used in different projects investigating wireless industrial LANs (see Section 50.6). Some alternative systems are HIPERLAN [14, 15], Bluetooth [22], and HomeRF [39].

Brief Description of IEEE 802.11

IEEE 802.11 belongs to the IEEE 802.x family of LAN standards. Basically, the standard describes an architecture, services, and protocols for an Ethernet-like wireless LAN, using a CSMA/CA-based MAC protocol with enhancements for time-bounded services. The protocols run on top of several PHY's: a FHSS PHY, a DSSS PHY offering 1 and 2 Mb/sec [41], a 5.5 and 11 Mb/sec extension of the DSSS PHY [42], and an OFDM PHY with 54 Mb/sec [43]. As for the architecture, the standard describes both an *ad hoc* mode and an infrastructure mode. In the latter, all communications is relayed through APs. An access point constitutes a cell, and mobile stations have to register with the closest AP. The APs are connected through a *distribution system,* which allows to forward data packets to mobile stations in different cells. A detailed description of IEEE 802.11 can be found in [44].

© 2005 by CRC Press LLC

The basic MAC protocol of 802.11 is called the DCF. It is a CSMA/CA protocol using the RTS/CTS scheme and different interframe gaps to provide priorities for certain kinds of frames, for example, acknowledgement frames; but data frames cannot be differentiated according to priorities. The IEEE 802.11 MAC provides a connectionless semireliable best-effort service to its users by performing a bounded number of retransmissions. The user cannot specify any quality-of-service requirements for his packets; he can only choose between contention-based and contention-less transmission (see below). Furthermore, it is not possible to specify attributes like transmit power, modulation scheme, or the number of retransmissions on a per-packet basis. This control would be desirable for treating different packet types differently, for example, for transmitting high priority packets with a high transmit power and small bit rate to increase their reliability.

The enhancement for time-bounded services is called *PCF* and works only in infrastructure mode. The PCF defines a *superframe structure,* with variable- but maximum-length superframes. A superframe consists of a *superframe header,* followed by a *contention free period* (*CFP*) of variable length and a *contention period* (*CP*) of variable length. During the CP all stations, including the AP operate in DCF mode. To initiate start of the CFP, the AP (also called *point coordinator,* PC) has to acquire the wireless medium before it can transmit its *beacon packet.* This implies that the beacon packets and therefore the start times of the CFPs show some jitter, preventing strictly isochronous services. This is called *superframe stretching.* The AP broadcasts the beacon packet to all stations. The beacon indicates the maximum time duration of the CFP. The AP has a poll list of station addresses. Members of this list are polled during the CFP and can transmit their data in a contention-free manner. When polled by the AP, a station A is allowed to transmit only one data packet or an ack packet in case of empty queues. The polling scheme is not fully specified. A station that wants to be polled has to signal this to the AP during the association process. The poll list membership ends upon disassociation or when the station reassociates itself without requesting contention-free service.

Real-Time Transmission over IEEE 802.11

The PCF is designed for providing time-bounded services, for example, to transmit interactive speech data. Many studies [61, 60, 53] confirm that indeed packets transmitted during the CFP receive substantially smaller delays than those transmitted during the CP, however, at the cost of substantial overhead: [61] show a scenario where eight voice calls of each 8 kbit/sec data rate require 50% bandwidth of a 1 Mbit/sec transmission medium (without channel errors). There seem to be no studies assessing the (stochastic) hard real-time capabilities of IEEE 802.11; furthermore, all cited studies do not take transmission errors into account.

When transmission has to be both timely and reliable despite channel errors, retransmissions are needed. When a time-critical packet transmitted during the CFP fails, the station can choose to try the retransmission during the following CP or during the next CFP one superframe later (except the case where multiple entries in the polling list are allocated to the mobile and thus it receives multiple polls during a single CFP). Hence, retransmissions of important packets receive no priority in 802.11.

50.8 Summary

This article presented some problems and solution approaches to bring WLAN technology to the factory plant and to benefit from reduced cabling and mobility. The basic problem is the tension between the hard requirements of industrial applications on the one hand and the serious error rates and time-varying error behavior of wireless channels on the other. Many techniques have been developed to improve the reliability and timeliness behavior of lower-layer wireless protocols, but up to now wireless fieldbus systems have not been deployed at a large scale as the problem of reliable transmission despite channel errors is not solved satisfactorily. It is not clear as to which combination of mechanisms and technologies has the potential to bound the number of deadline misses under all channel conditions.

It seems to be an open question whether just more and better engineering is needed to make wireless transmission suitable for fulfilling hard real-time and reliability requirements, or whether there is a fundamental technological limit or a limit in user acceptance, which prevents a more widespread use.

© 2005 by CRC Press LLC

Fortunately, WLAN technology is a very active field of research, and development. New technologies are created and existing technologies are enhanced, for example, the IEEE 802.11g and IEEE 802.11e working groups are working on delivering higher bit rates and better quality of service to users. It will be exciting to see how industrial applications can benefit from this.

51.1 Introduction

The Basic Idea

The keynotes for Bluetooth include the following points:

- Universal radio interface for *ad hoc*, wireless connectivity
- Data connection via short-range (10 m) *ad hoc* networks using the license-free 2.45 GHz (ISM) band
- Low-cost RF modules for mass market
- Low power consumption
- Voice and data transmission
- Applications mainly for all portable devices

The major technological difference between Bluetooth and other communication standards is that Bluetooth is a "lower layer" in communication model handling. Bluetooth's radio communication includes sophisticated security. Higher layers of the communication models include well-known application

© 2005 by CRC Press LLC

protocols such as RFCOMM, TCP/IP, and PPP. This means that two Bluetooth devices can communicate regardless of the application protocol.

History

In February 1998, Ericsson, Nokia, IBM, Toshiba, and Intel (promoter group) founded the Bluetooth Special Interest Group (SIG). In December 1999, the promoter group was extended by Microsoft, Lucent, 3Com, and Motorola.

Several other companies and institutions joined the SIG as adopters of the technology.

The aims of the project were as follows:

Common Bluetooth specification (*de facto* standard)
Certification of Bluetooth products ("Bluetooth inside")
Zero cost license agreement for all interested companies.

Today's Common Bluetooth Solution in Factories

The most widely spread Bluetooth application in industrial environment may be Bluetooth to serial adapters. These are usually internal modules or external devices directly attached to RS232 or RS485 serial port.

Some examples of actual used Bluetooth solutions are [Cox_John] as follows:

- Temperature and moisture sensors in a cement factory
- Water-pumping stations in Oslo
- Bluetooth-enabled sensors in metal industry
- Wireless physiological monitoring system

51.2 The Physical Layer

Bluetooth operates in the 2.4 GHz license-free ISM band, which is nearly worldwide harmonized (there are still restrictions in some countries. For example, reduced max. power for outdoor applications in France and Italy. Please contact the local authorities for details). The maximum transmitting power is limited to 20 dBm (100 mW), which leads to communication ranges from a few meters up to hundreds of meters, depending on power class, sensitivity, and the environment.

Channel Arrangement

Spectrum spreading is accomplished by Frequency Hopping (FH) with 1600 hops/sec with a pseudorandom sequence over 79 channels with 1 MHz spacing. During one hop, a bandwidth of less than 1 MHz is occupied. The hopping sequence is determined by the master of a piconet (Figure 51.5) and can be calculated by the masters Bluetooth address and a "phase offset," which is given by the master during call setup.

Frequency Hopping

The FH of Bluetooth solves several problems that appear in a license-free frequency band:

Collisions with other Bluetooth piconets: Different nets need not be synchronized in any way; there is only a statistical probability of collision that leads to single lost packets.

Coexistence with other systems in the 2.4 GHz Industrial Scientific and Medical band (ISM band): Packets can get lost if there are strong RF-Transmission systems in the same ISM band as Bluetooth; but due to the fast changing of the Bluetooth frequencies, the link remains stable.

Fading in usual environments, especially if there are several metal objects, single frequencies are transmitted perceptibly worser.

© 2005 by CRC Press LLC

Security especially with point-to-point connections, FH is an additional security feature, because it is nearly impossible to track the hopping sequence if you do not obtain the needed information from the master.

Adaptive Frequency Hopping

In the current Bluetooth core specification 1.1 [BT_1.1], each Bluetooth channel is used; but the subsequent Bluetooth core specification 1.2 [BT_1.2] includes a feature called Adaptive Frequency Hopping (AFH). This AFH allows to avoid (mark the channel as bad) usage of channels, which are used by other communication systems such as WLAN, microwave oven, or analog video transmission.

The "bad" channels are placed in a table at the master device. The entries in this table can be set by the host; this will be the usual case for a combined Bluetooth/WLAN device or may be derived during the communication by the master or by a slave.

Power Classes

Bluetooth features three different power classes:

Class I with 0 to 20 dBm, usually defined as 100 m device
Class II with − 6 to 4 dBm, "10 m device"
Class III with up to 0 dBm

The minimum sensitivity is defined with −70 dBm. It should be noticed that the max. Equivalent Isotropic Radiated Power (EIRP) output power is limited by ETSI and FCC; hence, a 20 dBm device must not be used with an antenna gain >0 dBi.

Range Estimation

An exact definition of the range is not possible, because die propagation of the electromagnetic wave depends strongly on the environment.

A rough estimation can be made using the following formula:

$$Range(m)=10\text{^}((P_{OUT}+Antenna\ Gain\text{-}Sensitivity-41)/K)\ [\text{dB,dBm}]$$

where K=25 is for line-of-sight and 35 is for non-line-of sight connections.

Table 51.1 shows some calculations for typical Bluetooth Modules and Antennas with 0 dBi gain.

As can be seen, a Class I device does not necessarily provide a higher Range as a Class II device.

Power Control

A Class I device must feature Power Control; for Classes II and III, this is an optional feature. Power Control works with a feedback message from the remote device, which gives information about the received signal strength.

Power consumption and interference with other devices are reduced. The Power Control must be able to reduce the output power at least down to 0 dBm in not less than 8 steps. If the remote device does not support information about the received signal strength, the transmitting power should be reduced to Class II or III limits.

TABLE 51.1 Range Estimation for Different Bluetooth Modules

Description	Output Power (dBm)	Receiver Sensitivity (dBm)	Line-of-sight range (m)	Non-line-of-sight range (m)
Excellent Class I device	20	−90	575	94
Average Class I device	15	−77	110	29
Bad Class I device	5	−72	28	11
Excellent Class 2 device	4	−90	132	33
Average Class II device	1	−80	40	14
Bad Class II device	−4	−71	11	6

© 2005 by CRC Press LLC

Modulation

The Bluetooth radio module uses Gaussian Frequency Shift Keying (GFSK), where a binary one is represented by a positive frequency deviation and a binary zero is represented by a negative frequency deviation. $B \times T$ (*Bandwidth* × *Time*) is set to 0.5, and the modulation index must be between 0.28 and 0.35.

The raw data rate of Bluetooth is 1 Mbit/sec. In future specifications [BT_2_RF], Enhanced Data Rate with up to 3 Mbit/sec will be introduced. In this case, the modulation scheme of the payload will be switched to 8 DPSK (Differential Phase Shift Keying) or $\pi/4$-DQPSK (Differential Quadratur Phase Shift Keying) for 2 Mbit/sec. The header and the access code of each packet remain unchanged; thus, the system remains downward compatible and does not change the occupied bandwidth. Also, an operating mode called "high data rate" is planned; this mode will change the modulation and channel allocation completely.

Physical Links

There are two types of links in the Bluetooth specification:

SCO Synchronous Connection-Oriented for speech transmission and
ACL Asynchronous Connection-Less for data transmission.

An SCO channel is always a symmetric point-to-point link. Its packets are transferred in fixed timeslots and never retransmitted in Bluetooth core specification 1.1; Bluetooth core specification 1.2 [BT_1.2] defines new packet types that allow retransmission of speech packets. One master can handle up to 3 SCO channels in parallel.

ACL channels can be both symmetric or asymmetric; usually, lost or damaged ACL packets are retransmitted.

Packets

Basic structure:

There are three different types of access Codes:

Channel Access Code (CAC)
Device Access Code (DAC)
Inquiry Access Code (IAC)

The Header consists of the following parts:

AM_ADDR: 3- bit active member address,
TYPE: 4-bit type code
FLOW: 1-bit flow control
ARQN: 1-bit acknowledge indication
SEQN: 1-bit sequence number

Packet Types

In Bluetooth core specification 1.1, 13 different packet types for data, voice, and signaling are defined (Table 51.2):

For speech transmission, usually HVx packets are used. These packets do not contain a CRC and are not retransmitted. An HV1 packet carries 10 bytes of information with 1/3 FEC (Forward Error

© 2005 by CRC Press LLC

TABLE 52.2 Bluetooth 1.1 Packet Types

	Slot occupancy	SCO	ACL
0	1	NULL	NULL
1	1	POLL	POLL
2	1	FHS	FHS
3	1	DM1	DM1
4	1	Undefined	DH1
5	1	HV1	Undefined
6	1	HV2	Undefined
7	1	HV3	Undefined
8	1	DV	Undefined
9	1	Undefined	AUX1
10	3	Undefined	DM3
11	3	Undefined	DH3
12	3	Undefined	Undefined
13	3	Undefined	Undefined
14	5	Undefined	DM5
15	5	Undefined	DH5

Correction). For a 64 kbit/sec PCM (Pulse Code Modulation) signal, every second timeslot must be used for one packet. HV2 carry 20 bits with 2/3 FEC and HV3 30 bytes without FEC; hence, HV3 packets have to be sent every sixth timeslot.

The Bluetooth core specification 1.2 introduces new packets for speech transmission, called extended SCO (eSCO), which allow packet retransmission and/or reduced bandwidth and power consumption while sacrificing the very low latency of the SCO packets. This packet type will lead to strongly improved audio quality, because up to 2 packet repetitions are possible. With HVx packets, a Packet Error Rate (PER) of 1% means a perceptible reduced quality, while a PER of up to 10% does not seriously affect a data link.

For data transmission DH1, DH3, DH5, DM1, DM3, and DM5 packets are used. DH are without FEC; DM packets use 2/3 FEC. These packets occupy 1 to 5 timeslots and carry a maximum number of data bytes between 18 (DM1) and 339 (DH5). Depending on the quality of the channel, DH5 packets do not necessarily feature the highest data rate. The maximum possible data rate is 723/56 kbit/sec for an asymmetric operation and 433 kbit/sec for a symmetrical operation.

51.3 Power Consumption

The power consumption of a Bluetooth device depends on four main parameters:

- Operation mode (duty cycles)
- Power consumption during transmitting,
- Power consumption during receiving, and
- Power consumption during standby/deep sleep.

The operation mode may have the strongest impact on the current consumption. Depending on the amount and frequency of the data throughput, the optimal configuration of packet size and sleep periods can save more power than any chip technology.

A typical Class II Bluetooth device needs about 50 mA peak current during transmitting and receiving and declines to 25 uA during deep sleep.

Some examples:

For a voice connection with HV3 packets it will need: 1 out of 6 timeslots for receiving, 1 out of 6 timeslots for transmitting, this results in (1×50+1×50)/6=17 mA with HV1 Packets: (3×50+3×50)/6=50 mA.

© 2005 by CRC Press LLC

An RS232 Cable replacement with 115 200 Bit/sec:

With DH5 Packets (less than 1/6 of the possible bandwidth used) : 8 mA (as Master)
With DH1 Packets (~2/3 of the possible bandwidth used) : 30 mA

If a device is not permanently connected but shall be detectable and/or connectable for other Bluetooth devices, the inquiry and/or page scan must be enabled. This means that the device activates its receiver in specified intervals for a specified period. In this case, you have to trade between the speed of detection and current consumption. The default settings are a 10 ms window every 1.28 sec for both page and inquiry scans. For the Bluetooth device described above this results in 0.85 mA.

If the window size is increased or the interval is decreased for faster detection or connection setup, the power consumption increases.

The Bluetooth core specification 1.2 features "fast connection setup," which allows to set up a connection in less than 2 sec by only increasing the current consumption on the active device.

51.4 Bluetooth in Practical Experience

Integrating Bluetooth HW

Today, there are different kinds of Bluetooth chip(sets)on the market:

- Single Chip solution with ROM or Flash ROM
- Single Chip with external Flash
- Dual Chip solution

Most of the chipsets are also available as modules; this solution is usually preferable for small and medium production quantities (Table 51.3).

Bluetooth Software Efforts

Standard Bluetooth Modules are so called "HCI-modules." This means that the lower layers up to HCI of the Bluetooth-Stack (the Protocol Stack) are running on the chip, and all layers above are running on the host processor. These Bluetooth stacks have a demand on processing power, which is too much for many common microcontrollers, and they are not available for every processor.

For simple applications, which do not need the full Bluetooth data rate, it is more effective to focus on a solution where the higher layers up to the application (Profile) are running on the Bluetooth chip. These solutions are available for widely used Bluetooth Profiles such as HID [BT_HIDP], serial cable, and Headset [BT_HSP]; some chipset manufacturers also provide SDKs to develop on-chip applications.

Cable Replacement

An obvious application for Bluetooth is the replacement of an RS232 cable in industrial environments to avoid, for example, service-connectors, which are sensitive to dirt and hard to reach.

TABLE 51.3 Comparison Module Solution

	Module	Chipset on main PCB
Advantages	Dramatically reduced effort in qualification and approval	Smaller solution, especially in height, possible
	No trimming in production necessary	Reduced cost
	Less RF know-how necessary	
Disadvantages	Many modules do not utilize the rf performance of the chipset	High-quality main PCB, with micro-vias needed
	One additional manufacturer in the production chain	Extra shielding might be necessary
	Not all Pins of the chipset accessible	More extensive production testing

© 2005 by CRC Press LLC

There are different ways to realize this cable replacement:

- The simplest way may be to replace both ends of the cable by two paired (*Pairing*) Bluetooth "dongles" with SPP [BT_SPP] running on it.
- A more sophisticated way would be to integrate a Bluetooth module(s) with SPP [BT_SPP] in the industrial device(s) and connect it to a laptop computer with a USB Bluetooth device via a virtual COM-port. The application running on the laptop computer can remain completely the same; it just has to use a virtual COM-port instead of the "physical" one.

Wireless Mouse or Keyboard

Most wireless keyboards or mice are based on infrared; the new Bluetooth HID profile enables this device to have Bluetooth as a wireless interface. The Bluetooth interface is much more powerful than the infrared one. It has more distance, application, and wireless interface in a single chip solution. Both are connected via a Bluetooth USB dongle on the backside or integrated in to the PC or laptop. Therefore, a simple mouse can be used as a long-distance mouse or as a powerpoint presenter with several additional functionalities as well. Instead of infrared interface, it is not necessary to have a Line of Sight (LOS) connection. For example, in an industrial application, it is very simple to connect a key panel or a keyboard on a long-distance position from the engine or the switchboard. This makes it much more easier to service or control the engine as well as to improve the security!

Sensors

In addition to all the mainstream applications, it is useful to have a powerful wireless technology with an interference robust Radio interface.

Most single chip solutions on the market have programmable pins, whereas the application has the possibility to measure voltage, temperature, and so on. The architecture tendency of the Bluetooth single chip is going toward ARM7. Therefore, a powerful core with several MIPS is available for intelligent applications for a new Sensor technology. Built-in and powered with a special Bluetooth battery package, it gives a long-term intelligent sensor technology with strong capability.

For example, in a medical center or at home, a patient gets an on-body unit for daily heart diagnosis; if a heart attack occurs, the Bluetooth wireless technology establishes a connection with an access point and sends the status of the patient in the hospital or at home.

Identification Plus Positioning

Bluetooth seems to be an overkill for an identification or positioning system, but it might be cheaper and easier than a proprietary system, especially if there is already a Bluetooth system.

For example, an automatic stockkeeping system with Bluetooth equipped trolleys could also have simple access points with reduced range, which detect every trolley passing by and read out its identity and charging. In this case, the identification can be done by the unique Bluetooth address, or in more safety-related tasks, by an authentication procedure.

Remote Control

Bluetooth has the potential to be used for a wide range of remote control tasks. On the one hand, there is the field of home entertainment and domestic work.

A variant for a very all-purpose remote control could be based on a simple webserver running on the Bluetooth chip integrated in every device to be controlled. Some of today's Bluetooth chips already have the potential to run a web-page and do controlling tasks via several Programmable Input–Output (PIO) pins. The speciality of this method is that any Bluetooth-enabled device with a web-browser can be used as a remote control and no special software at all is needed on this device.

© 2005 by CRC Press LLC

On the other hand, industrial remote control scenarios with special access points, which control up to seven remote devices at once, are also possible. The Bluetooth bandwith is sufficient for control and monitoring of most tasks in the environment of a production line and stock keeping; but it must be carefully checked if the latency and connection setup times are good enough.

51.5 The Protocol Stack

The Bluetooth core specification does not only define a radio, it also defines a software protocol stack to enable devices to work with one another.

This Bluetooth Protocol Stack is defined as a series of layers; beyond this, the Bluetooth core specification encompasses several of different profiles. These profiles enable the devices to have different capabilities like establishment of a voice connection between a mobile phone and a headset or establishment of a dial-up connection like a modem to serve in the World Wide Web, etc.

Figure 51.1 shows the fundamental part of the Bluetooth Protocol Stack, whereas the Radio, Base Band (BB) and Link Controller (LC), Link Manager Protocol (LMP), Host Controller Interface (HCI), Logical Link Control and Adaptation (L2CAP), and the Service Discovery Protocol (SDP) are used from all Applications.

In the *Radio,* the data are modulated and demodulated for the transmission and the reception.

Baseband [BT_BB] *and Link Controller* has to control the asymmetric data connections (max. 7) and/or the symmetric voice connections (max. 3) via the radio. This controlling includes all necessary encroachments like packets reassembling and controlling of the FH. The new Bluetooth core specification [BT_1.2] provides better techniques to control and adapt the FH Kernel to improve the coexistence with other wireless connectivity techniques like WLAN (802.11b) (Figure 51.2).

The *Link Manager* [BT_LM] is used to control and negotiate all aspects of the operation of the Bluetooth between two devices. For this, a separate Protocol (LMP) is provided in the Bluetooth Core.

The *Host Controller Interface* [BT_HCl_Func] provides a few different hardware interfaces to handle the communication between the host controller and the host. This is necessary if the host and the host controller are separated (see Figure 51.3) and connected via one of the possible interfaces like the Universal Asynchronous Receiver Transmitter (UART) [BT_HCl_UART], USB, RS232, and the new 3 Wire UART Interface [BT_HCl_3 Wire]. In case of an embedded solution where the host controller and host are not separated, the host controller interface is not required.

The *Logical Link Control and Adaptation* [BT_L2CAP] provides connection-oriented and connectionless data services to upper-layer protocols with protocol multiplexing capability, segmentation and reassembly operation, and group abstractions. L2CAP also permits per-channel flow control and retransmission via the Flow and Error Control modes.

The *Service Discovery Protocol (SDP)* [BT_SDP] provides a means for applications to discover as to which services are available. It also gives the possibility to characterize these available Services (Profiles) more in detail, for example, how to connect.

The *RFCOMM* can emulate the typical nine RS 232 lines and the signaling on air. This gives Bluetooth the capability to be an RS232 cable replacement. Several Applications (Profiles) are based on the RFCOMM. RFCOMM also provides the capability to have multiple concurrent connections by relying on L2CAP to handle multiplexing over single connections, and to provide connections to multiple devices.

Wireless Application Protocol *(WAP)*, Object Exchange *(OBEX)*, Bluetooth Network Encapsulation Protocol (*BNEP),* Human Interface Devices *(HID) class driver ..,* provide interfaces to the higher layer parts of other Communications Protocols.

The *Telephony Control Protocol Specification (TCS)* defines the way to send telephone calls across a Bluetooth link; it also gives guidelines regarding how to establish a point-to-point or a point-to-multipoint (max. 3) call.

In mobile phones, for example, different Profiles like Handsfree [BT_HFP], Headset [BT_HSP], or Phone Access Profiles [BT_PAP] are used to phone via a headset or a car kit unit. The source for the Synchronous (SCO Audio Signals) is plugged in at PCM or I²S Interface.

© 2005 by CRC Press LLC

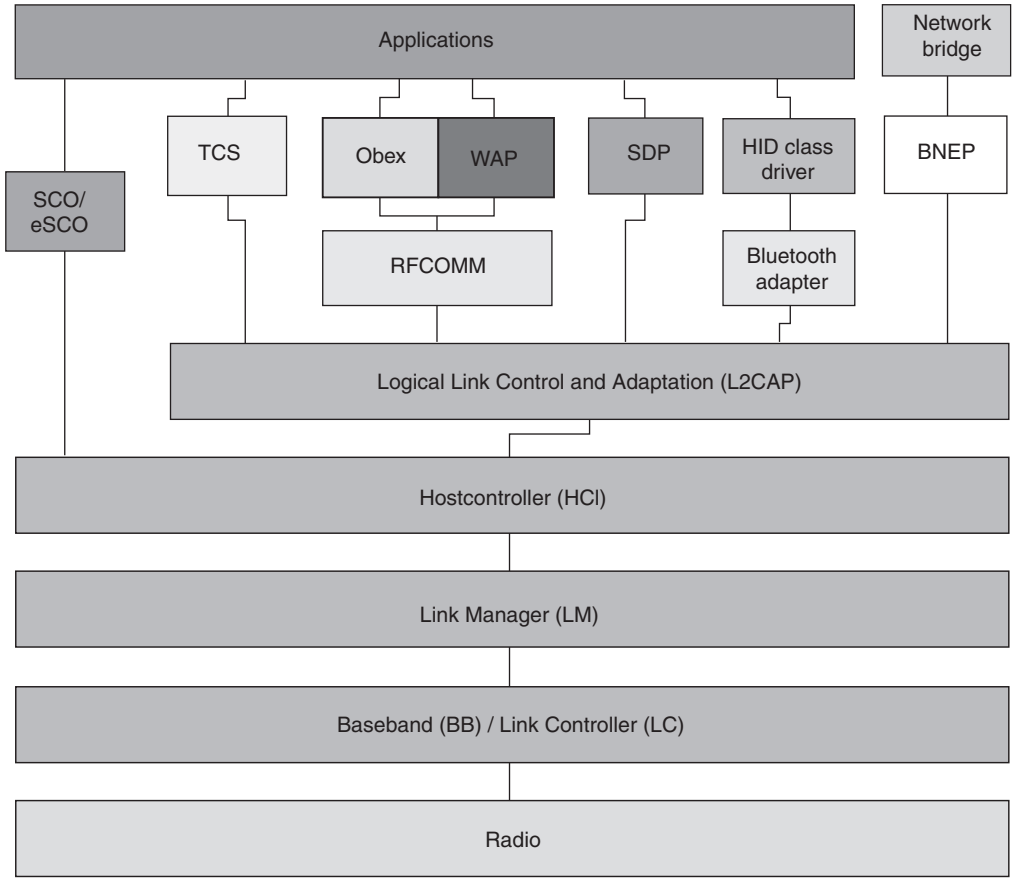

FIGURE 51.1 The Bluetooth protocol stack.

The *Applications* (Bluetooth Profiles) enable the devices to have access to different Services and therefore these Profiles give guidelines regarding how to serve the Bluetooth Protocol Stack to guarantee the interoperability with Bluetooth devices with the same Application from different Vendors. This capability should improve the success and the quality as well as make it more fun to use Bluetooth in the modern way of life.

51.6 Using Bluetooth

The normal way to use Bluetooth enforces a few steps within the Bluetooth connection establishment process that has finished successfully.

Discovering Bluetooth Devices

Discovering means that the device sends a series of inquiry packets (ID) and eventually all the devices in the range max. 100 m reply with a Frequency Hop Synchronization (FHS) packet. This FHS includes all required information that the device needs to create a connection to this device. Also, it is required that the discovered devices in the area are in discoverability mode, which means that the device activates the inquiry scan mode. The inquiry scan mode enables the device every 1.28 sec to catch the ID packets; after the first ID is received the scanning devices use a random back-off to reduce the interference with other responses; hence, it answers with the FHS after it receives the ID the second time. The ID packets contain

© 2005 by CRC Press LLC

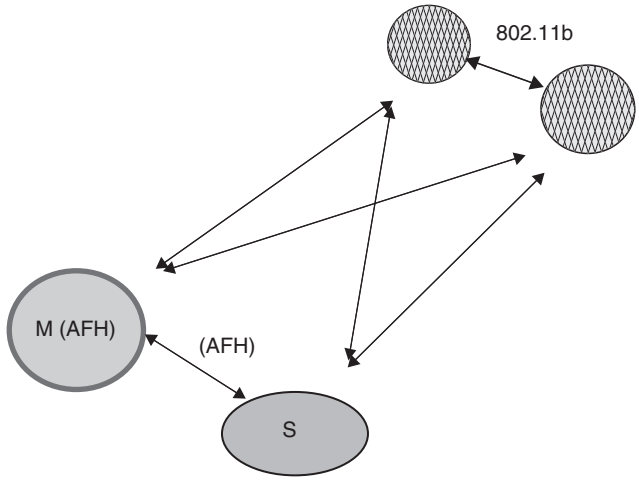

FIGURE 51.2 Coexistence improvement between Bluetooth and 802.11b with AFH.

search information, for example, General Inquiry Access Code (GIAC), Dedicated Inquiry Access Code (DIAC),…; therefore not all devices reply with these FHS.

As an optional feature, the searching device has the possibility to find out the name of the remote device without requiring an explicit ACL connection.

After this process, the application has considerable information like Bluetooth address, Name, Clock offset, class of device,.., about the devices in range.

Connection Establishment and Paging

To understand the paging procedure (connection establishment is called paging), it is useful to understand the Bluetooth behavior in its roles like the master and the slave. To establish a connection, one device (master role) must initiate the connection by addressing the other device (slave role), the request of a connection. The slave is listening for such a request, and this is called page scanning. The page scanning is activated in the page scanning mode, which means that every 1.28 sec, the receiver is listening for the ID packets [BT_CWC].

The master sets the frequency hopping sequence and the slave synchronizes to the master's frequency and clock by following the master's hopping sequence. In earlier versions of Bluetooth devices, the slave was only able to follow one master in frequency and time. The newer Bluetooth devices as well as the Bluetooth core specification allow the devices to follow more than one master in frequency and time. This means that one device has the possibility to handle more than one connection as a slave in a so-called scatternet slave/slave scenario (Figure 51.4). Another scatternet scenario is called slave/master, where the master can serve more than one slave.

The normal point-to-point connection is called piconet. A master in a piconet has the ability to serve up to seven slaves (Figure 51.5).

The pager transmits ID packets with the page scanner's address. If the page scanner receives its ID, it replies with another ID, again using its own address. Bluetooth gives the guarantee that every device around the globe has its unique ID. The pager receives the requested ID and sends the FHS to the page scanner. The FHS includes all the required information for the scanner and replies with another ID packet. The scanner now has the ability to extract all information to calculate the pager's hop sequence; it stops its own and swap with this. Both devices move into connection state, the pager as master and the scanner as slave. Further, both devices have the ability to switch their roles.

In the new Bluetooth core specification, the inquiry and paging processes are modified to obtain connections faster and more successfully. This is very important in industrial applications to guarantee the connection within a defined time window.

© 2005 by CRC Press LLC

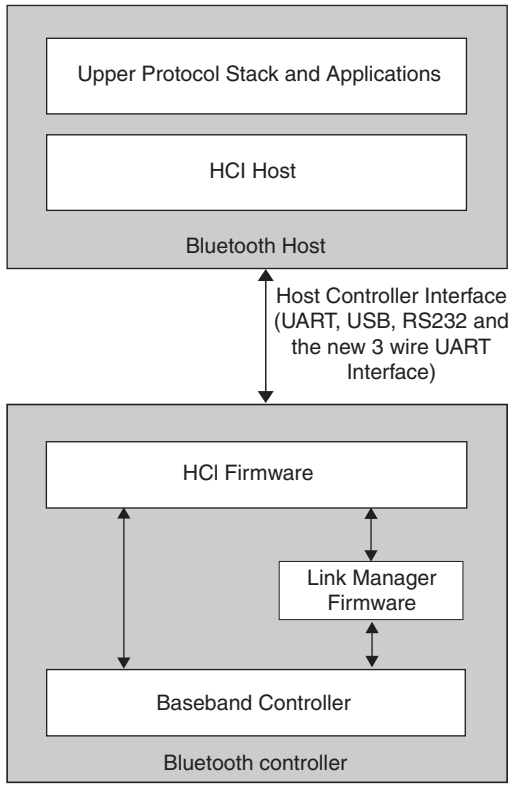

FIGURE.51.3 HCI interface.

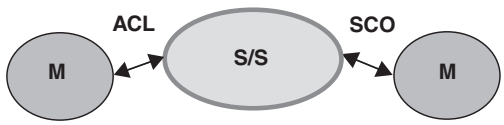

FIGURE 51.4 Typical slave/slave scatternet scenario.

One modification in the inquiry process is the first FHS; this means the scanning device answers without any random back-off after the first hit. This provides more success to find all devices in the range.

There are two other modifications within the setup to speed up the process even more. The first includes using special DIACs to limit the inquiry responses to devices of the correct type and second, using RSSI to help filter the responses. Both limit the number of SDP records that need to be returned.

More complicated changes are made in the scanning behavior of the page or inquiry scanning device. Paging can also be slow when the estimated clock starts the procedure on the wrong train. Depending on the paging configuration, paging may take 1.28 sec (R1) or 2.56 sec (R2) longer than the nominal time. It is desirable to speed up connections when the clock estimate is wrong or out of date. If a scan is unsuccessful, the scanning device will switch to another frequency. The other frequency is chosen such that it belongs to the complementary train. This single mechanism serves to speed up inquiry, paging, as well as to improve reliability in setting up connections. The improvement is called an interlace scan.

In this chapter, it is too complicated to explain the complete scanning process. The need for faster connections is a trade-off between speed on the one hand and bandwidth, power consumption, latency, time to market, and cost on the other.

© 2005 by CRC Press LLC

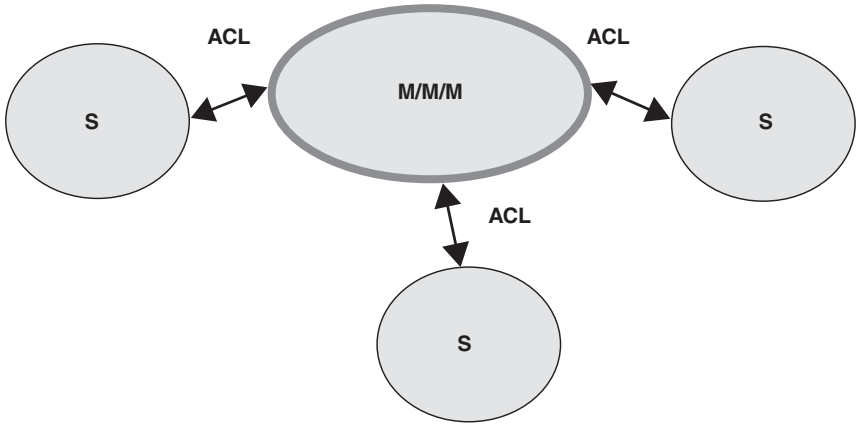

FIGURE 51.5 Typical piconet with three ACL connections.

51.7 Encryption and Security

In many levels of the Bluetooth core specification, security [Sec] is an issue. In Bluetooth security, white paper is a security architecture that may be used to implement Security Mode 2 (Service Level-enforced security) on Bluetooth devices. This method of implementing security does not have any effect on interoperability.

In the Generic Access Profile, three security levels are defined:

1. Security Mode 1 is nonsecure, which means no security process will never be initiated.
2. Security Mode 2 gives Service Level-enforced security; after an L2CAP [BT_L2CAP] channel has been established, it is decided whether or not it needs authorization, authentication, and encryption and its processes.
3. Security Mode 3 is Link Level-enforced security; the security process is initiated before the link is fully established on the LMP level. The completion of the security process in this level is mandatory to complete the connection.

In addition to the Security Modes, Bluetooth has several different security Levels that can be defined for devices and services. In the security white paper [Sec], the devices are split into three categories and two trusted levels [Sec_Arch]:

Trusted devices: paired or bonded device; the device has an entry in a database as trusted; therefore, it gains access without any restriction to all services.

Untrusted or unknown devices: it has no security information stored in the database to this device. The access to services is restricted.

The security white paper suggests that the security requirements for authentication, authorization, and encryption of services could be set separately:

No additional security for the services: any device may access this service.

Authentication only service: any device that can go through the authentication process may have access.

Authentication and authorization services: only trusted devices, after the security process in mode 2 a device is trusted, may access these.

Authentication and authorization are defined as follows [Sec_Arch]:

Authentication is the process of verifying "who" is at the other end of the link. Authentication is performed for devices (BD_ADDR). In Bluetooth, this is achieved by the authentication procedure based on the stored Link Key or by pairing (entering a PIN).

Authorization is the process of deciding if device X is allowed to have access to service Y. This is where the concept of "*trusted*" exists. Trusted devices (authenticated and indicated as "trusted") are allowed

© 2005 by CRC Press LLC

access to services. Untrusted or unknown devices may require authorization based on user interaction before access to services is granted. This does not principally exclude that the authorization might be given by an application automatically. Authorization always includes authentication.

Pairing is the name of the combination of Link Key generation on Link Level and the authentication procedure. If this process is done and the known Link Key between two devices is stored, these devices are *bonded*.

In industrial applications the pairing and bonding are a major part, for example, two serial dongles as serial cable replacement have to be paired at production level. Later, it is also necessary to give the guarantee to pair these devices again, for example, if one of the dongels is damaged. On the other hand, a headset device is produced in a nonpaired state. The first action to use a headset with a mobile phone is the pairing process; therefore, an initial PIN Key has to be delivered with this headset device. The PIN Key is required to generate the Link Key.

Connection Setup Procedure General Concept

The following procedures are performed:

1. Connect request to L2CAP
2. L2CAP requests access from the security manager
3. Security manager: lookup in service database
4. Security manager: lookup in device database
5. If necessary, security manager enforces authentication and encryption
6. Security manager grants access
7. L2CAP continues to set up the connection.

51.8 Low-Power Operation

Bluetooth specifies three different ways to remain connected and reduce the power consumption at the same time. This is especially important for battery-driven devices to maximize their lifetime. The Bluetooth core specification solved the problem with the three low-power modes. Within these modes, the device remains connected, but switch off the receiver for as long as possible.

(a) *Hold mode*: The hold mode is used to stop the ACL traffic for a specified period of time. During this period, the slave shall not support ACL packets on the channel; apart from this, this process does not have any effect on the synchronous SCO or eSCO traffic. The hold mode gives the devices the chance to enable major process like scanning, paging, or attending another piconet, for example, in a scatternet scenario.

(b) *Sniff Mode*: The sniff mode may reduce the duty cycle of the slave's activity in the piconet. The slave in the active mode on an ACL logical transport shall listen in every ACL slot to the master traffic. The only exception is if the device is being treated as a scatternet link or is absent due to the hold mode or an absence mask. In some cases, the normal link operating mode can be sniff, since with a short sniff interval, for example, the HID profile may still be able to transmit data fast enough to meet the latency and data reporting requirements of the application. Instead of the Park mode, the Sniff mode maintains its active member address, and data reports may be sent without exiting this mode.

(c) *Park Mode*: As explained in the sniff mode, in the park mode, the device loses its active member state (AM_ADDR), it enters into the park state, and gets a parked member address (PM_ADDR). During the parked state, the parked member uses the masters beacon to be synchronized. One of the major problems of the parked mode in the number of possible parked members as well as a completly used piconet (e.g., master with 7 slaves), it is impossible to get an active member. Therefore, the reaction time is very long. First the master has to park another device or the parked member has to wait until a connection is released.

51.9 Profiles

The Bluetooth Special Interest Group (SIG) has a series of different Working Groups. These Groups develop and specify various new Bluetooth Profiles to expand the usability of Bluetooth. The purpose of

Bluetooth Profiles is to provide a clear description of how to use and fulfill the specification of a system to impart a special function to a device. All these Profiles go through a complicated review process; after a series of draft versions, the Profile is adopted to the core specification.

Figure 51.6 gives an overview of several profiles; all these profiles provide a way for the Bluetooth technology to slot into different devices [BT_CWC]. The profiles in this overview are organized into groups, whereas the profiles are built upon the one beneath and also includes these features. The Bluetooth profiles should avoid the implementation of proprietary applications and profiles by different vendors to reduce the problem of interoperability; therefore, it gives Bluetooth more chance to be successful on the market.

FIGURE 51.6 Profile dependencies and their effects on requirements on LC and LM protocol layers (with each profile, it is indicated whether requirements different from the ones defined for the parent profile or underlying protocol layers are valid).

51.10 Bluetooth Qualification

The Bluetooth qualification process gives the guarantee that products comply with the Bluetooth core specification. To use the Bluetooth brand on the device and the package as well as the free license to all patents required to implement Bluetooth wireless technology, it is necessary to pass the Bluetooth qualification process. This qualification process also improves the interoperability of Bluetooth devices. It is also necessary to pass all government-specific radio tests where it will be sold.

Four categories are defined:

- Bluetooth radio link requirements
- Bluetooth protocol requirements

52.1 Introduction and Historical Background

If one believes contemporary advertisements and marketing articles in various automation domains, the interconnection of fieldbus systems and the Internet is *the* topic in automation. More specifically, but less appropriate for marketing purposes, we are talking about a linkage between arbitrary automation systems — which may also involve dedicated automation networks — and networks based on the Internet Protocol (IP). For the sake of simplicity, we will stick to the familiar terms fieldbus and Internet, however, keeping in mind that the fieldbus is not a must and that the Internet may as well be an intranet or any other network governed by IP and the protocol suite on top of it. What is being advertised as the major benefit of such an interconnection essentially boils down to two major, nonetheless interwoven aspects: remote access to automation systems and the promise of easy integration of automation data in a user-friendly environment. In other words, there are two reasons why a fieldbus/Internet connection can be worthwhile:

To extend the physical dimensions of an automation system. Mostly for historical reasons, the extension of a typical automation network is rather limited due to length restrictions in fieldbus segments and the lack of routing capabilities. If an Internet infrastructure is available, it can be used as a kind of backbone to connect distant segments of the installation.

To provide vertical integration. In the automation domain, this widely used term essentially means bringing information from an automation system into a framework used in the office domain, where it can be used not only for data acquisition but also for strategic operations such as system management or resource planning.

Especially, the second aspect is currently the focus of substantial marketing efforts connected to the growing use of Ethernet in industrial automation. However, it must be stated that the idea of vertical integration is nothing entirely new. The roots date back to the 1980s when the Computer Integrated

© 2005 by CRC Press LLC

Manufacturing (CIM) concept was developed. The hierarchical model with typically five levels (Figure 52.1) was an early attempt to structure the information flow within a company. There are many ways to draw this pyramid, and the names of the individual levels differ according to the application area. But the ultimate goal has always been the same: to provide transparent data exchange between the various levels.

The first attempts to implement the CIM concept were more or less futile, for a number of mostly technological reasons. On the one hand, the protocols designed for the communication inside the automation system — essentially the Manufacturing Automation Protocol (MAP) as a full-fledged implementation of the ISO/OSI model — were too complex; on the other, the progress of microelectronics as a technological backbone had not yet been far enough to provide sufficient computing resources at a reasonable price. Therefore, integration of CIM in the field level turned out to be nearly impossible. In addition, fieldbus systems as low-level automation networks were only at a very early stage of their evolution; hence, there was, from a networking point of view, a missing link between the actual source of the process data and the already existing company networks.

Figure 52.2 shows a few milestones in the evolution of both IT and automation networks and demonstrates how the situation has changed over the years [1]. Partly driven by the insight that MAP was too clumsy to use (but still following its basic ideas), partly driven by application-specific needs, fieldbus systems as dedicated automation networks emerged. They filled the networking gap in the lowest levels of the automation pyramid, providing an anchor point for subsequent integration efforts. The great leap forward for integration itself emerged with the success of the Internet and more precisely, with the invention of the World Wide Web (WWW). While in the fieldbus domain, a large variety of approaches still exist even after a lengthy and cumbersome standardization process [2, 3], the office world is dominated by the Internet Protocol suite and a small number of well-known, widely used applications.

The reason why the old idea of vertical integration was revived in recent years was merely a psychological one. As the timeline in Figure 52.2 shows, the Internet and its basic technologies have been available (and used) for a long time. However, it took the sheer simplicity of the web browser as a ubiquitous tool to boost the acceptance of the Internet and to secure the dominant role of the IP suite. From the user's point of view, a web browser allows access to distant data in a nearly trivial manner. Hence, it is no wonder that the easy navigation through hypertext documents was soon adopted as a model also for the remote access to automation data. Consequently, many solutions of fieldbus/Internet connectivity rely on WWW technology and a web-browser interface. Still, the impression that "the Internet" naturally entails a uniform way of remote access to automation networks is deceptive. The user interface is only one aspect, the underlying mechanisms and data structures are another. In fact, when it comes to implementing an interconnection between IP-based networks and an automation system fieldbus, there is a surprising variety of possibilities even in the considerably "standardized" Internet environment. In particular, the web-based approach is by no means the only one.

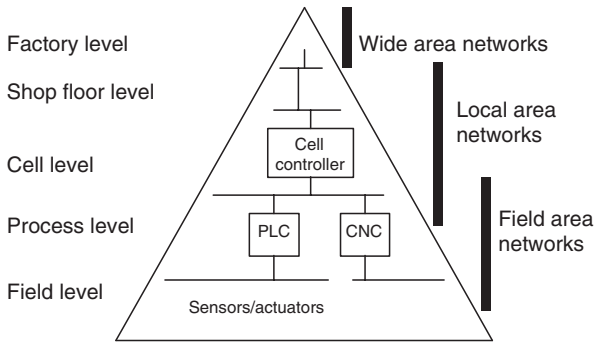

FIGURE 52.1 CIM pyramid and network types used in the various levels.

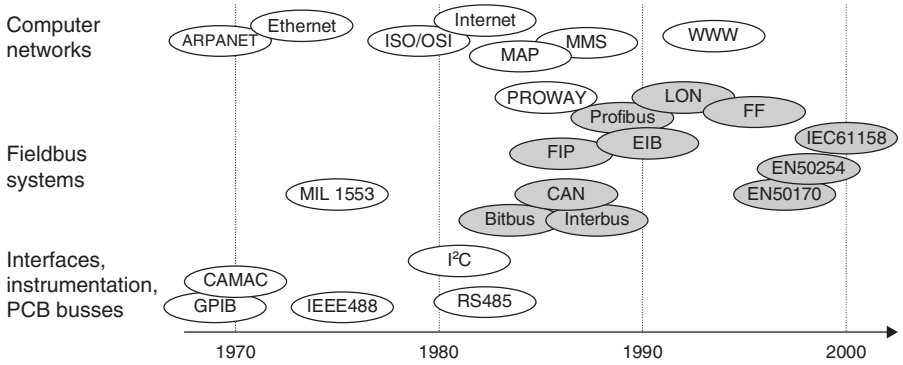

FIGURE 52.2 Evolution of networks in automation and information technology.

52.2 Interconnection Approaches

From an architectural point of view, there are two main possibilities to achieve a fieldbus/Internet interconnection, both of which are being used in practice:

- Tunneling of one protocol over the other
- Providing protocol and service translation via a gateway.

As far as the network topology is concerned, both approaches are very similar. In both cases, a central access point between the networks is either required or at least reasonable. What differs is the way the information is processed by this link or more accurately, how the processing is distributed between the devices involved in the communication.

Protocol Tunneling

In communication networks, tunneling essentially means that data frames of one protocol are simply wrapped into the payload data of another protocol without any modification or translation. The tunneling approach in the automation context falls into two categories. The currently more common solution is to encapsulate IP packets in fieldbus messages, which also opens a channel for the upper-layer protocols required, for example, for direct web access to the field devices [4]. While in most cases not foreseen in the beginning, this possibility has recently been included in several fieldbus systems, a move that has to be seen mainly in connection with the discussion about Ethernet in automation. At first glance, IP tunneling does provide an easy way to achieve vertical integration, as Figure 52.3 shows. The field devices run an IP-based service such as a web server providing data for a respective application in the Internet, which can directly access the device or process data.

A second look, however, reveals that the integration is not at all that easy. There are a few critical points to be considered to properly design such a system.

Computing resources at the field device: First of all, it is evident that the field device as an endpoint of the tunnel must be able to run the complete IP stack with all additional protocols required for the particular application. In addition, memory space is required for the actual application program handling the data that are to be accessed via IP. With today's embedded systems, all this may not be overly problematic, as there are very lightweight protocol implementations available (typically at the expense of detailed error handling). At any rate, this often requires additional hardware at the device and might be a cost factor, especially for simple devices like sensors or actuators.

Traffic handling at the access point: The node that connects the IP-based network and the fieldbus has to encapsulate the IP packets and forward them to the appropriate fieldbus node, where they are unwrapped and handed over to the IP stack. To this end, the access point has to act as an IP router. More

© 2005 by CRC Press LLC

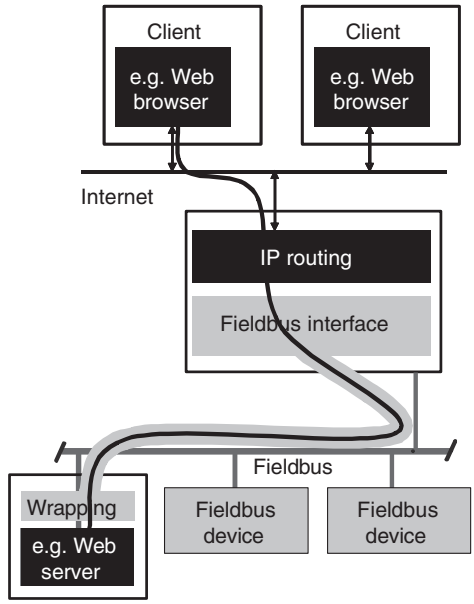

FIGURE 52.3 Structure of IP tunneling over a fieldbus.

than that, it has to map the IP connections to the respective fieldbus communication channels. This requires an address translation on the fieldbus side of the access point. On the Internet side of the node, an additional translation can become necessary if the IP addresses in the fieldbus are not public ones, but taken from a private address range, which is the usual network configuration. The access point thus acts as a simple masquerading firewall with network address translation (NAT). Unlike the case where the IP addresses in the fieldbus are public, the fieldbus as a whole is accessible only via one single IP address, and the distinction between the individual devices (e.g., web servers) hidden behind the firewall can only be done via port forwarding. This means that the services are not reachable through their well-known standard ports, but via dedicated ones which, of course, have to be configured appropriately at the client side in the Internet.

Performance issues: IP packets tend to be rather large, whereas fieldbus data frames are usually optimized for the transmission of only small pieces of data at a time. Squeezing IP packets in the small payload data fields of a fieldbus message therefore requires segmentation, which in turn increases the transmission time. An extreme example is Interbus, where IP traffic can be transported in the parameter channel [5]. This channel has only a small capacity of, say, eight bytes per cycle in order not to interfere with the real-time process data, and one byte is needed for control purposes. Depending on the size of the network and the selected baud rate, one cycle may take a few milliseconds. As an IP packet usually is of the size of several hundred bytes, it is clear that the performance is rather limited. In other fieldbus systems, the data frames are large enough to avoid excessive segmentation. At any rate, the efficiency of IP over fieldbus tunneling depends strongly on the fieldbus.

The alternative way of tunneling works the other way round. Fieldbus messages are wrapped into IP packets (or those of other protocols such as TCP, depending on how the tunnel is set up) and sent to a distant network node (Figure 52.4). From the viewpoint of vertical integration, the disadvantage of this approach is immediately visible. The fieldbus data must be interpreted at the client side, which requires a fieldbus-specific application or at least an experienced user with detailed knowledge about the particular automation system.

This approach does not fulfill the requirements of user-friendliness posed by the idea of vertical integration. In fact, fieldbus tunnels over the Internet are rather used to connect remote segments of an

© 2005 by CRC Press LLC

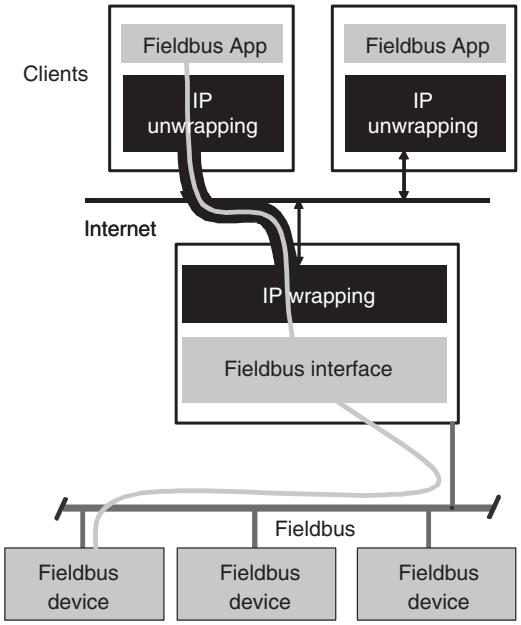

FIGURE 52.4 Structure of a fieldbus tunnel over the Internet.

installation as mentioned in the introduction. A wide field of application for this concept are network-based control systems, for instance, in building automation [6]. It has to be noted, though, that the interconnection of two fieldbus segments over an Internet tunnel is not fully transparent, but has to cope with timing problems introduced by the processing of the data packets and the transmission delays. Therefore, this concept is useful only if the fieldbus protocol provides some routing functionality, where timing requirements can be relaxed.

Gateways

The alternative approach to achieve fieldbus/Internet connectivity is to design the central access point as a gateway. As with the tunneling approach, the gateway is a full member of the fieldbus on the one side and can be accessed through IP-based mechanisms via the Internet (Figure 52.5). What is different, though, is the way the information exchange is handled. In the IP tunneling approach, the client connects directly to the server running on the field device. The access point just forwards the IP traffic, but is not further involved in the data transfer. In the gateway approach, the access point takes the role of a proxy representing the fieldbus and its data to the outside world. It fetches the data from the field devices using the usual fieldbus communication methods and is the communication partner addressed by the client.

Unlike the tunneling approach, where each field device has to provide and maintain its data on an individual basis, information processing for the client in the Internet here is centralized. This enables the gateway to set up a comprehensive and consistent view of the automation system, which is undoubtedly a benefit. In addition, the field devices need no special equipment to process IP-based data and services.

For the sake of completeness, it should be noted that a gateway would in principle also allow for the reversal of the communication direction. Therefore, field devices could as well access resources in the Internet, for example, different fieldbus systems connected to the LAN via compatible gateways. Although there have been efforts to foresee this possibility by providing harmonized interfaces (as in the NOAH project [7]), it is irrelevant in practice.

There are implementations for both the tunneling and the gateway approach available. The gateway is the more pragmatic and also more flexible solution. Furthermore, it is compatible with existing

© 2005 by CRC Press LLC

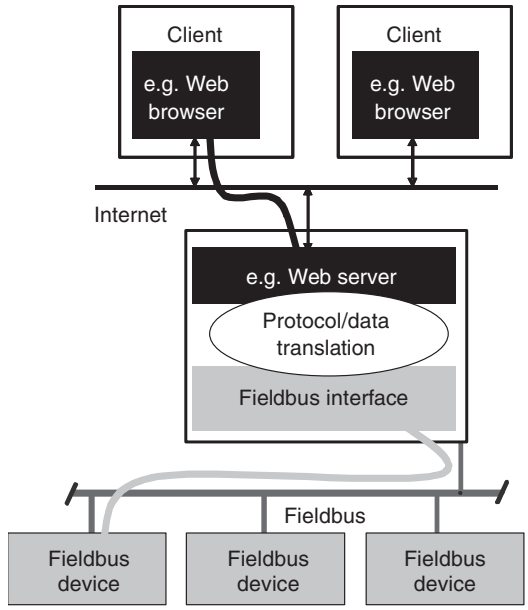

FIGURE 52.5 Network topology for a gateway-based interconnection.

installations, whereas the tunneling approach requires changes on the fieldbus level, both inside the field devices and in the protocol. Gateways are therefore dominant, and the remainder of this paper will focus on the gateway approach. Still, many considerations are also valid for the tunneling concept.

52.3 Design Considerations for a Gateway

There are no general guidelines regarding how to implement a gateway between a fieldbus and the Internet. From the user's perspective, however, there exists a clear-cut requirement for the integration: as the automation data are brought into the office world, the ways and means employed must comply with the standards used there. In particular, this requires some sort of abstraction for both data and functionality. There is a good reason for this. Within the scope of vertical integration, the automation data are accessed from a "strategic" level (rather than control level); thus, the user wants to have a clear picture of the most relevant data. Too many fieldbus-specific details can obscure this picture and be distractive. After all, the user is typically not a fieldbus expert, let alone the one who set up the automation system.

Another argument in favor of an abstract view to the automation system is the desired user-friendliness of the interface. Typically, the user wants to retrieve data from different systems with only one tool. Therefore, the user interface should be as independent of the underlying system as possible. It is important to notice that the way data and functionality abstraction can actually be achieved also depends on the protocols and mechanisms used on the Internet side of the gateway. In the sequel, we list and discuss a few design issues. They may vary with the concrete target application. The model for the present discussion is a simple and cost-effective residential gateway for linking a home network to the Internet [8].

Services

The basic function of a gateway evidently is to provide read and write access to process and device data on the fieldbus for monitoring and control operations, but also for network management purposes. However, as the gateway has to accomplish protocol (and maybe data) conversion and therefore needs a certain amount of computational intelligence anyway, additional services can be included. With the

© 2005 by CRC Press LLC

gateway acting as a proxy server for the automation data, there are a number of autonomous functions it can (or should) provide. Some of these add-on services can be described as *events* in an abstract way. Events are triggered by predefined criteria: if a criterion is fulfilled, an action is taken. Criteria can be the expiration of timers (time-based events) or the crossing of thresholds by the value of a data point (value-based events). The actions to be performed upon the occurrence of an event can be manifold.

Data logging: The storage of data point values based on either time or the recognition of certain trigger conditions enables the gateway to perform stand-alone operation independent of the availability of an on-line connection to the high-level network. Especially in remote access via unreliable channels (e.g., wireless or heavily congested service providers), the possibility of creating log files (and retrieving them at a later time) may be an essential requirement of the application. A management station can then retrieve logs (fully or incrementally) to perform subsequent analysis or feed specialized software with control system data.

Asynchronous notifications: Contrary to the predominant client/server communication model in the Internet, where the client has to continuously poll the server (the gateway) to obtain information, the gateway should become active as a resonse to certain events. The availability of such a mechanism is an important criterion for the choice of a suitable protocol on the Internet side of the gateway. In practical implementations, the lack of native asynchronous notification mechanisms is usually circumvented by the use of services based on some kind of e-mail.

Two other types of services are independent of the fieldbus data and cannot be modeled as events.

Security: Fieldbus systems are traditionally security-unaware. When a connection to the Internet is provided, however, the security of protocols that are able to communicate with the gateway is vital for both the field area networks that the gateway is connected to and the gateway itself [9]. The gateway has to take care of access control, the minimum level of security being authentication.

Network structure updates: A last point that might be relevant for the gateway depending on the desired application area is some kind of plug and play functionality. By this, we understand that the gateway is capable of recognizing changes in the network structure autonomously and adapt its internal data point structure. This does not necessarily eliminate the need for preconfiguration, but it may help to keep the gateway operational. A typical application for this feature are residential gateways that — once installed — have to be as autonomous as possible and must cope on their own with devices joining or leaving the field area network. In this case, the underlying fieldbus must of course also support basic plug and play features. A key issue here is the ability of the high-level protocol on the Internet side to reflect structural changes in the field area network: nodes in a field area network can be removed, added, or replaced. This can influence the mapping between protocol addresses and fieldbus addresses. It has to be taken into account as to how a protocol deals with such changes in the network structure and how objects that existed before a change can be consistently addressed after a change.

Gateway Structure

There is no best architecture for a gateway. Its primary function is to act as an abstract interface to a automation system, independent of both the fieldbus protocol (because it operates on application level) and the fieldbus-specific coding of the data. Therefore, the gateway provides unified access to maybe more than one fieldbus simultaneously. The software structure of the gateway implementation can reflect this demand for versatility and exhibit a modular structure [8, 10]. Alternatively, the architecture can as well be monolithic and tailored to one specific case. A modular approach will have to provide abstraction as a matter of course, the three-level approach shown in Figure 52.6 is just one possibility.

What has to be considered separately is the low-level access to the fieldbus. One degree of freedom is the strategy used to fetch the data. This can be based on a caching mechanism, where the gateway autonomously retrieves the data with a predefined refresh rate. Upon request from the client, the response is taken from the cache and returned without further delay. This approach provides immediate answers and can reduce the fieldbus traffic, especially in situations where multiple access from different clients needs to be handled. For proper operation, a time stamping should be foreseen, so that the client can keep track of the age of the data values.

© 2005 by CRC Press LLC

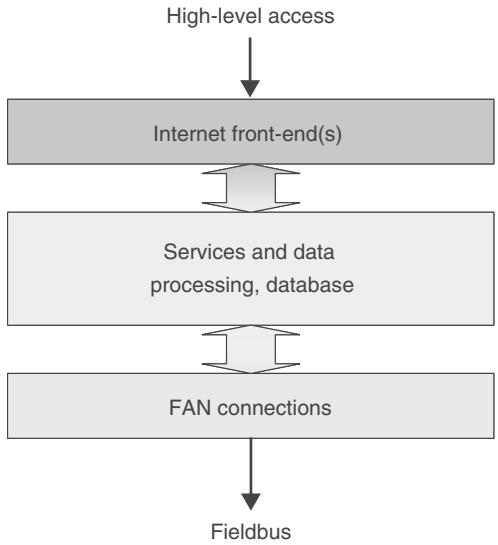

FIGURE 52.6 Modular three-level gateway structure.

The alternative is to obtain the data from the fieldbus only when requested to do so by the client. This avoids cyclic updates as well as time stamps; but the gateway may have to cope with substantial delays of the response from the field device. The connection to the client has to be kept alive in the meantime.

Which strategy can be used depends both on the properties of the fieldbus and the capabilities of the interface used. To avoid excessive bus load in the caching scheme, the gateway can passively listen to the network traffic. Provided the fieldbus interface supports such a monitoring mode, this approach is convenient to track cyclic (in systems like Interbus or Profibus-DP) or event-driven data transfer (in fieldbusses based on the producer/consumer model like CAN and EIB). Unfortunately, many of today's integrated fieldbus controllers perform a low-level data filtering inhibiting straightforward monitoring. In these cases, the gateway must actively retrieve the data from the bus. The same applies to data that are not normally transferred on a regular basis, such as diagnostic data (e.g., in Profibus-DP). Even worse, the transmission of such specialized information often requires the execution of dedicated commands that cannot be mapped to simple read/write commands. Such fieldbus-specific communication sequences (but also other peculiarities like remote program invocation or special network management functions) must be handled differently. As the high-level access via the Internet most likely will not provide methods for direct command execution, such special functions can be triggered by an ordinary read/write access to specially assigned data points.

Another important restriction may be the medium access control scheme employed by the fieldbus. There are no problems with multi-master systems; here, any node can host the gateway. Single-master systems, on the other hand, imply that the gateway must either be the fieldbus master or cooperate with it, in the sense that there is a dedicated and typically nonstandard communication channel through which the gateway can tell the bus master as to which data values are to be read or written. Otherwise, writing data points will inevitably lead to inconsistencies, when the gateway sets a value and the bus master overwrites it during a regular update cycle.

Data Representation

A crucial point in the design of a gateway is the way the fieldbus data are represented. A *data point* is the smallest information unit available via the gateway. To achieve fieldbus independence, the data points have to be arranged in a rather general, high-level way. The question regarding how to find a unified view and coding for the sometimes extremely heterogeneous fieldbus objects is an interesting topic on its own

© 2005 by CRC Press LLC

and will be left aside here. More relevant for our purpose is the way the complete set of data points is structured inside the gateway. Basically, there are two different possibilities to do so. The first is a function-oriented approach. In this case, emphasis is put on the content of the individual data point, and the underlying network structure is completely irrelevant. The gateway thus offers a simple flat list of data points [10].

The second approach is a structure-oriented one. Here, the data points are arranged according to the structure of the field area network. The gateway offers a list of nodes, and each node can contain one or several data points [8]. In addition to the simple form of a data point, a data point can also contain a set of values instead of only a single value. This type of data point is referred to as an *aggregate* data point. Data points can also contain multiple values of different types (structures). The advantage of the structure-oriented solution is that properties of nodes (and not only properties of data points) can also be modeled on the gateway. These properties are, for example, a self-identification of the node or a location information that describes the position of a node in a field area network.

Which of the two possibilities is actually used is a matter of taste and also depends on the target application. Furthermore, the choice might be limited by the high-level access protocol and its capabilities of describing and managing data. Every object that is available to a client needs an address that uniquely identifies the object. Protocols typically define their own addressing scheme; the gateway, on the other hand, also defines an addressing scheme that may be similar to or completely abstract from the fieldbus network addressing. These two schemes need to be mapped onto each other to make data points available.

Another point to be observed is how the information of a data point is encoded. This again might be limited by the capabilities of the way the data are transferred from the gateway to the client. Not every protocol may support special data types or encodings used in a particular fieldbus, so that there must be some form of data translation and — necessarily — abstraction. This might not be too problematic for scalar data points like temperatures (although there are obviously many possibilities to encode a temperature value), but it will become increasingly difficult for such common things as date and time, not to speak of aggregate data points available only as a structure on the fieldbus level. For all these more complex data points, no one-to-one mapping is possible, and there are basically only two options to cope with the situation: one is to find a compromise in the form of abstract data representations that omit excess information, and the other is to collapse the complete data point into a flexible and unspecific data format such as a string — with the disadvantage that the client needs to take the string apart and to interpret it, which again requires fieldbus-specific knowledge.

In addition to the actual value, a data point may also need some attributes to facilitate interaction with the client. Such attributes can be a description of the data point type and encoding (to tell the client how the data are to be handled) and maybe a string providing a textual description of the data point. In some fieldbus systems, such a self-description is foreseen for data objects anyway. Last but not the least, there can be a specification of the access mode, that is, what the client is allowed to do with the data point. It should be noted that although the restrictions concerning data representation have been discussed for the gateway approach, they also apply to the IP tunneling solution. In this case, the list of data points has to be maintained by every field device on its own. Typically, the implementation is up to the vendor, and unless there are very stringent rules, this may lead to a substantial inhomogeneity stemming from the many degrees of freedom mentioned before.

52.4 Gateway Access From the Internet

The primary goal of vertical integration is to bring automation data into an IT context, and consequently there are many ways to incorporate data provided by a gateway into office-level applications. To this end, it is not necessary to employ full-fledged application-level protocols on top of IP/UDP/TCP. A very common approach used in contemporary SCADA systems is OPC, which relies on the Windows-specific mechanism OLE and COM/DCOM [11]. With the extension OPC DX, it is in principle even possible to interconnect different fieldbus systems because OPC DX also permits server–server communication over

© 2005 by CRC Press LLC

an Ethernet network [12]. A more unconventional idea is to treat the gateway as a database and use SQL to retrieve the data [13].

The protocols discussed in the sequel have been evaluated with respect to their feasibility for home network access, specifically for remote meter reading [9]. The criteria for the evaluation were described in the previous section: a reasonable way of structuring and handling data, a possibility to send asynchronous notifications, and of course security provisions. In addition, the protocol (together with its data representation) should be able to cope with changes in the network structure. This requirement is a direct consequence of the target application in an intended mass-market with a high number of installations, where updates calling for specially trained personnel are not affordable. Likewise, the overall costs of such a gateway should be low, which typically means limited computing power and memory space. Compact implementations on possibly embedded devices are therefore a must.

SNMP

SNMP is a comparatively old protocol and has been designed for remote administration of networked devices [14]. Data are represented in a tree structure called *Management Information Base* (MIB) where each branch and each leaf have a unique identifier, called *Object Identifier* (OID). SNMP *managers* (i.e., the client that connects to an SNMP-enabled device) use this MIB to get extended information about the managed *agent* (i.e., the device that allows SNMP access; in the present case, the gateway). The MIB is a static representation of all the objects available at the managed agent. As SNMP does not provide mechanisms to download the MIB from the agent, the mapping of OIDs and data points needs to be transferred to the manager over mechanisms, which are beyond the scope of SNMP (usually this is done by the administrator of the system during setup). SNMP is based on the connectionless User Datagram Protocol (UDP) running on top of IP. This is rather efficient because of the low overhead; but unlike TCP, UDP does not guarantee delivery of packets, so packets can be lost on the network without being noticed by the sender.

The major commands provided by SNMP are GET and GETNEXT for reading data (GETNEXT allows the manager to traverse an unknown MIB tree and to retrieve the OIDs) and SET for writing to data points. In contrast to the standard manager-driven communication (in typical client/server fashion), SNMP also defines the unacknowledged TRAP command (from version 2 on also the acknowledged INFORM command), which can be sent by an agent to asynchronously inform a manager about special conditions in the agent. This possibility to reverse the client/server communication is a rare exception among the investigated protocols and together with the good protocol efficiency is a strong argument in favor of SNMP.

One of the major problems of SNMP is the static structure of the MIB together with the lack of native transfer mechanisms between the agent and manager, which does not allow dynamic updates of the network (or data point) structure. Therefore, the list of nodes and data points needs to be stored in an SNMP table rather than as a set of separate objects in the MIB [15]. To access individual objects, the manager needs the OID of the table, which is fixed once and for all, and the number of the row containing the object. If the structure of the field area network is changed, the table can be updated by adding or removing the rows that represent the according nodes. This is a critical issue in that SNMP requires the rows in an SNMP table to be numbered consecutively; therefore, the insertion or removal of a row changes the numbering of all subsequent rows.

The workaround of using tables to add a somehow dynamic behavior also raises problems if the gateway is accessed by more than one client simultaneously. It is possible that data in a table are modified by one client (e.g., rows are deleted or added), while another client is in the process of reading the table. This results in an inconsistent set of data. A possible solution used in the case study was to introduce a sequence number for every table. This sequence number changes every time data in the table change. The workaround for achieving data consistency is to read the sequence number, read the table, and afterwards read the sequence number again to check if it changed. In case it remained unchanged, the table data are consistent; otherwise, the whole process has to be repeated. To this end, for write access the protocol had

© 2005 by CRC Press LLC

to be slightly changed in a way that every SNMP SET command contains a sequence number that uniquely identifies the version of the table to which a data point is written.

Another problem of SNMP is security. The commonly used version of SNMP is version 1, which does not contain any considerable security features. In the most recent version 3, security mechanisms have been introduced that are sufficient (although not widely used at present) [16]. Still, difficulties arise from the connectionless UDP used as a transport protocol. UDP traffic is usually not permitted to pass through a typical firewall. But even if communication is possible, the underlying UDP does not guarantee packet delivery. This means that an SNMP manager communicating with an agent cannot rely on the last action he has taken on an agent to be successfully finished. Neither can an agent be sure about the status of a communication with a manager. Hence, error monitoring must be implemented within the manager application.

LDAP

LDAP [17] is the lightweight counterpart to X.500 directory services. It is oriented toward directories that are organized in a tree, the *Directory Information Tree* (DIT). The DIT is a hierarchically structured organization of data items, the directory entries. Every entry consists of a collection of attributes. Every attribute has an attribute name, an attribute type, and a value associated with it. One special attribute that is mandatory for every tree entry determines the position of the entry in the tree — the *distinguished name* (DN), which is used as a unique "address" for the entry. It specifies the path by listing all parent entries up to the root entry. The directories contain mostly (but not necessarily) small pieces of data, which are mainly read and searched for. Writing of data is intended to occur only rarely, as well as changes in the tree structure.

LDAP offers a set of data querying and manipulating commands for accessing the directory service. The SEARCH command is very powerful and allows to specify search filters that are applied to each entry. It is possible to request just a subset of the available attributes and in order to narrow a search even more, the scope can be limited to a certain level of the directory tree (search only the current level, one level deeper or the whole subtree). With the commands ADD, DELETE, and MODIFY, single entries can be added, deleted, or modified, respectively. The COMPARE command is used for comparison of two entries.

Since LDAP uses TCP as a transport protocol, there are no problems with firewalls. Also, all security extensions designed for TCP-based protocols such as the *Transport Layer Security* (TLS) [18] can be used. LDAP version 3 also provides appropriate authentication mechanisms in combination with those already defined in TLS [19].

Dynamic update of the directory information tree is also not particularly problematic, although the changes are not automatically taken over by the client. The DIT as such is not confined to a static structure like the SNMP MIB, which facilitates the adding and deleting of entries even at runtime. Consequently, there is also no problem with the consistency of data, because the address of a data point can be added as an attribute to the directory entries to unambiguously identify the data points. As operations on a DIT entry are always atomic, simultaneous and consistent access to one single data point from multiple clients is inherently handled by the built-in mechanisms of the protocol.

A general difficulty of LDAP is that its original application idea does not exactly fit the purpose of fieldbus gateway access. The main application of LDAP is the access to data that are related to humans, for example, telephone numbers, employee data, or classical white pages services. The client support reflects this field of application, and although clients exist, they are not widely used and very different in their performance with respect to network load. A second point is that the access to white pages directories is typically read-only. Therefore, the powerful search command can provide a convenient means to retrieve fieldbus data. Writing, on the other hand, is more difficult and likely becomes a bottleneck. Hence, LDAP is not so well suited for control tasks where intensive write access is required. Another problem is the lack of an asynchronous notification mechanism, so that workarounds (like e-mails or the like) have to be used.

Web-Based Approaches

For many solution providers in the area of fieldbus/Internet connectivity, web-based approaches seem to be the only conceivable solution; at least they are strongly favored. However, unlike the protocols described so far, methods based on the WWW are very heterogeneous. They include communication and data representation using web browsers as clients. The common transport protocol is HTTP, which is typically used to transmit HTML documents. HTML documents can contain embedded objects and script languages (e.g., JavaScript) and can be created by multiple technologies on the server side (such as CGI, ASP, JSP). They all have in common that the client receives a predefined view of a set of data. This view can be modified by the user (e.g., by selecting specific objects in a page and filtering out the others), which requires the creation of a new document on the server side. This process is usually not very responsive because of the necessary communication and computation overhead.

The two main commands that the HTTP protocol supports are GET (for sending requests to a server to retrieve data) and POST (so send data to the server). This, however, does not cover the whole spectrum of possibilities that are based on this mechanism. In many cases, however, the user is presented with a view based on a template, which is filled with data by some server mechanism.

A definite strength of web technologies is the availability of many different clients. Several Internet browsers for multiple platforms exist, leaving hardly any white space on the map of supported systems. The main problem of pure HTML is the response behavior that is imposed by the necessity to refresh (i.e., completely reload) a page in order to receive current data (this can be circumvented by advanced mechanisms, which only retrieve, e.g., the data point value). There is also another performance problem with this approach: As the view on the data depends on HTML documents, typically several data points will be collected on one page to have a better overview. Therefore, even for very small amounts of data (e.g., the value of just one data point), a complete document needs to be created and transmitted. This causes a considerable amount of both computational overhead and network traffic. Likewise, it is not possible to collect data from multiple servers in a single document, which considerably limits the use of this approach. In an IP tunneling scheme, for example, every device providing data needs to maintain a set of HTML pages, and the client needs an instance of the browser for each device. An integrative view of the entire installation, let alone an automatic data acquisition, is not feasible and has to be done manually.

A positive point about the web approach is the comparatively unproblematic security issue. As HTTP is based on TCP, TLS can be used. Furthermore, HTTP is conveniently routable through firewalls, which is an important point in an environment becoming increasingly aware of security — although it has to be noted that the simple routing possibility actually opens a way to circumvent security. A drawback is that there is no way for the server to send data to the client without request. Like with all other protocols except for SNMP, other ways have to be found to accomplish such notifications (e.g., special applets or e-mail-based services). The support of different data types is also very poor. In fact, the data have to be sent as strings and processed appropriately by the client. This lack of ample data type support ideally supports (and also demands) pragmatic, proprietary solutions, but is a severe obstacle to standardized, interoperable implementations. A possible way out of this dilemma is the increasing use of XML. If the data are based on (standardized) XML descriptions, they are not only readable for a human operator (a major drawback of HTML) but also machine parsable, which makes gateway access based on web technologies finally also suited for automatic data acquisition.

A further step in this direction could be the XML-based simple object access protocol (SOAP), which defines methods for data exchange typically used over HTTP. A tremendous benefit is an utmost platform independence as both HTTP and XML are available everywhere. However, as SOAP is a protocol on its own, client applications are still needed; today, a web browser is not sufficient. A potential weak point is, as with the somehow related technology CORBA, the relatively complex structure, which does not lend itself to a lightweight implementation on those resource-limited devices that make up a significant portion of a typical automation system today.

52.5 The Role of Industrial Ethernet

A discussion of fieldbus/Internet connectivity is incomplete without consideration of the growing use of Ethernet in automation. After all, Industrial Ethernet is often praised as *the* solution to vertical integration overcoming all problems encountered in the design of heterogeneous network interconnections. Beyond all well-sounding marketing slogans, it is a matter of fact that the dominant use of Ethernet in local area networks has renewed efforts to use Ethernet also in the automation domain. These efforts date back to the early days of Ethernet development, but only recent technological advances in the development of full duplex and switching techniques made high data rates possible without the old drawbacks of the CSMA/CD medium access control. Although it is still disputed whether or not Ethernet really fits the requirements of a field-level network, the main benefit is clear: if Ethernet was used as a replacement for the fieldbus, and if IP plus the common transport protocols were used on top of it (which is not necessarily the case in all Industrial Ethernet approaches), Internet technologies would be the natural way of accessing automation data. It is thus not astonishing that many contemporary concepts of vertical integration rely strongly on Ethernet as an automation network. For the old CIM pyramid, the penetration of LAN technologies into the classical fieldbus domain has the ultimate consequence that intermediate levels become obsolete. The hierarchy thus gradually turns into a flatter structure with only two, maybe three levels.

How do the facts of Industrial Ethernet compare with the characteristics of vertical integration discussed so far? It is of course short-sighted to postulate that the use of Ethernet alone entails an interoperability with "the office world" — although it is often done. In fact, Ethernet is but a transport medium. Using Ethernet for both office and automation applications may allow for a coexistence on a shared medium (within certain limits posed by, e.g., bandwidth considerations), but does not mean integration. What is much more important to this end is the protocol stack used on top of Ethernet. Indeed, most solutions rely on the Internet and LAN standards TCP/UDP/IP as a transport layer; however, this is already where compatibility ends. The higher layers of all serious approaches are in fact *fieldbus* protocols:

- Ethernet/IP (IP standing for Industrial Protocol) uses the Control and Information Protocol (CIP) already known from ControlNet and DeviceNet [20]. This application layer protocol is simply sent over TCP or UDP, depending on whether configuration or process data have to be transmitted.
- The High Speed Ethernet (HSE) variant of Foundation Fieldbus is in fact an application of the existing Fieldbus Foundation's H1 protocol wrapped in UDP/IP packets [21].
- Modbus/TCP [22] is based on standard Modbus frames encapsulated in TCP frames.
- PROFInet is rather a new protocol development [23]. Its integrability into the IT environment relies on the COM/DCOM mechanism used for communication between devices. Legacy fieldbus systems can be included via so-called proxies (which are essentially gateways in our sense).
- The IDA (Interface for Distributed Automation) proposal is an entirely new protocol on top of UDP for real-time data communication plus a web-based human–machine interface [24].

In the light of our taxonomy sketched in Section 52.2, all these approaches (with maybe the exception of PROFInet and IDA) essentially implement some sort of fieldbus protocol tunneling approach. Of course, they have the benefit of a — thanks to the possibility of using the same medium for office and automation tasks — tight integration from a network point of view. Unless a traffic separation seems reasonable for performance or security reasons, no dedicated connection node is necessary. On the application level, however, integration is by no means so tight. Even though the inclusion of automation data into office applications is simplified by, for example, object-oriented techniques borrowed from the IT world, there is still a substantial amount of fieldbus-specific information to be handled. Consequently, an abstract view on the automation data — one of the requirements for vertical integration — is not a matter of course. Nor is an "automatic" inclusion of Industrial Ethernet into the office world easy to achieve. In fact, the effort that needs to be spent on a gateway design has in this case to be put into the development of appropriate non-standard application-level tools. The only exception where Ethernet together

© 2005 by CRC Press LLC

with standard protocols definitely brings an advantage is a web-based human–machine interface used, for example, for configuration purposes. But this is only one small aspect of automation.

52.6 Summary

The classical fieldbus systems have been devised as highly specialized communication systems for the factory floor. Their development, although innovative at that time, was aimed at conventional self-contained automation applications. Today's automation tasks, however, are usually no longer stand-alone systems. At least supervisory control and data acquisition is required in many cases, with the respective SCADA software running in a typical office environment as regards hard and software platform or network environment. More advanced demands are remote data access for monitoring or maintenance, or the inclusion of automation data in company-wide management systems. All these functions are in fact not a part of the factory floor or the process control level; they belong to a higher, more strategic level of information processing, which is governed by office networks. This circumstance calls for an interconnection between automation and office networks.

As different as the goals of interconnection are the possible realizations. Although the systems on either side are standardized, the link is not — not even in a coarse architectural sense. One reason for this is the still existing plethora of fieldbus systems. On the Internet side as well, the IP suite is just a least common multiple of an equally large set of possible applications serving as targets for the interconnection. The preceding sections have highlighted the basic system architectures and the many design options to be considered. Evidently, the properties of the networks together with the applications have an important influence on these options and in fact limit the designer's flexibility with respect to the implementation.

Contrary to an initial guess, the architectural approach (i.e., gateway or tunneling) does not seem to affect the overall system complexity very much. As the discussion showed, it rather influences the distribution of the implementation efforts among the involved entities: field devices, clients on the Internet side, and a possible central access node. The particular choice must largely depend on the intended application; there is no golden rule for it. In fact, all approaches have their own strengths and shortcomings. Even though the major part of the article discussed the subject from the viewpoint of a gateway solution, this does not imply that the tunneling approach is inferior. It is simply suited for slightly different types of application, and most of the points described for a gateway are equally valid.

The overall complexity of the interconnection is — according to practical experience — chiefly determined by the desired level of data and functionality abstraction and the degree of vertical integration to be achieved. A direct forwarding of fieldbus data packets "as is," with the interpretation left up to the client (and, ultimately, the user), is easier to achieve than a reasonable data and protocol translation with the aim of a smooth integration into a non-fieldbus-specific application. Not always is true vertical integration and abstraction really an issue. But if it is, the price to be paid is necessarily a loss of precision, mostly from a functional point of view. The higher the abstraction level, the fewer functions and specific pieces of information can be mapped to the "other side" without problems. Timing precision or real-time behavior should not be a requirement at all because timing relations are typically lost in the node linking the two different networks. Timestamps can help, but only to a certain extent.

The great flexibility of fieldbus/Internet connections sketched in this article is a bit deceptive. In practical implementations, one has to live with a number of inconveniences. Timing is just one. Especially if one goes for vertical integration, the high-level target application and the underlying protocol may not support services provided by the automation system. This frequent lack of a one-to-one relation between the two networks requires some creativity from the designer, especially on the Internet side. A good example are the basic gateway services discussed in Section 52.3. Vital mechanisms such as asynchronous notifications rarely exist as native protocol features and have to be replaced by workarounds outside the actual application. In a number of case studies, it was found that none of the investigated high-level protocols really satisfies all needs. In this respect, the large number of different interconnection approaches is not astonishing, but only reflects the fact that the one ideal solution for all occasions does not exist.

53.1 Introduction and Overview

Control networks also known as fieldbus systems started to emerge rapidly in the early 1990s. Back then, control networks were designed to be used in closed systems exchanging data packets on dedicated network channels. These channels included twisted pair media, power-line networks, wireless, and infrared communication. Dedicated network channels have more or less well-defined properties for bit error rates, propagation delays, average and maximum response times, and they guarantee to maintain the packet order on the network.

With the upcoming hype of the Internet in the late 1990s, requests were made to extend control networks to not only span local communication within relatively small areas but to cover networks that are spread out over cities, countries, and even continents. In building automation, facility managers wanted to connect facilities to a central location for monitoring, logging, alarming, trending, and remote maintenance.

This meant that the engineers had to either go back to the drawing board and redesign the control network protocol to make it work in large networks or use the existing technology like the IP service available on the Internet to transport control network data packets across continents. Of course, there are still restrictions regarding defined maximum response times, proper packet ordering, defined packet loss — all properties that are easily manageable on dedicated network channels but can be more or less unknown or undefined in IP (Internet Protocol) networks.

For the engineers, there was the challenge to live with the restrictions of the control network protocol and add a software layer in between the IP service and the control network protocol to conceal these limitations of the IP transport service from the upper layers of the control network protocol. Figure 53.1 shows the software architecture for a typical fieldbus node connected to a dedicated network channel on the left and if it is using the IP transport service on the right side. One can see the software module that is called ANSI/EIA-852, which is sitting between the control network protocol stack and the TCP/IP and UDP socket interface, and tries to conceal the limitations of the IP service from the control network protocol stack but also packs the control network data packet into an IP packet when transmitting a packet and

© 2005 by CRC Press LLC

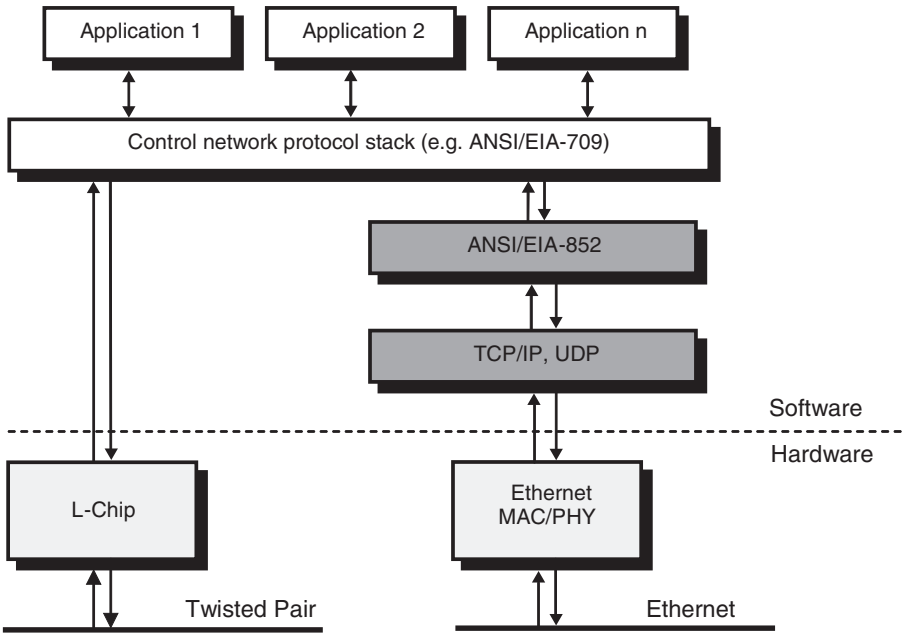

FIGURE 53.1 A dedicated software layer named ANSI/EIA-852 conceals limitations of the IP transport service from the control network protocol stack and sticks the control network data packet into an IP packet.

unpacks the control network data packet from the IP packet when receiving a packet. In this chapter, we concentrate on the ANSI/EIA-709 control network protocol but the technique described here will also be used for EIA-600 and other control network protocols.

The challenge in tunneling control network data packets through IP networks is to minimize the effect of the unpredictable IP timing parameters on the control network protocol stack.

53.2 EIA-852 Standard

The EIA-852 standard [8] was created to ensure interoperability of control network (CN) devices, which communicate over an IP network using a native CN protocol. The basic idea is to exchange CN packets over an IP network by embedding them in IP packets. This technique is known as tunneling. In EIA-852, there are no application-layer transformations involved as in other approaches, which use gateways. The tunneling approach is beneficial in systems where a number of CN devices communicate and use the IP network purely as another medium.

One major design criteria of the EIA-852 standard is to be generic enough to apply it to different CN networks. Currently, the usage for EIA-709 (LonWorks) and EIA-600 (CEBus) is defined. Most EIA-852 implementations on the market today are LonWorks-based. Therefore, the description of the standard is focused on its application to EIA-709. The network elements defined in the context of the EIA-852 standard are CN devices. These CN devices are computing systems (e.g., PCs, embedded systems) equipped with a TCP/IP stack, the EIA-852 software, and a LonWorks protocol stack. A number of CN devices are connected over the IP network where they form a logical network known as the *IP channel*. The IP channel functions as a LonWorks communication channel and CN devices exchange data over the IP channel. The CN devices part of the IP channel are referred to as *channel members*.

It shall be noted that there may exist more than one IP channel on the same IP network. Although the CN devices are connected to the same physical network in this case (e.g., Ethernet), the IP channels are still isolated in the LonWorks domain.

© 2005 by CRC Press LLC

CN devices can have different functions. Depending on their primary function, the EIA-852 standard defines the following CN device types:

CN nodes: They operate solely as nodes in a distributed control application and are members of one IP channel. They have the same functionality as LonWorks nodes on their native communication channels and are connected to the IP channel only.

CN/IP routers: These CN devices are LonWorks routers that connect one native LonWorks channel with one IP channel. These devices are available on the market as stand-alone LonWorks/IP routers or EIA-852 routers, for example, the L-IP by LOYTEC or the i.LON 1000 by Echelon Corp.

IP/IP routers: These CN devices are LonWorks routers that connect two IP channels. These devices are less common on the market today.

CN proxies: These are CN devices, which function as LonWorks proxy nodes to establish cross-domain communication, for example.

The EIA-852 addressing scheme defines to address types. First, there are IP addresses associated with each CN device on the channel. Second, there are logical CN addresses based on the LonWorks address space. The Unique ID is equivalent to the LonWorks node ID or Neuron ID and functions as a unique hardware address. Each CN device is accessible by its unique ID. Logical network addresses include a subnet/node (S/N) scheme, where individual channels are assigned subnet numbers and CN devices on that channels' node addresses. As a convention, subnets must not span over multiple channels, if the CN routers are used as configured LonWorks routers. The group address identifies a number of nodes without looking at subnet addresses. Consequently, groups can span different channels. Finally, those logical addresses are local to a domain.

The mechanisms in the EIA-852 standard are designed to take care of typical CN protocol properties, which differentiate them from common IP application protocols such as Email, Web access, or multimedia streaming. The key characteristics of control network traffic are

- low throughput,
- small packet sizes, and
- higher sensitivity to packet loss and latency.

While low throughput allows CN devices to perform more lengthy per-packet calculations, small packet sizes will lead to significant overhead in the encapsulation process. The implications of packet loss and latency on the IP network are two-fold in EIA-852 systems:

- The control application has to be designed to cope with timing parameters, which differ from native CN channels. This has an impact on the soft real-time properties of some applications. It is important to know the time constants in the application and determine whether the application could break if run over an IP channel [15,16].
- The EIA-852 standard has to ensure the functionality of the CN protocol itself. LonWorks, for instance, makes strict assumptions on maximum end-to-end delay and packet ordering.

The resulting functional domains defined in the EIA-852 standard to implement a CN protocol tunnel over an IP-based network can be summarized as follows:

Assuring correct and efficient data communication: CN packets must be encapsulated and decapsulated, packet ordering must be ensured, message overhead must be minimized, timeliness must be checked, and optional security measures can be used.

Routing CN payload to their correct destination on the IP network: The EIA-852 standard defines two ways to choose destination CN devices, either by using IP multicasting, or by performing selective forwarding.

Managing the IP channel members: This includes configuring the CN devices, distributing information between the CN devices, performing access control on the IP channel, and retrieving statistic information.

© 2005 by CRC Press LLC

53.3 System Components

In addition to assigning logical addresses to the network node as specified in the control network protocol, network nodes must get an IP address assigned. Hence, IP-based network nodes now have a logical CN address and an IP address. In order for a node to transmit data packets to another node on the network, it must not only know the CN address but also the IP address of the target node. Hence, an instance is required that manages the relationship between the CN address and the IP address for a logical IP channel. This logical IP channel is called CN over IP or short IP channel and the instance that is managing the address information for the IP channel is called configuration server or short CS. Figure 53.2 outlines the systems components required to set up and manage a IP channel. The network in Figure 53.2 is split in half and consists of two traditional EIA-709 networks with subnet numbers 2 and 3 and a brand new IP channel consisting of 4 IP client devices and a configuration server CS node. Two out of the four IP client devices act as routers between the traditional EIA-709 network channels and the IP-852 channel. Let us assume that network node with S/N address 1/1 on the IP-852 channel wants to send a data packet to the network node with S/N address 1/2. Both nodes reside on the IP (IP-852) channel. In order for node 1/1 to send out a packet to node 1/2, it must know its IP address 192.168.1.102. This information is maintained in the configuration server CS hosted on IP node 192.168.1.105 and distributed to all nodes on the IP-852 channel at system startup. From now on, node 1/1 knows the relationships between S/N address and IP addresses for each node on the IP-852 channel. In our example, node 1/1 will generate a UDP packet, which is sent to node 1/2 at IP address 192.168.1.102. If this packet was sent using acknowledged service, then node 1/2 would send an Acknowledgement packet to node 1/1 at IP address 192.168.1.101 like it would do on a traditional EIA-709 channel except that node 1/2 must now know that the packet must be addressed to the IP address of node 1/1, which is 192.168.1.101. To summarize the above, every node that joins the IP channel must send out its so-called channel routing packet to the configuration server CS, which defines its relationship between CN protocol addresses and IP addresses. Whenever this information changes for a client node on the lP channel, this client node must create a new channel routing packet and send it to the CS, which in turn distributes the new information to all other members on the IP channel.

CN router devices can bridge the gap between traditional EIA-709 networks and IP channels as shown in Figure 53.2. If, for example, node 1 on Subnet 2 wants to send a message to node 1 on Subnet 3, then the router with IP address 192.168.1.103 forwards the packet to the router with IP address 192.168.1.104, which

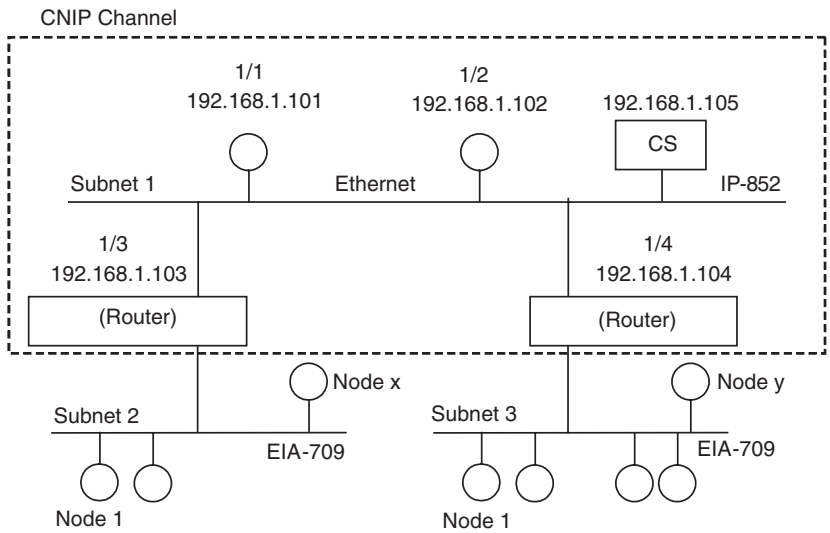

FIGURE 53.2 System components for an IP channel including the IP channel, the configuration server CS, configuration clients called nodes.

© 2005 by CRC Press LLC

forwards the packet to the destination node 1 on Subnet 3. One can see that there is also an IP channel on the communication path between node 1 on Subnet 2 and node 1 on Subnet 3. The source node 1 on Subnet 2 does not even notice this IP channel in between the source and the destination node. As a result, it is now possible to connect different local control networks with IP channels that can either be Intranets or the Internet.

The IP channel can be built- up using different network media that are offering the IP service. Most of the time, 10BaseT or 100BaseT Ethernet networks are used for the IP channel but emerging wireless technologies like 802.11b or 802.11a and Bluetooth, POTS and ISDN lines, cable networks, and fiber optic cables are used as well. This gives existing CN protocols new application areas that could not be satisfied with the traditional technology.

53.4 Data Communication

CN devices exchange CN data packets over the IP channel. This is referred to as data communication to distinguish the traffic from management communication between the CS and the CN devices. There is always a source of a CN data packet and a sink. In the following, we shall refer to a CN device which acts as a source as the sender, to the CN device, which acts as the sink as the receiver. It shall be noted that the sender–receiver relation is only valid in the context of a single data packet or a series of data packets in the same direction. Generally, each CN device acts as a sender and a receiver on the IP channel at the same time.

CN nodes are true sources and sinks of CN data. CN/IP routers are more intermediary devices between the actual sources and sinks of the communication. This detail shall be neglected as the CN/IP routers appear on the IP channel as senders and receivers as well. The diagram in Figure 53.3 shows the functional blocks in the sender and the receiver. When a data packet is generated in the CN node or has to be passed on to the IP channel by a CN/IP router, the sender packs the CN packet in an EIA-852 data packet, adds a sequence number and a timestamp, routes the EIA-852 packet to the appropriate channel members, and finally may collect a bunch of packets before actually sending them on the wire (bunching). The receiver performs the reverse operations: it separates the aggregated packets (debunch), runs them through a sequencer, a stale packet detector, and unpacks the original CN frames. These details are explained in more detail in the following sections.

Encapsulation

The function of packing EIA-709 packets in EIA-852 data packets is referred to as encapsulating. The native EIA-709 packets are encapsulated in UDP frames and routed to the respective CN devices on the IP channel. EIA-852 uses the reserved port number 1628 for EIA-852 communication on CN devices. The configuration server uses port 1629. This makes it possible to combine a configuration server and a CN device on the same system.

The choice of UDP transport over TCP has several advantages: first, because of the connectionless nature of LonWorks communication, it would incur unnecessary overhead to manage connection setup in TCP. Second, TCP ensures delivery through retransmissions. Because of the (soft) real-time requirements

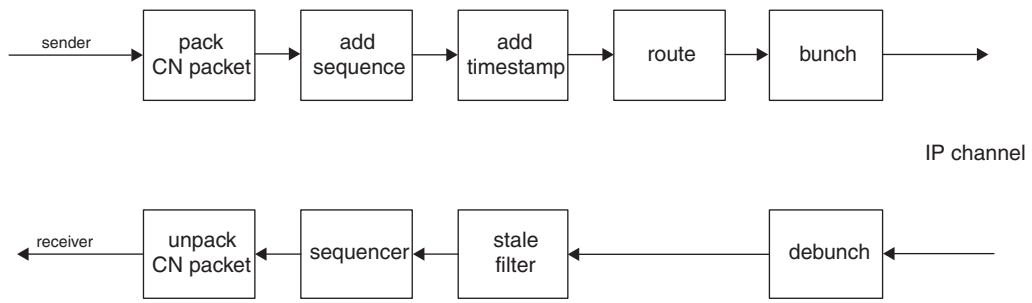

FIGURE 53.3 Functional blocks in EIA-852 data communication: sender and receiver.

© 2005 by CRC Press LLC

of control applications, retransmission will most likely miss the deadlines. Third, the LonWorks protocol implements its own retransmission scheme where necessary.

Figure 53.4 shows the format of the native LonWorks packet format. The preamble bits and the code violation after the CRC are used for bus arbitration and end-of-frame marking on native EIA709 channels. The frame data beginning with the control field up to and including the CRC information are subject to encapsulation. Figure 53.5 shows the EIA-852 common header encapsulation format, which is the payload of a UDP frame. Data fields in EIA-852 packets are defined in network-order, transmitting the most significant byte first. The data packet length specifies the complete length of the EIA-852 packet including the two length bytes. The version number is currently set to 1. The packet type specifies how the EIA-852 payload after the common header is to be interpreted.

An EIA-852 data packet, which encapsulates the CN frame, is of type 0x01. For more packet types, refer to Table 53.1. The extended header size can be used to add more fields to the common header. It specifies them in quantities of 4 bytes. This ensures that the common header is always a multiple of four bytes. The protocol flags define as to, which CN protocol is to be tunneled, for example, 0x00 for LonWorks. The vendor code allows implementors to include their own vendor-specific extensions, which can be transported along with standard EIA-852 messages. The session ID is a 32-bit value that a CN device keeps at random. After a CN device reboots or resets, the session ID must be different from the previous one. The sequence number field is valid for EIA-852 data packets and is used to detect out-of-sequence packets. The timestamp is also used for EIA-852 data messages and is a millisecond value. Therefore, it wraps around every 49 days.

Packet Sequencing

Packet sequencing in EIA-852 is based on the pair session ID and sequence number, which are both part of the EIA-852 common header. An EIA-852 receiver remembers the session ID/sequence number pair for each sending CN device (i.e., for each source IP address). If EIA-852 data packets from a given source are received with the same session ID they are in-sequence, if their sequence numbers are increasing. If data packets get reordered or are dropped on the network, there appear gaps in the sequence numbers. A receiver basically has two choices: (i) continue and drop the missing packets later, or (ii) wait for the missing packets.

If the receiver waits, it has to keep data packets after such a gap in escrow until a defined escrow timeout (ETO). If the missing packets arrive before the timeout, the packets are passed on in their correct sequence. If they do not arrive in time, they will be dropped later. Without escrowing, all out-of-sequence packets are dropped immediately. This may cause unnecessary packet loss on IP channels where packets may get reordered in a small time window.

If the session ID changes, the receiver has to assume that the source has been reset and it accepts the first packet with that new session ID as in-sequence, clearing the sequence numbers from the previous session. This is a design choice of EIA-852 and can cause problems with replay attacks. See the Section on security for more details on this issue.

The ETO is a CN device parameter in most implementations. This time constant has to be considered when designing a control application. It is always a trade-off between unnecessarily losing reordered packets and delaying escrowed packets for too long when packets actually are lost on the IP link. If the ETO is large, more packets can be reordered, because the waiting time for them is longer. For the same reason, if a packet is actually lost on the IP link, the waiting time can approach the ETO in the worst case.

Applications that primarily rely on request/response style communication on LANs should choose a small ETO (e.g., 5 ms) or disable it. Applications that are based on a continuous unidirectional sample stream over a WAN link should choose a large enough ETO. A typical default value on most implementations is 64 ms.

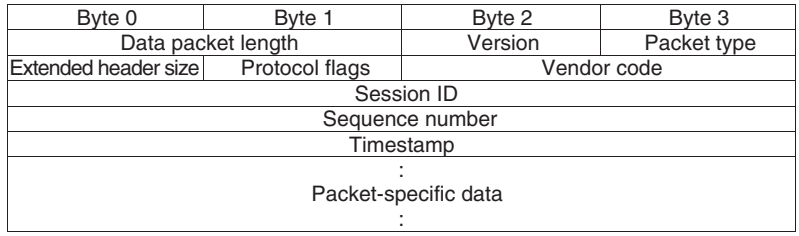

FIGURE 53.5 EIA-852 Common header format.

TABLE 53.1 ETA-852 Packet Types

Packet name	Packet type	Function
Data Packet	0x01	Encapsulates the the CN frame.
Device Configuration Request(DC-REQ)	0x63	Request a DC from the CN device.
Device Registration (DEVREG)	0x03	Device registers with the CS.
Device Configuration (DC)	0x71	DC requested firm the device or unsolicited DC sent by the CS.
Channel List Request (REQ-CM)	0x64	Device requests CM from the CS.
Channel List (CM)	0x04	The CS responds with the CM.
Send List Request (REQ-SL)	0x66	Request the send list from the CS.
Send List (SL)	0x06	The CS responds with the send list.
Channel Routing Request (REQ-CR)	0x68	The CN device requests a CR from the CS for a specific member.
Chancel Routing Packet (CR)	0x08	The CS responds to a CR request.
Acknowledge (ACK)	0x07	Acknowledgment message from device or CS.
Segment (SEG)	0x7F	Segment of a large data structure.
Statistic Request (REQ-STAT)	0x60	Request statistics from a CN device.
Statistic Response (STAT)	0x70	CN device responds with statistic data.

Packet Aggregation

The native message sizes of typical CN traffic are small, around 10 to 20 bytes in LonWorks. Encapsulating each CN packet into a UDP frame adds the UDP, IP, and Ethernet headers (or other media specific headers), which account for more than 40 bytes. This incurs unnecessary overhead, which may lead to noticeable performance problems on embedded implementations. Those systems typically suffer from an IP transmission bottleneck.

A technique to reduce this overhead is to aggregate more than one EIA-852 data packet in a single UDP frame (packet bunching). Clearly, the more packets are bunched, the less per-CN packet overhead is added by the encapsulation. When aggregated, EIA-852 data messages are concatenated in the UDP frame. The UDP packet is then transmitted to the destination IP address. Therefore, messages can only be aggregated when they share the same destination. The sender may thus be configured to keep data packets and aggregate them until an aggregation timeout (ATO) before sending the UDP frame on the IP link. The ATO value is a CN device parameter in most implementations.

The effect of packet bunching has to be considered in the control application design. There is a trade-off between overhead reduction and extra delay, In the worst case an EIA-852 data packet is delayed for the full ATO until it finally gets on the wire. For highly responsive applications with low packet rates on LANs packet bunching should be disabled. For applications with high packet rates over WANs packet bunching should be enabled. A typical default value in most implementations is 16 ms.

Stale Packet Detection

One of the major issues on EIA-852 channels are packet delays on the IP link. They can be highly random with a large standard deviation on wide area IP links [17,18]. There are two problems with this: (i) the

© 2005 by CRC Press LLC

control application may miss some of its deadlines, and (ii) the CN protocol may break if packets are received after they are delayed too long. For example, the LonWorks duplicate detection mechanism is sensitive to high delay variance on the network. While the first problem must be solved by carefully designing the control application [10], the second problem can be eliminated by discarding packets that are delayed beyond a certain time limit (stale packets). The mechanism is called stale packet detection and is based on one-way packet delay measurements. In order to make such measurements, CN devices must synchronize their clocks. Clock synchronization in EIA-852 is performed via SNTP [21]. The sender generates a millisecond timestamp and puts it into the EIA-852 common header. If its measured delay exceeds the channel timeout (CTO), the packet is called a stale packet and the receiver discards it in the stale packet filter.

The CTO is a channel parameter and distributed among the CN devices. Applications on LANs can disable stale packet detection because the delay variance it typically very low and comparable with native LonWorks channels. On WAN links, it is recommended to enable the CTO. Typical values are the average ping delay on the IP channel plus aggregation timeout. The lower bound of the CTO is restricted by the resolution of the clock synchronization. On certain systems (e.g., Windows), the resolution may drop to 50 ms. Practical CTO values start at 200 ms. If certain CN devices are Windows implementations, it must be ensured that the Windows system clock is synchronized. Dropped packets due to stale packet detection can be observed in the ETA-852 statistics of stale packets; see Table 53.2. Stale packet filtering also plays an important role in the context of security. Refer to the Section on security for more details.

EIA-852 Data Packet Routing

One of the EIA-852 CN device tasks is to route EIA-852 data packets to the appropriate IP channel members. In this context, it is important to notice that each channel member is associated with an IP address. If a given CN data packet needs to be routed to multiple IP addresses, it is copied into several EIA-852 data packets, each sent to one of the selected CN devices on the channel. It shall be noted that sequence numbers are associated per destination address. If CN data packets are routed to different IP addresses, the sequence numbers need not necessarily be the same among all destinations. This stems from the fact that some messages are routed to a specific destination and some are not.

Depending on the available channel data, three variants of routing the CN data packets are possible:

1. *Send List Routing*: A send list (SL) is an optimized list of IP addresses to reach all channel members. Typically, SLs are used when IP multicast addresses are assigned to groups of channel members. In

TABLE 53.2 EIA-852 Statistics Data

Data	Explanation
Seconds since cleared	Number of seconds since the statistics have been reset.
Date/Time of clear (GMT)	Date and time when the statistics have been reset.
No. of members	Current number of channel members.
LT Packets received	CN packets received from LonWorks.
LT packets sent	CN packets sent to LonWorks.
IP Packets sent	CN packets sent onto the IP channel.
IP Bytes sent	Aggregate number of bytes in CN packets sent onto the IP channel.
IP Packets received	Number of CN packets received from the IP channel.
IP Bytes received	Aggregate number of bytes in CN packets received from the IP channel.
LT Stale Packets	Number of packets dropped because they are stale.
RFC Packets sent	Number of management data packets sent to the CS.
RFC Packets received	Number of management data packets received from the CS.
Avg. aggregation to lP	Average aggregation of transmitted CN packets on the IP channel.
Avg. aggregation from IP	Average aggregation of received CN packets from the IP channel.
UDP Packets sent	Total number of UDP packets sent (including both data and management).
Multicast Packets sent	Total number of multi-cast packets sent (only for send lists).

© 2005 by CRC Press LLC

the best case, all channel members are in the same IP multicast group. In this case, the SL contains this one multicast address. CN devices send EIA-852 data packets to all destinations in the SL.

2. *Channel Routing*: Channel routing is used when only unicast IP addresses are available. The basic idea is to select those destination IP addresses that will accept the packet based on the LonWorks address information. To advertise which LonWorks addresses a CN device accepts, it publishes channel routing (CR) information to the other channel members. Each channel member collects all the available CR and can route outgoing CN data packets in an optimized way. It shall be noted that with CR, all data packets have to be copied multiple times if there are multiple advertised recipients. Especially for large groups and broadcast addresses, send lists appear much more efficient. For S/N or NID) addressed packets, CR is beneficial because the packets are routed to a single unicast address only, not burdening other CN devices with packets that they do not want.
3. *Brute Force*: Neither SL nor CR information is available. The CN device resorts to the channel list and transmits every data packet to all channel members using unicast addresses. This mode is the least efficient.

The CR algorithm is based on the CR information provided by the CN devices on the channel. The CR information for each channel member contains the following fields:

- The CN device IP address and port
- The CN broadcast flag
- The CN device type (router, node, IPIP router, proxy)
- The CN router mode (configured, bridge, repeater)
- A list of node IDs
- A list of S/N addresses
- A list of domain items (including subnet and group forwarding flags).

The domain items deserve a more thorough discussion. First, they contain a domain number. Then, they specify forwarding flags for both subnets and groups. If the *n*th subnet flag is set, the CN device accepts all packets destined for subnet *n*. If the *m*th group flag is set, the CN device accepts all group packets for group *m*. CN routers need to specify the subnet and group forwarding flags, while CN nodes only specify the group flags. This is because CN nodes do not forward any packets, but they can be members of multiple groups.

Figure 53.7 summarizes the CR algorithm implemented in most CN/IP router implementations. The CR algorithm iterates over all channel member CR information for each EIA-852 data packet. § I checks the CN broadcast flag and routes all packets if the router type is a repeater and it has at least one domain item. The CN broadcast flag is set when the channel member is unconfigured and does not yet have a valid domain. Otherwise, those devices could not be reached over the IP channel by broadcasts.

Leaving the special case of unconfigured CN devices aside, there are two types of devices on a channel: (i) CN nodes accept only CN packets addressed to them (e.g., their subnet/node address, their NID, their group), (ii) CN router, which forward packets to other channels behind them. The CR algorithm therefore distinguished those two cases (Figure 53.7).

In § II, the packet is routed by looking at the channel member as a CN router (e.g., configured router, bridge). This step only regards the domain items in the CR information. Therefore, a forwarding device must define at least one domain item in its CR information. § II(i) skips the channel routing for a certain domain item if the domain does not match. § II(ii) is responsible for forwarding group addressed messages if the corresponding group forwarding flag is set in the domain item. § II(iii) checks the destination subnet part for S/N, NID, and broadcast-addressed messages. If they are domain-wide (i.e., subnet equals "0"), the message is forwarded. Otherwise, those messages are only forwarded in § II(iv) if the corresponding subnet forwarding flag is set in the domain. item. As a consequence, CN routers must supply domain items for all domains they need to receive packets in.

In § III, the message is routed by looking at the channel member as a CN node on the IP channel. The IP channel is assigned a separate individual subnet number, and all nodes on that channel get their individual node numbers. Therefore, devices that represent nodes on the IP channel must supply at least one

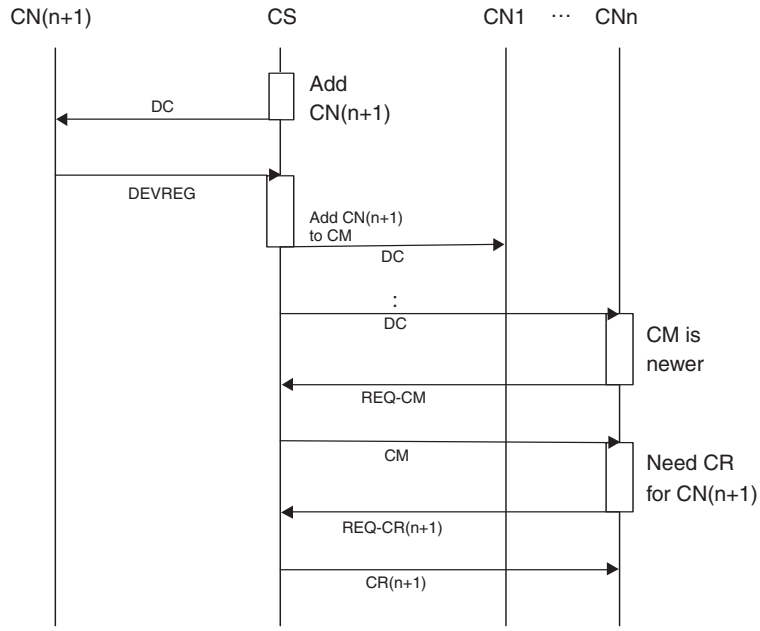

FIGURE 53.6 CS configuration data distribution.

I. If (CN broadcast flag is set and address == FMT_BCAST) or (router type == REPEATER and there is a domain item) then route to member.

II. Route to CN router

  (i) If domain is incorrect skip to III.

  (ii) If address == FMT_GROUP and group forward flag is set for GROUP route to member.

  (iii) If SUBNET == 0 route to member.

  (iv) If subnet forward flag is set for SUBNET route to member.

III. Route to CN device

  (i) If address == NID and NID matches route to member.

  (ii) If DOMAIN does not match skip to IV.

  (iii) If address == FMT_SN and S/N item matches route to member.

  (iv) If address == FMT_BCAST and SUBNET == 0 route to member

  (v) If address == FMT_BCAST and SUBNET matches S/N item route to member.

IV. Go to next member CR information.

FIGURE 53.7 Channel routing algorithm.

S/N, one NID, and one domain entry in their CR information. § III(i) checks if an NID addressed message matches with one of the NID items in the member CR information. If the NID matches, the message is forwarded to that member not regarding the domain. Therefore, unconfigured nodes on the IP

© 2005 by CRC Press LLC

channel can be reached via NID addressed messages. For all other messages, § III(ii) checks if the domain matches with one domain item. If it does not, the algorithm skips to § IV. In § III(iii) S/N addressed messages are routed to the member if they match one of the S/N entries. § III(iv) routes all domain-wide broadcasts to a node on the IP channel. § III(v) routes all subnet broadcasts to the channel member if one of its S/N items has a matching subnet number. §IV iterates to the next member in the channel until the CR algorithm has gone through all channel members.

The CR mechanism has the following consequences for CN devices regarding the CR they must provide:

- Unconfigured channel members must set the CN broadcast flag in order to get configured by LonWorks network management tools such as LonMaker.
- CN routers (configured router, bridges, etc.) must provide corresponding domain items in the CR for all domains they want to exchange packets in.
- CN nodes must provide corresponding S/N, NID, and domain items.

53.5 Management

Apart from data communication, a large part of the EIA-852 functionality is used for the management of IP channels. Management functions include access control on which CN devices can be a member of a specific IP channel, configuration of individual CN devices, distributing information between CN devices, and retrieving statistics information about CN devices.

The EIA-852 management concept is based on a client/server model. A configuration server (CS) is the central part in the system, which is responsible for managing an IP channel. CN devices act as configuration clients (CCs) and request data structures from the CS. The CS only actively sends the device configuration (DC) to CN devices, if the IP channel has been updated and it needs to announce that change. Therefore, the DC is an unsolicited message from the CS. If no channel changes are pending, the CN devices can operate without a CS. As soon as the IP channel needs to be updated, for example, a CN device is added or recommissioned, the CS must be available again to distribute the change.

The management data structures are the per-device DC, a channel membership list (CM) specifying the members on the IP channel, an SL for SL routing that is optional, and a per-device CR information . All management data in EIA-852 are versioned. The version is a 32-bit value, which increases for newer versions. The version is usually date and time information in NTP second format, which may or may not be synchronized to UTC. Hence, the version is called datetime and is nonzero for valid data structures. Local data structures are checked against published datetime versions and requested if newer data are available. The CM, SL, and per-device DC are versioned by the CS, whereas the CR data are versioned by the individual CN devices.

The CN devices, which constitute the IP channel, are defined in the channel list on the CS. Each CN device is uniquely identified by its IP address in the channel list. An important restriction in EIA-852 is that there cannot be two CN devices on a channel, which share the same IP address but have different IP ports.

Each CN device in the channel list is configured by a DC. The DC is entered on the CS, for example, through a serial console or a web interface. The following information needs to be supplied, in order to add a CN device to an IP channel:

- IP address and port of the CN device
- Name of the CN device (typically 15 characters)

This message flow when adding or configuring a CN device is depicted in Figure 53.6. The CS adds a CN device to the channel by sending an updated and unsolicited DC message to the device. Once a CN device is added or has accepted a new configuration, it registers with the CS by sending a device registration (DEVREG). Knowing the channel is updated, the CS sends a new unsolicited DC to all the other members to announce the channel update. The other CN devices in turn request the updated data structures from the CS, starting to request the channel list (REQ-CM). If the CN device finds out that the CM advertises new CR information for certain members, it requests them from the CS (REQ-CR) one by one.

© 2005 by CRC Press LLC

If a CN device is not available when it is added on the CS, it is usually marked as "unregistered" in the channel list. In this case, the CS tries to recontact the CN device using an exponential back-off for the retry interval. It starts at one second, doubles each time, and is limited by 32 sec. As a consequence, it may take up to 32 sec for a device to become functional on the IP channel when it was not reachable at the time of adding it. CS implementations usually display CN devices, which have registered successfully, as "registered." If a device has been registered once, but is not responding to a channel update, a CS may display it as "not responding." The operator can then take appropriate action for those devices.

Access control on the CS is also defined through the channel list. If a CN device tries to register with a CS that does not include this particular device in its channel list, the CN device is rejected from the IP channel. Rejected CN devices cannot send or receive CN packets over the IP channel and usually indicate this condition as an error, for example, a red status LED. Some CS implementations collect information about those CN devices in a so-called orphan list. The operator can then select an orphan device and add it manually to a given IP channel.

An important part of EIA-852 is the routing of CN packets to the correct CN devices over the IP network. As described in the previous section, there are two possibilities: (i) creating an SL, or (ii) distributing CR information. The CS generates the SL by looking at the IP address information in the channel list. By appropriately grouping IP multicast addresses and unicast addresses, the SL typically becomes much shorter than the channel list. The SL is also versioned and distributed to the CN devices by sending an updated DC to the members.

The other possibility is to distribute CR information. The CR, however, does not originate at the CS but at the individual CN devices because they are commissioned and only they have knowledge of their CN address information. Each CN device sends a CR update to the CS if its CR changes. The CS in turn generates a new channel list, which reflects the updated CR datetime version of the device. The other devices will request the new channel list and discover that a specific device has a new CR. The other devices then request this CR from the CS as described before. If more than one CR information has changed, the CN devices request all newer CR data from the CS. This is an important detail, because CN devices never request the new CR from the original device directly. As an implication, the CS must be available, when any CN device is recommissioned.

The management part of EIA-852 also defines a statistics information structure. This structure can be requested outside of the client/server model. Any CN device or the CS can request the statistic information from a CN device. The statistic data supplied are listed in Table 53.2.

53.6 Security

Security is a growing area of concern on IP networks. This also includes EIA-852 traffic. While native LonWorks channels are local (e.g., to a building) and can be accessed only locally, IP channels are established on an open media that may even span across WAN links. Typical security issues are privacy, authenticity, and integrity [19,20]. Security measures defined in EIA-852 refer to the problem of authenticity only. They assure that a received data packet is actually sent by an authentic channel member and not by an attacker.

The principle is based on secure message authentication codes and a shared secret. The secure hash function algorithm MD5 [22] is used to create a unique fingerprint of an EIA-852 message. A Secret key is included in the fingerprint calculation, which is not transmitted over the wire. The receiver can perform the same calculation, supplying its own copy of the secret key and compare the hash codes. If they match, the message is authentic.

The MD5 hash is transmitted right after the EIA-852 message. Its fixed length is 128 bits and is not included in the EIA-852 packet size field. Instead, channel members are configured for secure operation (MD5 mode) and expect the extra 128 bits after each EIA-852 packet. This is especially important for bunched UDP frames. If packets are bunched, the next EIA-852 message follows the MD5 hash.

The calculation principle is depicted in Figure 53.8. The MD5 hash following the EIA-852 message it set to zero (MBZ). The MD5 algorithm is run over the EIA-852 message, the zero hash placeholder, and the 128-bit shared secret. The calculated hash value is copied into the placeholder and the message is

© 2005 by CRC Press LLC

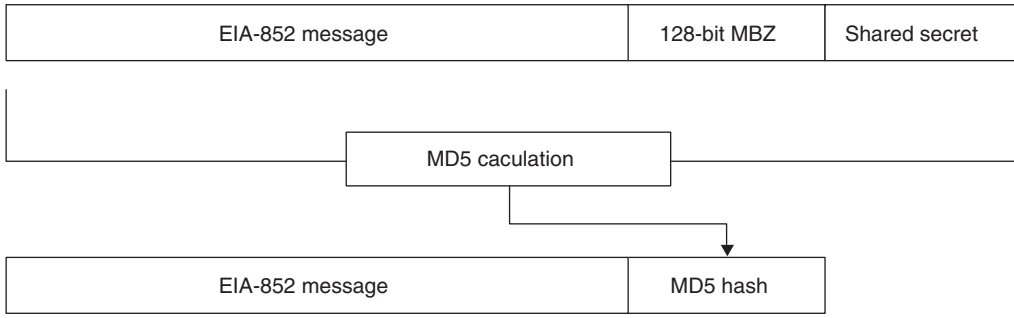

FIGURE 53.8 MD5 authentication of EIA-852 packets.

transmitted excluding the shared secret. The receiver performs the same calculation. It just saves the MD5 hash and then sets it to zero before calculating the MD5 hash locally. If the saved and the locally computed hash values match, the message contents are authentic.

To prevent replay attacks, stale packet detection must be enabled. The reason for this is the sequencing algorithm in EIA-852. An attacker may record a sequence of authenticated messages known to trigger a specific action. These messages will share a common session ID. At a later point in time, the CN device may have chosen a different session ID (e.g., after a power outage). In this moment, the recorded sequence can be replayed successfully because the CN device would accept the old session ID as a new one and start over with counting the sequence numbers. Stale packet detection solves this problem because the EIA-852 messages also include timestamps. Since the CN devices are synchronized to UTC, a playback at a later time is not possible. The CN devices would drop those packets as stale packets.

Another security aspect in modern networks are firewalls and network address translators (NAT). Firewalls in principle only filter traffic. Therefore, CN devices can be operated behind a firewall if the filter rules are set accordingly, namely allowing UDP traffic on ports 1628 and 1629 to pass.

The case with NAT routers is different. NATs actually alter IP addresses and port numbers. This is a problem for EIA-852 because channel members on the IP channel are uniquely identified by their IP address. If that address is changed in the public realm, they could not be part of the IP channel. Some implementations of CN/IP routers therefore allow for a special NAT mode (e.g., the L-IP by LOYTEC). In this mode, a CN device is configured with the public address of its NAT router. It represents this public address in its DC and other members will see its public address in the channel list and CR information. The NAT itself must be configured with a port-forwarding rule to route all EIA-852 packets from the public interface to the CN device in the private realm. Figure 53.9 illustrates this setup. NAT1 contains a port-forwarding rule to route all packets it receives at IP address 80.41.6.3 on ports 1628 and 1629 to the private IP address 192.168.1.250 on the respective ports.

The drawback of the current solution is that only one CN device per IP channel can be operated behind a NAT. This is because there would be only one public IP address visible for multiple private CN devices. This violates the rule that each CN device must have a unique IP address in the channel list. System designers have to split the IP channels if they want to operate more CN devices in the private realm. Figure 53.10 shows a possible solution where one IP channel is established over the public realm having one CN device behind each NAT. The CN device can be either an IP/IP router or two back-to-back CN/IP routers to transfer the CN packets to the private IP channel. In any case, NAT configurations require a careful and handcrafted configuration on the NAT routers.

53.7 Applications

So far, we have learned what the new IP tunneling technology following the ANSI/EIA-852 standard can do in theory. Here, we show the application scenarios that utilize this new technology. We have seen that it is possible to connect CNs via Intranets and this is exactly what is starting to emerge in larger buildings.

Typically, office buildings do have a sophisticated IP infrastructure; therefore, it is beneficial to utilize this IP infrastructure for services other than PC networking. As shown in Figure 53.11 CN to IP routers like the L-IP from www.loytec.com can utilize the existing IP infrastructure to form a high-speed backbone network in order to connect the control networks on the different floors. This setup allows transparent communication between offices on different floors and to a central SCADA system using the IP backbone.

Another steadily growing application area is internetworking between different buildings that are either connected via an Intranet or the Internet. Once the building infrastructure is "on-line," it is only a small step to remote facility management and remote maintenance. Figure 53.12 shows a typical scenario regarding how building complexes are networked to form one large CN. A management PC connected anywhere to the network allows remote network maintenance, remote trending, alarming, logging, and preventive system repairs.

Another advantage, which was initially not quite obvious, is the fact that network management tools and network-troubleshooting tools can be used together with the new IP technology. This means that thousands of installers and system integrators that have been trained over the past 10 years will use this knowledge with a little bit of additional training to install networks that span Intranets and the Internet.

Once the CN is able to use the IP service as a transport media, modern wireless technologies can be utilized to create new application areas. One can, for example, walk around a building with a wireless PDA and control the building infrastructure such as lighting, heating, AC, blinds, and even carry out network maintenance tasks on the spot by himself. It is now possible to monitor and control remote wastewater pump stations that are connected to the control center via an RF link.

53.8 Conclusion

The world is getting more and more connected and one of the driving factors is the Internet Protocol (IP). Connecting PCs to the Internet was the hype of the 1990s, connecting everyday devices to the

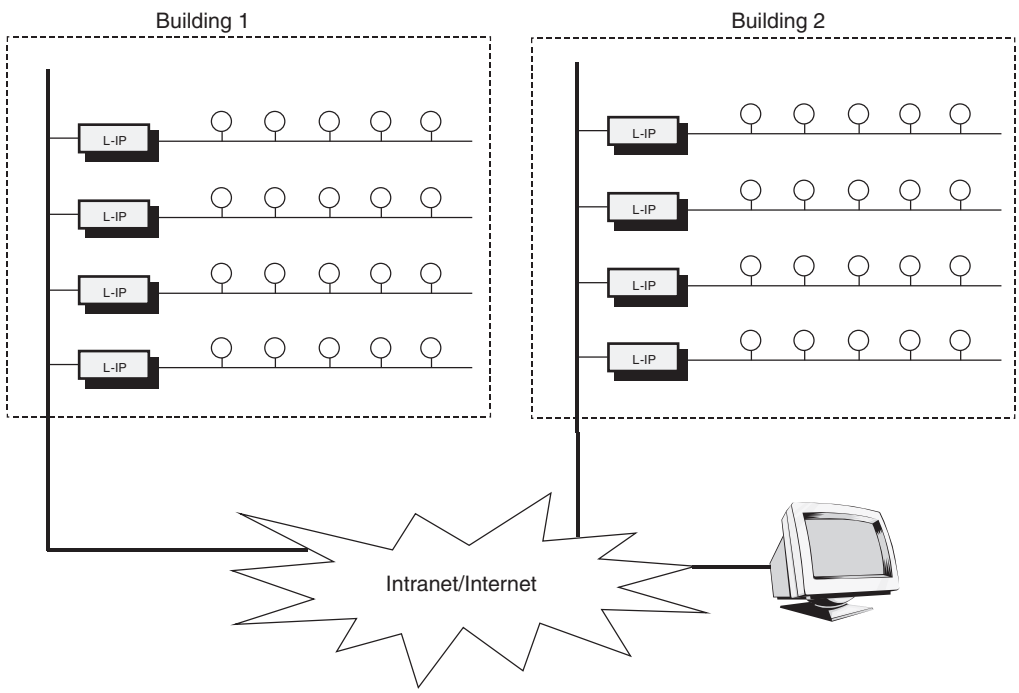

FIGURE 53.12 Connecting different buildings over an Intranet or the Internet allows transparent communication of CN data between nodes on either network.

© 2005 by CRC Press LLC

Internet is the challenge of the new millennium. The groundwork has been done to provide technologies that will satisfy those demands. It is now a matter of time until your bathroom fan can be controlled from your cell phone. In the meantime, facility managers are concentrating on applications that are saving money, protecting environmental resources, and improving the reliability of the network.

We have shown that existing CN protocols have by far not reached the end of their lifecycle, but experience a revival by the push of the IP technology.

Jean-Dominique Decotignie
CSEM (Centre Suisse d'Electronique et de Microtechnique)

54.1 Introduction

Networking at the factory floor is now commonplace. Solutions are available at different levels: sensory, cell, plant, etc. In this chapter, we focus on the sensory level where networks usually called fieldbuses (Pleinevaux and Decotignie, 1988) link sensors and actuators to the first level of automation. This kind of network is no longer exclusive of factories and finds its way into cars, planes, and buildings.

Since the first solutions were designed in the early 1980s, a number of proposals have flourished and the field is well established both in terms of research and industrial use. Most solutions use wired transmission (twisted pairs, coaxial cables, optical fibers). Very early, the need for mobile nodes and the difficulty in installing cables have pushed for wireless solutions based on radio or light transmission. Today, most solutions use radio transmission. Due to the special properties of wireless transmission, it is not desirable to have all nodes of the fieldbus as wireless. On the other hand, the wired devices need to communicate with the wireless nodes thus prompting the necessity for interconnection means. However, the differences between the properties of wired and wireless transmissions introduce constraints in this interconnection. This is even exacerbated by the special requirements put on fieldbuses.

© 2005 by CRC Press LLC

The chapter is organized as follows. Section 54.2 gives some definitions that will be used in the sequel of the paper. It also explains the relevant properties of wireless transmission. Section 54.3 details the different interconnecting mechanisms that can be used. Section 54.4 presents the different architectural options that are used when designing an interconnection architecture. Section 54.5 details how the various options are used in the different proposals and the associated difficulties. Section 54.6 uses the model to derive solutions that were not yet proposed, and discusses their applicability. Some conclusions and possible future work are given in the last section.

54.2 Context and definitions

As mentioned above, this chapter concentrates on field-level devices that communicate through a mix of wireless and wireline transmission. Although this is a very important topic, in this chapter, we do not consider the issue of power consumption in the wireless nodes.

Fieldbus Requirements

Requirements for fieldbuses are numerous and cover all the lifecycle activities. We restrict ourselves here to those properties that are particularly relevant for the interconnection (for a detailed explanation, the reader is referred to the chapter entitled "Which network for which application" in the present book):

- handle periodic traffic with different period durations. In many fieldbus solutions, this requirement is translated into some cyclic traffic. The real need it to be able to transport the information well before the end of the period at which the data have been sampled;
- handle sporadic traffic with bounded latency;
- allow for quasisimultaneous sampling of a number of inputs on different network nodes;
- provide an indication for temporal consistency. The fact is that control or acquisition systems expect that different sensed values correspond to sampling instants that should be within a few percent of the sampling period. The network should hence provide ways to know if a set of values exhibits this property, named relative temporal consistency. Sometimes the age (time elapsed since sampling) of a data, also called absolute temporal consistency (Kopetz, 1988), is also important to its users;
- for sporadic traffic, provide ways to know the order in which events have occurred. An application will take different decisions depending on the order in which events have occurred. As the events are potentially detected on different nodes of the network, there should be a way to find out the order;
- transfer data from one node to another or one node to a number of others; and
- rugged solutions in terms of resistance to interference, vibrations, etc.

It is important to notice the special temporal requirement, which will have a direct effect on the interconnection.

Important Radio Transmission Properties

Wireless transmissions come in two main categories: radio- and light-based systems. They both exhibit characteristics that make them very different from cable-based transmission.

For radio transmission, the main properties are as follows:

Property 1: Compared to cables, radio transmissions suffer from bit error rates (BER) that are some orders of magnitude higher. BER of 10^{-3} to 10^{-4} are usual, whereas in cables one may expect BER ranging from 10^{-7} to 10^{-9}. Error detection schemes should hence be enhanced accordingly. This is especially a concern for token-based systems because the token recovery takes quite a long time compared to the temporal constraints.

Property 2: Spatial reuse is low as spectrum is limited. This means that coexistence of several systems in the same area should be either planned (code or frequency allocation) or the medium access control should be designed in a way that takes care of the interference between systems.

© 2005 by CRC Press LLC

Property 3: Perturbing systems can easily jam radio transmission. This is especially true in the ISM (instrument, scientific, and medical) bands. For instance, in the 2.4 GHz band, high-power medical devices are allowed. They may completely suppress all communications for long periods of time.

Property 4: Transmission distances are smaller. Typical ranges are a few tens of meters indoors and up to 300 m outdoors. Obstacles may further limit this distance.

Property 5: Collisions cannot be detected while emitting. The power of remote emitters is much lower than the power of the transmitter emission that masks the others.

Property 6: A transceiver needs a longer time (up to a few milliseconds) to switch from emission to reception and vice versa. This has to be taken into account when designing the protocol. In particular, protocols that require immediate answers to incoming requests cannot be used.

Property 7: Radio transmissions suffer from frequency-selective multipath fading. Waves may follow different paths that interfere destructively at the receiver site. Communication may be impossible at some points.

Optical waves may be used as an alternative to radio transmission. Here, we will restrict the discussion to infrared transmission as it is the most commonly used. Its special properties are as follows:

Property 8: Transmission operates only in the line of sight. An emitter and a receiver should have direct visibility. This constraint is often relaxed by using satellite-like techniques. A special device that acts as a repeater is located in a place where it "sees" all the other devices. This location is often on the ceiling of the room, thus named satellite. Communication may, however, be impossible at some points.

Property 9: Sources of heat (sun, machines, heaters, etc.) interfere with transmission and induce errors.

Property 10: Spectrum reuse is limited as all systems share the same wavelength.

As a summary, wireless transmission means exhibit properties that are significantly different from those of wires. This will have an impact on the solutions that can be used to interconnect wired and wireless nodes.

Definitions

In order to clarify the different architectural options, it is useful to define some terms:

Data circuit (ISO/IEC 7498:1: 1996) — "a common path in the physical media for OSI among two or more physical entities together with the facilities necessary in the physical layer for the transmission of bits on it."

Subnetwork (ISO/IEC 7498:1: 1996) — "an abstraction of a real subnetwork."

A real subnetwork (ISO/IEC 7498:1: 1996) — "a collection of equipments and physical media which form an autonomous whole and which can be used to interconnect real systems for the purpose of data transfers."

Data link (ISO/IEC 8802:2: 1998) — "an assembly of two or more terminal installations and the interconnecting communication channel operating according to a particular method that permit information to be exchanged. In this context, the term terminal installation does not include the data source and the data sink."

LAN — a data link using the same physical layer and medium access control protocols.

Segment — synonymous to data circuit when the nodes are connected through wires.

Cell — synonymous to data circuit but in the case of wireless medium.

54.3 Interconnection means

Generally speaking, networks may be interconnected in various ways, repeaters, bridges, routers, and gateways (Perlman, 2000).

Repeaters

Repeaters operate above the physical layer. Conventionally, they work bit-by-bit receiving the input signal, regenerating the signal, and emitting it on the other side. In the last decade, we have seen the blossoming of repeaters with multiple ports that are called hubs (Ethernet, USB). In the context of wireline to wireless (or vice versa) repeaters, this may imply changing the encoding scheme (i.e., NRZI to Manchester). However, theoretically, repeaters operate transparently to the protocols above the physical layer.

As wireless transmission is more error-prone than transmission on cables, a different kind of repeater may be designed, (Morel, 1996) namely a word repeater. Instead of repeating the incoming signal bit by

© 2005 by CRC Press LLC

bit (bit repeater), the word repeater waits until a number of bits have been received from the wired side, calculates a forward error correction code (FEC), and transmits the bits together with the error correction code. A different modulation scheme (for instance, spread spectrum) may be used to improve the spectral efficiency or the robustness. When receiving from the wireless side, the word repeater receives uses the FEC code to correct possible errors and retransmits the (possibly) corrected information bits to the wire side. This kind of repeater introduces a longer delay, although shorter than the delay of a bridge, a router, or a gateway. It reduces the error rate on the wireless side and brings it closer to the wired side bit error rate (Morel, 1996).

Some practical considerations limit the use of repeaters. Repeaters should, in principle, forward what comes from on port to the other port and vice versa. This would be possible with full duplex lines with on line for each direction of transfer. However, all popular wireline fieldbuses use a single line for both directions (half duplex). The repeater must hence switch from one direction to the other one according to the flow of data. This may be performed using additional lines but is not practical. In practice, wireline repeaters use some mechanism to sense the direction of travel (Murdock and Goldie, 1989) and autonomously switch accordingly. When an incoming signal is sensed on one side, the repeater is switched so that the signal is regenerated and emitted on the other side. The opposite happens when the signal is sensed on the other side. When signals are sensed on both sides, the repeater is put in isolation mode. This behavior is adequate as long as the medium access control does not rely on collisions. In such a case, when a signal is sensed on both sides, the repeater must emit a jamming signal on both sides so that the collision can be detected on both sides. It must also send this jamming signal on the input port when, after switching to one direction of travel, it senses a collision on the output port. A repeater is thus not completely independent of the medium access control scheme used in the overlying network.

Using radio communications on one side of the repeater does not change this picture much unless the medium access control uses contention. Remember that collisions cannot be detected directly on the wireless side (property 5). The repeater thus has no means to detect the collision and propagate it on the other side (assumed to be wired). This precludes the use of protocols exclusively based on collisions. Property 6 will also lengthen the delay incurred in the repeater.

It is important to notice that, if the bit rate is different on both sides of a repeater, the repeater must buffer the information. As repeaters are usually bi-directional, the buffering policy will differ from one direction to the other. Let us assume that the bit rate is higher on side A than on side B. As soon as information is received from side A, emission may start on side B. However, bits are emitted more slowly on side B and the repeater must buffer the incoming bits before they can be emitted on side B. Conversely, when something is received from side B, the repeater cannot start relaying the information on side A immediately. It must wait until a sufficient number of bits has been received to emit the complete packet at the A side bit rate. This means that the repeater must know the maximum size of a packet.

Bridges

A bridge is a data link layer relay. A bridge receives a complete MAC or LLC frame, checks it, and possibly forwards it on the other side. Contrary to repeaters, bridges filter the information that is relayed from one LAN to another. The different types of interconnected LANs lead to various categories of bridges (Varghese and Perlman, 1990):

- passthrough bridges can be used when the LANs on both sides offer identical data link layer functions and addressing. The frames can then be passed unchanged. Ethernet Switches are a recent example of this category of bridges;
- translation bridges are used when both LANs have data link-layer function and addressing that are sufficiently similar to allow a direct translation of data link-layer PDUs;
- encapsulation (or tunneling) bridges may be used when the translation is not possible. An incoming frame is encapsulated in the data link layer format on the other link before being forwarded. This is the kind of bridge used when two, or more, LANs of identical technology need to be interconnected through another one of a different kind.

© 2005 by CRC Press LLC

A bridge participates as a node in each of the LANs it interconnects. It receives a copy of all frames transmitted on each one. Obviously, not all frames need to be relayed. For instance, a frame received on side A, whose destination is also on side A, does not need to be relayed on side B. The bridge thus has to learn which frames should be relayed and which ones should not. In particular, special care should be taken to avoid frame looping when several paths exist between two nodes that communicate (ISO/IEC 7498:1: 1996).

Routers

Routers operate at the network layer level. The main difference between bridges and routers is that the latter are not transparent. Routers modify the packets they forward, in particular, their address fields. Routers exchange information between themselves in order to find a route on which the packet is conveyed. They can thus find an optimum path between two nodes, whereas bridges only use a subset of the available topology. As the network layer is most of the time absent in fieldbuses, we will not deal with this case further.

Gateways

Gateways relay the information on top of the application layer. When a gateway node receives some application service indication, it converts it in a serviced request on the other LAN on which it is connected. When the corresponding confirmation is received, it transforms it in a reply on the other side. Depending on the available services, an invocation may correspond to more than one request. Similarly, the reply may be constructed from a number of confirmations.

In order to overcome the additional delay in the reply to an indication on the LAN on one side, some gateway may make requests on the other side in advance. This is especially true in fieldbuses where the gateway may keep an image of all inputs on one side so that, when a read indication is received on the other side, the cached value is returned in the response. We shall refer this kind of gateways as proxy gateways.

54.4 Major Design Alternatives

If the interconnection mean is the prime choice, there are other degrees of freedom in the architecture of a mixed wired/wireless network.

Single vs. multiple wireline segments: The wireline portion of the system may be composed of a single fieldbus segment on which all the devices are hooked. It may be made of several segments that need to be interconnected.

S*ingle vs. multiple wireless cells*: As in the previous case, the nodes that are connected through wireless means may be organized in a single cell or multiple cells.

Separate or integrated wireless and wireline subnetworks: In the first case, the various nodes connected through wireless means form a single subnetwork that is interconnected to the wireline network at some points. This is very similar to the integration of the GSM network and the telephone system. The other solution is to have one or more subnetworks in which wireless and wired nodes are mixed.

Single point or multiple points of interconnection: The interconnection between wireless and wireline transmission can be done at a single point or at a number of points.

Ad-hoc, single base station or multiple base stations for the wireless subnetwork: In the first case, all nodes cooperate without any one playing a role different from the others. In the second option, a single node acts as a coordinator for the traffic between the various wireless nodes. A third one is to have a number of these stations. Another option is whether the base station is the node that serves as an interconnection point.

Wireless networks vary along other parameters such as:

Total or partial interconnection: All wireless nodes can see each other when total interconnection is achieved.

Multiple hops or single hop: In case of multiple hops, traffic from a node addressed to a node that cannot be seen (beyond transmission range) is routed by other nodes to the destination.

© 2005 by CRC Press LLC

Satellite: The absence of full visibility can be compensated by a satellite node that retransmits all the emissions from the nodes at a different frequency. This is equivalent to a network of mobile nodes using a satellite to relay the communications.

However, we believe that these additional parameters are not prime parameters in an architectural model. We shall not consider them further.

Although a given interconnection solution is a combination of these options, not all combinations lead to a feasible system. For instance, a wireless cell (data circuit) and a wired segment cannot be interconnected through more than a single repeater per cell. In the next paragraph, we will detail and discuss a number of proposals. When available, relevant references will be mentioned and commented.

54.5 Solutions for the Interconnection

In this paragraph, we explore the design space and look at the feasibility of various solutions. The practicality of each solution is discussed and reference to existing work is given when available. Solutions based on routers will not be explored as most of the fieldbuses do not offer any network layer, thus excluding this solution. The only noticeable exception is LON (EIA-709.1 1998), which has a 7-layer stack and provides routing between wired segments and wireless nodes.

Repeater-Based Solutions

A solution based on a repeater gives the impression that all nodes share the same medium. The same medium access control scheme must be used on the wireless part and on the wired part. This kind of interconnection has a number of advantages. There is no need for a base station in the wireless cells. It is easier to ensure periodicity because a single MAC scheme is used. The same applies to the guarantees for the latency bounds. However, the latency may increase as an effect of a higher number of nodes sharing the same medium. Furthermore, the higher BER on the wireless part has a direct impact on the frame error rate on the network. This causes higher latency bounds because of the necessary retransmissions. Finally, repeaters introduce some restrictions in the design freedom. Between a segment and another or a wireless, only a single repeater can be used. Furthermore, loops are excluded from the topology (for instance, S6 could not be a repeater in Figure 54.2). This precludes using multiple interconnection points.

The properties of wireless communications impact all the possible solutions in the same way. Assuming that the same bit rate is used on both sides of the repeaters, properties 1, 3, and 7 will limit the throughput and increase the latency. Property 5 imposes restrictions on the type of MAC protocol. All protocols that need collision detection cannot be used directly. Finally, property 6 will increase the latency and the response time for request response protocols.

According to the degrees of freedom explained above, several solutions are possible:

RPS1: single wireless cell and single wired segment: This is an interesting solution to interconnect a number of isolated wireless nodes to a single segment. An example of this solution is given in Morel et al. (1996) (Figure 54.1). The solution can support multiple wireless cells as long as the wireless nodes in two different cells do not receive the radio signals of each other.

RPS2: single wireless cell and multiple wired segments: When there is no isolated wireless node, this solution can be used to interconnect two or more wired distant segments together when no cable can be installed in between.

RPS3: multiple wireless cells and single wired segment: The wired segment may be considered as a backbone for the wireless cells. Alternately, the cells may form a single subnetwork (using wireless to wireless repeaters) connected to the wired segment through a single repeater. For this, the wireless cells must overlap and it is necessary to use a different channel for each cell. When wireless nodes may move and traverse different cells, they have to change the frequency of emission and reception. To trigger this process, special messages are sent regularly by a given node of the network. A mobile station that does not receive such a message starts to listen on other channels until it receives one. More sophisticated procedures are also used, in particular, to reduce the time necessary to find the right channel (Rauchhaupt, 2002).

© 2005 by CRC Press LLC

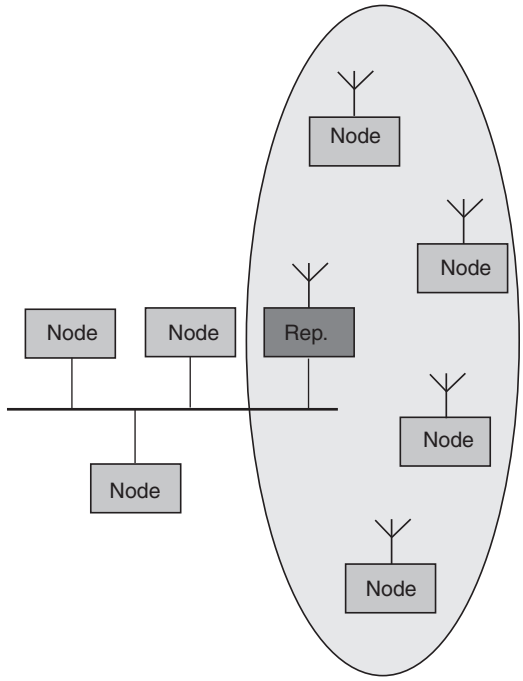

FIGURE 54.1 Repeater-based single segment multiple cell architecture.

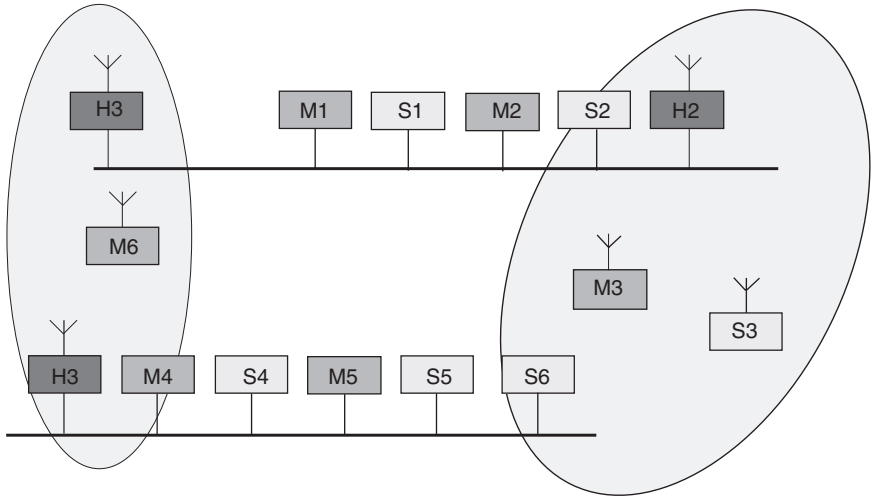

FIGURE 54.2 R-Fieldbus architecture (M: master station, S: slave station, H: repeater).

RPS4: multiple wireless cells and multiple wired segments: This solution is basically a generalization of the previous one. The integrated wireless and wireline case is the basis of the R-Fieldbus approach (Rauchhaupt, 2002)(Figure 54.2). R-Fieldbus uses a token bus medium access control and is thus very sensitive to token losses. As tokens go through the wireless cells, it has been necessary to reduce the BER on the wireless part. This has been done using a different encoding, direct sequence spread spectrum, and special countermeasures on the receiver side (Rake receiver). As the bit rate is not the same on the wired part (1.5 Mbit/sec) and on the wireless part (2 Mbit/sec), buffering is necessary as explained above.

© 2005 by CRC Press LLC

Bridge-Based Solutions

Bridge-based solutions may be used when repeaters cannot be used. For instance, in the presence of a large number of nodes, a repeater-based solution may lead to unacceptably long periods or latencies. Using a bridge will partition the nodes into two data links. The number of nodes than will share each link will hence be reduced. The latency will follow. Bridge-based solutions may offer a significant reduction in latency compared to repeater-based architectures. This is particularly the case when most of the traffic remains on each data link (cell or segment) and the traffic that goes through the bridge is minimal. Bridges also remove the need to use similar bit rates on the wired part and on the wireless one.

They are, however, not without drawbacks. In a bridge-based solution, a frame emitted on the segment (or cell) on one side is retransmitted on the other using the medium access control protocol of the latter. There is hence an additional waiting time before the frame is actually emitted on the second segment. The maximum delay depends on the medium access control protocol used. With a token passing protocol, the maximum delay is at minimum the token rotation time. If a master–slave configuration is used, the maximum delay is the maximum time that may elapse between any two successive polls.

In many cases, this delay has to be doubled. Many fieldbuses proceed by transactions in which one station, the initiator, sends a frame and the responder replies with another frame that can be an acknowledgment or contain some data. In order to bound the transfer latency, the delay that may elapse between the initiator frame and the response if bounded by a upper limit. This is also used to set a timer that will trigger a retry if it times out. The bridge introduces an additional delay in the initiator frame as well as in the response when the initiator and the responder are on different segments or cells. These two delays must be added to the timeout limit, accordingly increasing the maximum latency of the fieldbus. In other words, bridges have a negative impact on the real-time guarantees.

The properties of wireless communication have a lower impact than on repeater-based solutions. Property 1 may be mitigated using forward error correction on the wireless cell. Using error detection and consecutive retries would not be a good solution because this would further increase the maximum additional delay in the bridges. Imagine, for instance, the architecture depicted in Figure 54.3. A station on the

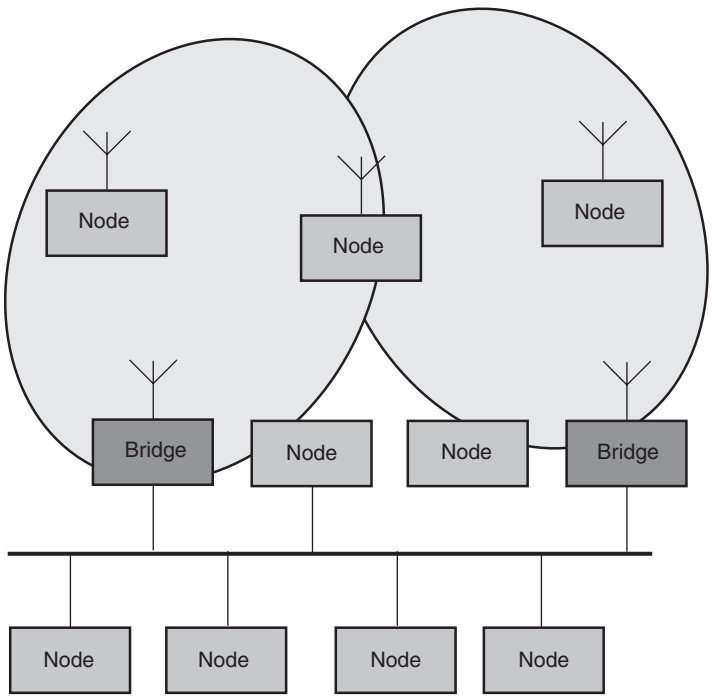

FIGURE 54.3 Isolated node approach.

© 2005 by CRC Press LLC

wired segment initiates a transaction. The responder is a wireless node. One of the bridges retransmits the request over the corresponding wireless cell after some medium access delay. The responder replies before the maximum response delay. The response is not received correctly by the bridge that retries, thus extending the maximum delay before the response is sent to the initiator. The same happens if the reply is lost as a result of properties 7 or 9.

According to the degrees of freedom explained above, several solutions are possible:

BRS1: single wireless cell and single wired segment: The bridge may be used as the base station for the wireless cell. In the office world, this is typically what is obtained using an 802.11 cell coordinated by an access point connected to an 802.3 segment. In the fieldbus domain, this architecture would be a alternative to RPS1 that relaxes the constraints of the repeater but is likely to increase the achievable latencies and periods.

BRS2: single wireless cell and multiple wired segments: This solution has been suggested to interconnect two fieldbuses that cannot be linked through wires (Cavalieri and Panno, 1998). This is depicted in Figure 54.4. In the proposed solutions, both segments use the same protocols and the connection is made through tunneling bridges. The solution offers a better reliability than solution RPS2 because the wireless part may be rugged. Buchholz (Buchholz et al., 1991) reports a similar approach in the in-building context. The system is composed of a number of Ethernet segments that are interconnected through a number of wireless cells. The options are identical, with two exceptions. There may be more than a single wireless cell. Due to the higher bit error rate, each Ethernet frame is segmented before it is encapsulated in an LLC frame of the wireless protocol.

BRS3: multiple wireless cells and single wired segment: This architecture is of two types. Each cell may use a different channel as presented by Leung (1992). In this approach, a number of wireless nodes are connected to a wired segment through a number of bridges. The set of wired nodes (including the bridges) use a protocol different from the wireless protocol but the functions of the data link layer are identical and the addressing is common to all nodes whether wireless or wired. The bridges are thus of the transparent or translating categories. To avoid duplicate transmission, bridges have to learn the topology so as to decide whether to forward a received frame or not.

A second option is to use the same channel for all cells and rely on time or code to separate the traffic.

BRS4: multiple wireless cells and multiple wired segments: Contrary to RPS4, in this solution, there may exist more than a single path between any two nodes. Bridges protocols will ensure that no message looping will occur.

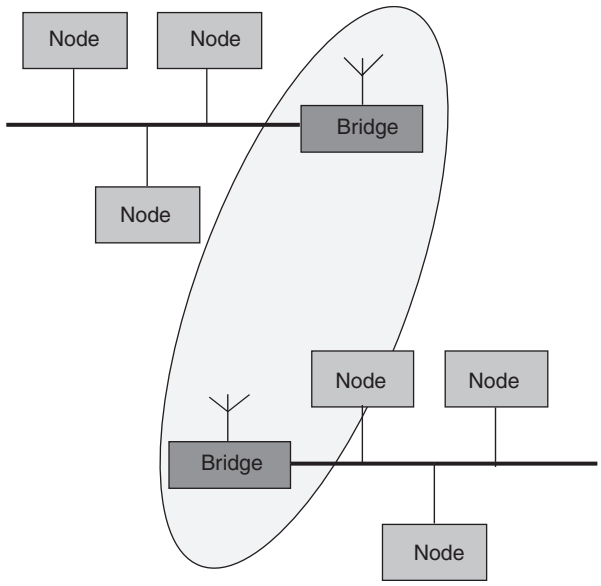

FIGURE 54.4 Interconnection of two wired fieldbuses through a wireless cell using tunneling bridges.

© 2005 by CRC Press LLC

Bridges are sometimes interesting solutions either when repeaters cannot be used or to partition the network into smaller domains. Note that, in general, a bridge requires that the upper layers (network to application) be identical on both sides.

Gateway-Based Solutions

With gateways, operation of each segment or cell may be governed by completely different protocols at all OSI (Open System Interconnection) levels. This is useful when the wireline segment and the wireless cell are built around protocols that are not compatible at the data link layer precluding the deployment of bridges. For instance, a protocol based on the client server model such as Profibus (CENELEC EN 50170, 1996a) will not include the same information at the data link layer than a protocol based on producer consumer on top of broadcast source addressing such as worldFIP (CENELEC EN 50170, 1996b). The first one will include the address of the source node and the address of the destination node. The second will only include the identification of the data. It is clearly impossible to use a bridge in such a case. It is also necessary when the application layers differ on each side. A wireless worldFIP (Roberts, 1993) (Solvie, 1994) on one side and a wired CAN Open (CENELEC EN 50325-4, 2002) on the other, despite their compatible medium access control frames, cannot be bridged.

As both networks operate asynchronously, in terms of latency, gateway-based solutions suffer from the same drawbacks as the bridge-based solutions. The latency is even slightly higher because of the additional overhead introduced by higher protocols layers. Except in special cases (see below), the worst-case latencies (worst case response time) may be estimated as the sum of the values for the individual networks traversed increased by the penalty introduced by the gateways themselves. This may or may not be worse than using bridges, although as a rule of thumb, worse is more likely. Let us give a case in which the worst-case latency is better. In a bridge-based solution, the timeout length for transactions will be increased to take into account the longer response times of nodes that are on another data link (segment or cell). If we take into account these new values for timeout and the higher probability of loss due to the wireless part, the worst-case latency may be increased significantly. Basing the approach on a gateway means that the original values for timeouts are preserved. The higher probability is accounted on the wireless part (not on all transactions). The result is that the bridge-based solution will give a higher worst-case latency than the solution using a gateway.

An interesting solution to improve the worst-case latency or decrease the sampling period for process values is to have a gateway that acts as a proxy. The gateway responds on one of its side as it was a node of the network on its other side. An example of this approach is illustrated in (Morel and Croisier, 1995). A wireless cell is connected through a single gateway to a WorldFIP (CENELEC EN 50170, 1996b) fieldbus. The gateway acts as a base station for the wireless cell. The gateway approach has been selected because of the strict temporal constraints in WorldFIP. This fieldbus requires that a maximum of 70 bit times separate the last bit of a request and the first bit of the corresponding response. This requirement cannot be fulfilled using bridges. It is very difficult to fill using repeaters. The gateway acts as a proxy representing the wireless nodes to the wireline part. The wireless cell is exploited in a round-robin manner according to a constant cycle. At the beginning of the cycle, the gateway broadcasts to all wireless nodes their update values in a single message. The wireless cells use this message as a sampling order, capture the values, and prepare their responses. Each node sends its response after the previous one. No explicit polling is done because of property 6 that would increase the response time (Figure 54.5).

54.6 Amenability to Comply with the Fieldbus Requirements

Table 54.1 gives a summary of the capability to satisfy the fieldbus requirements (see beginning) with the different architectures. For events and messages, latency is what matters. This issue has been discussed at length above, and the results are summarized in Table 54.1.

The objective to have periodic sampling and exchange of process data can be easily satisfied using some broadcast mechanism to sample and an adequate control of the medium access control (Fonseca and Almeida, 1999) when repeaters are used. With bridges and gateways, the same level of control is possible

© 2005 by CRC Press LLC

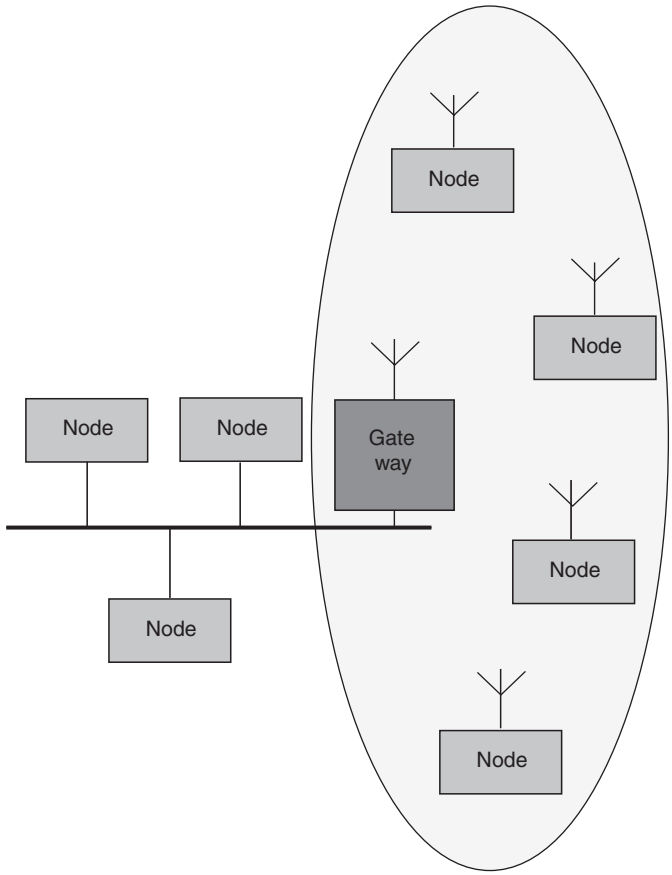

FIGURE 54.5 Interconnection using a proxy gateway.

TABLE 54.1 Repeater Ability to Help in Fulfilling the Fieldbus Requirements

Field bus requirement	Degree of fulfilment using		
	Repeaters	Bridges	Gateways
Bounded latency	Easier to prove if MAC is adequate. Longer delay due to higher number of station in the same link	Possible but more complex to calculate than with repeaters	Possible, sum of figures for each individual network
Periodicity	Easier as the same MAC scheme is used	Difficult to achieve unless synchronized clocks are used	Difficult to achieve unless synchronized clocks are used
Simultaneous sampling	Easily implemented through broadcast	Requires synchronized clocks	Requires synchronized clocks
Consistency indication	Simple to implement (i.e. CENELEC EN 50170 1996)	May be obtained using time stamps	May be obtained using time stamps
Event ordering	May be based on frame ordering	Requires synchronized clocks	Requires synchronized clocks
Rugged	Higher BER in wireless part will increase overall frame error rate and latency	Better than repeater because wireless part may use a different protocol	Similar to bridge based case

© 2005 by CRC Press LLC

in each individual segment or cell but the combination does not give the required periodicity and simultaneous sampling (Saba, 1995). The solution lies in the definition of a distributed clock synchronization algorithm. Simultaneous sampling is then based on this clock. The accuracy is highly dependent on the medium access control protocol, the network adapter interface hardware, and software implementation.

Absolute and relative temporal consistency may be obtained easily using mechanisms like those of WorldFIP (CENELEC EN 50170, 1996b) when repeaters are used. They fail when bridges and routers are used. Here again, synchronized clocks can be used, each information being stamped with its production instant, the stamp being transported with the data. By comparing the stamp values, the two kinds of consistencies may be evaluated.

Event ordering may use the distributed clock. When repeaters are used, one can save the burden of implementing such protocols and use the frame sequencing provided the required granularity is not too small. Finally, the repeater-based solution is more sensitive to the higher bit error and frame drop rate (properties 1, 3, 7-9) unless some of the wireless links are made more robust by some form of forward error correction or by improving the receiver design (Rauchhaupt, 2002).

54.7 Conclusion

There are numerous architectures that combine wireless cells and wireline segments. The choice of a solution for a given problem depends on the used protocols, the kind of guarantees to offer, and the constraints, in particular with regard to time. Here,we have explored the solution space and discussed the applicability of the various options as well as their pros and cons. The study has also shown that some architectural choices may not be offered for some fieldbus protocols and also some combinations of protocols. In general, the lower the interconnection mean in the OSO model, the better the performances. We have seen that this general rule must be carefully verified in each particular case. This can be verified in a few cited examples.

55.1 Introduction

During the last 20 years, the main focus in the development of field area networks (FANs or fieldbus systems) was on meeting the technical requirements of different application areas, which led to a wide variety of different systems. The accompanying standardization efforts (that still continue) led to the —widely accepted today — conclusion that in order to successfully cope with the requirements found in the application areas of interest, different co-existing FAN solutions are needed [1].

At the same time, the technologies that make up today's Internet were conceived, which ultimately led to the enormous surge in the use of the Internet in the 1990s together with the wide adoption of the IP protocol family for use in LANs. The ubiquitousness of the Internet sparked new interest in vertical communication flows according to the CIM pyramid and led to different solutions to connect FANs to the Internet either via a tunneling approach or through a gateway where different solutions based on either Web technologies such as HTTP, Java, and XML [2,3] or on higher-level protocols such as SNMP or LDAP [4,5] can be found.

While it is not clear today as to which is the best means (if one exists) to connect a FAN to the Internet, the notoriously bad security reputation of the Internet, which in its original form provided no security at all, mandates an awareness in FAN security issues. In this respect, it is necessary not to limit oneself to the study of security issues that arise in the connection of a FAN to the Internet. Rather, a more general approach has to be chosen, which includes security measures on the FAN level itself, where appropriate. Clearly, the final goal has to be the integration of security characteristics to the list of properties (like topology, structure, bus access, safety features, and others) that is ultimately used to decide which FAN to choose to realize a task at hand.

© 2005 by CRC Press LLC

The rest of the article is structured in the following way: Section 55.2 introduces the most basic security measures that are applicable to a wide range of systems. Section 55.3 gives an overview of where security measures can be applied at the FAN level. Section 55.4 covers remote security for connections to a FAN and presents an exemplary solution for a FAN–Internet gateway, which might today be the security topic that is of the most interest to the FAN community. Finally, section 55.5 points to several topics that are of immediate interest if secure FAN technology should become a reality.

55.2 Basic Security Measures

Security measures for IT systems in any organization aim at the achievement of three basic security goals, namely *confidentiality*, *integrity,* and *availability* (CIA), which protect data from unauthorized entities and unauthorized manipulation and ensure that data are accessible when needed, respectively. Another security goal that is often desired is *nonrepudiation,* which binds an entity to a commitment it made earlier. Solutions that are implemented to achieve these goals have to be based on a *security policy* that typically:

- explicitly states the security objectives and the scope of the policy and
- states who is responsible for implementing the policy.

Any security policy has to be backed by the management and communicated to the users of the IT system in question. A good informal starting point for developing a security policy is the "Site Security Handbook" [6], which is geared toward systems that are connected to the Internet. Another good introduction is the "IT Baseline Protection Manual" [7], which aids in the establishment of a security policy and additionally offers common best practices for the implementation of security measures similar to the British Standard 7799, which was adopted as ISO/IEC 17799 [8]. Unfortunately, no guidelines for developing a security policy for FANs exist.

Below, we discuss security in context with the life cycle of IT systems and give an overview of the most common technical means to enforce security goals that are also applicable to FANs.

Security System Life Cycle

While security activities can be started at any time in the life cycle of a system, it is usually desirable (although often not possible) to integrate them in the whole life cycle as described in [9], where five stages are distinguished[1] as shown in Figure 55.1.

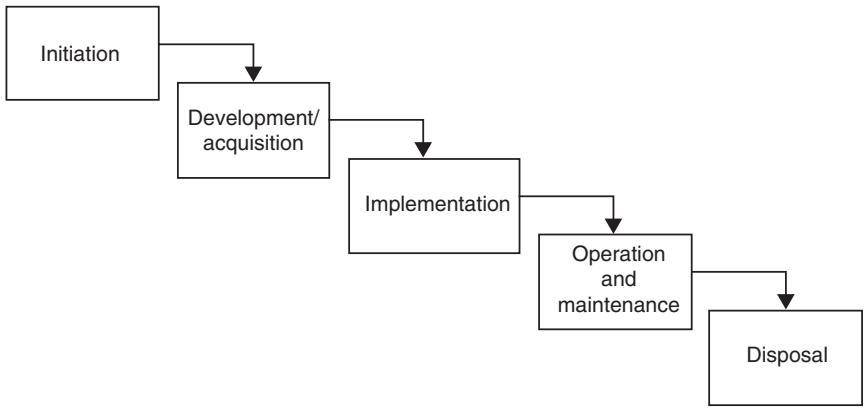

FIGURE 55.1 Basic waterfall life cycle model.

[1]The activities that follow can also be applied (in a slightly modified way) to other life cycle models like, for example, the spiral model by Boehm [34].

© 2005 by CRC Press LLC

During the *initiation* phase where the system is designed, a basic security design is also established by means of a sensitivity assessment where the data to be handled by the system as well as its impact on security are estimated. During the *development* stage, the security requirements as well as methods to implement them are selected and included in the overall system specification. During *implementation,* security features of the system are activated and tested. In the *operation and maintenance* phase, security-related operations such as key changes and others take place. Also, in this stage, system audits and monitoring may lead to system changes if new security risks are found that need to be addressed. Finally, the disposition of information hard- and software needs to be handled where the long-time storage of cryptographic keys is a major task.

Common Security Measures

Cryptography

Cryptography is often used to implement services where confidentiality and integrity are needed such as, for example, access control, described below. The major building blocks of cryptography are as follows:

- Cryptographically secure pseudorandom number generators (CSPRNG) to generate seemingly random entities, for example, for secret keys or as random nonces in protocols,
- Cryptographic hash functions, which are often used in conjunction with electronic signatures or to generate message authenticate codes (MAC) to protect data integrity,
- Symmetric and asymmetric encryption functions used to protect the confidentiality of data or may be used to construct MACs or electronic signatures.

An in-depth discussion of cryptography can be found in [10], which covers the above topics (except for randomness) and in [11], which covers the above topics and some more.

Authentication and Access Control

Authentication measures are used to establish the identity of an entity (which might be an actual user, a process that acts on behalf of a user or a role a user assumes during a session). A major distinction is made between *weak authentication* as found in password-based systems like Unix or Windows and *strong authentication,* which is usually based on *challenge–response* protocols that either rely on symmetric or asymmetric cryptography like Kerberos [12] and X.509 [13], respectively.

Authenticated entities can be subjected to access control mechanisms that allow to decide if an entity's desired action is allowed. Apart from simple models like access control lists and other discretionary models, mandatory models exist that are mainly found in military systems. Both models can be implemented by the newer *role-based access control* (RBAC) [14] schemes.

Firewalls and Intrusion Detection

Firewalls (see, e.g., [15–17]) and Intrusion Detection Systems (see, e.g., [18, 19]) are somehow complementary technologies, which are usually associated with LAN/FAN connections to the Internet. While the former try to prevent illegal access to inbound and outbound connections by, for example, packet filtering, the latter monitors and analyzes network access patterns and tries to recognize security breaches and/or attacks, which are referred to a system administrator.

Apart from protecting LANs from intruders from the Internet, both technologies can also be used in a LAN-only environment or where a LAN is connected to a FAN.

Security Evaluations

The construction of a secure system is a complicated task involving a variety of different skills and knowledge and might still not succeed even if the necessary care is taken [20]. A prominent example for a failed security system is *wireless equivalent privacy* (WEP), which was designed to protect 802.11 wireless LANs and miserably failed in doing so [21].

A method to build confidence in a new system is a security evaluation by a third party according to international security standards. The *Common Criteria 2.0* (CC) [22] is the latest in an evolving series of international security standards. A positive evaluation of a security target that is evaluated against the CC

© 2005 by CRC Press LLC

according to a security standard chosen by the system manufacturer leads to an internationally acknowledged certificate. To help with the preparation for a certification, so-called *protection profiles* (PP) for different security areas such as firewalls already exist, which can be built upon.

55.3 FAN Security

A natural way to bring security to a FAN would be the adoption of well-known security principles and protocols from the Internet world. Unfortunately, it is not so easy. One reason for this is that security protocols for the Internet domain such as SSL/TLS [23] or the newer IPSec protocol suite [24] operate on top of or at network layers (according to ISO/OSI) that are not defined in most FANs, where — for reasons of speed and simplicity — we usually find only layers 1 and 2, as well as sometimes specifications of layer 7 and above (sometimes called layer 8 or user layer, but outside the OSI model). Another problem in applying Internet security standards is that no provisions for any real-time support are made, which could lead to problems if applied to a FAN. Furthermore, because of the assumption that communicating parties do not know each other in advance, many Internet security protocols heavily rely on asymmetric cryptography, including the ones listed above, with the notable exception of the Kerberos authentication protocol, which was designed with an institutional scale in mind. Finally, in consideration of FAN security, we may face a situation where one or all of the communicating nodes are not under the control of their rightful user(s), which is an unusual situation in conventional LANs.

Security of a FAN system itself has seldom been discussed in the literature. In [25], a secure FAN node is discussed and [26] gives an overview of possible security classes for FANs that have different security implications, which will be detailed below. The major problems that have to be faced when FANs should be made secure are:

- FANs have no built-in provisions for security and are usually designed with a specific application area in mind, which will contribute to the problems that are inevitably encountered when security services should be added to an existing system.
- Cryptographic operations such as encryption needed to secure FAN communication might be prohibitive because of the limited processing power of current FAN nodes, and even more so if real-time needs have to be addressed.
- The FAN nodes as well as the communication media might be under total control of the adversary.
- The number of FAN systems is overwhelming and securing all of them is an infeasible task.

On the other hand, some traits of FANs make them more easily accessible to security engineering than other systems, most notably:

- FANs have a very limited complexity. In comparison to the general-purpose machines found on the Internet, FAN nodes are designed to solve one special problem, which makes them easier to understand and analyze.
- The protocols used in FAN systems are also less complex than those found in other network systems. This can be attributed to either a restriction to only the lower layers of the protocol stack and the application layer, or in cases where this does not hold, to the limitation to a single protocol, contrary to the protocol proliferation that can be found on the Internet. Additionally, the easier a protocol is, the more amenable it is for efficient implementation, which is desired if real-time behavior is of concern.
- As a consequence of the above, the operating systems (OS) found in FAN nodes need not be as complicated as a typical computer OS.

The following discussion will use the data listed in Table 55.1, which shows basic security services and the layers in the OSI model [27] where they may possibly be implemented.

According to [26], the following subsections try to classify typical FAN application scenarios with respect to their impact on security. Essentially, we can distinguish between controlled and uncontrolled FANs.

© 2005 by CRC Press LLC

Security for Controlled FANs

A controlled FAN (CFAN) environment is a FAN installation where the physical access to FAN nodes as well as may be the access to the underlying communication media is controlled by the owner of the FAN system. This situation is comparable to the situation found in the usual Internet environment where one computer or a LAN of a company is connected to the Internet.

For a CFAN, we can further distinguish three different scenarios, which are mutually inclusive as shown in Figure 55.2. The stand-alone FAN (SAF) consists of a FAN-only installation that is not connected to the outside. The LAN-integrated FAN (LIF) and Internet-integrated FAN (IIF) correspond to a FAN installation, which can be accessed via a connected LAN or via the Internet, respectively. The inclusion relations in Figure 55.2 correspond to the actual security threats and solutions (STS) that are applicable to the different scenarios. While the inclusion relationship always holds, it has to be noted that the set STS is highly dependent on the underlying security policy, which shows the importance of deriving a security policy for a specific system at hand.

Considering the CIA security goals as mentioned in Section 55.2, we focus on possible solutions for confidentiality and integrity and mention that provisions to achieve availability in a FAN environment (apart from provisions that are already designed into the FAN) will be hard to come by. In the following discussion, the placement of security functions according to ISO/OSI (see Table 55.1) will be helpful. Moreover, the fact that most FAN systems only implement OSI layers 1, 2, and 7 is of importance. The

TABLE 55.1 OSI Security Services in the Different Layers.

Security Service	Possible Layer(s)
Peer entity authentication	3, 4, 7
Data origin authentication	3, 4, 7
Access control service	3, 4, 7
Connection confidentiality	1, 2, 3, 4, 6, 7
Connectionless confidentiality	2, 3, 4, 6, 7
Selective field confidentiality	6, 7
Traffic flow confidentiality	1, 3, 7
Connection integrity with recovery	4, 7
Connection integrity without recovery	3, 4, 7
Selective field connection integrity	7
Connectionless integrity	3, 4, 7
Selective field connectionless integrity	7
Nonrepudiation origin	7
Nonrepudiation delivery	7

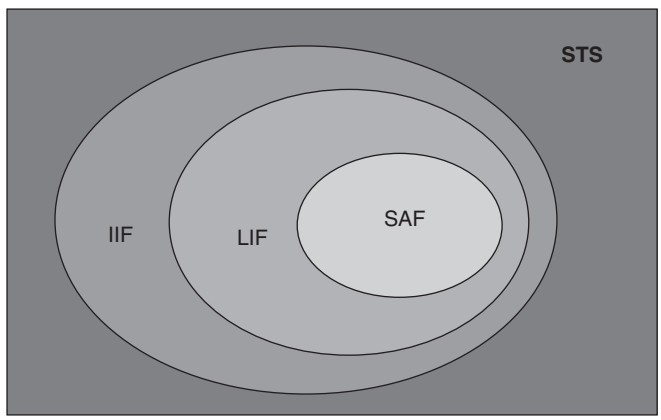

FIGURE 55.2 Three controlled FAN scenarios.

© 2005 by CRC Press LLC

reduced OSI stack of modern FANs is usually a result of efficiency considerations. In application domains such as in building automation where time requirements are more relaxed and extensive networking capabilities are needed an implementation of the full OSI stack may also be found.

With respect to the placement of confidentiality services in the network stack, we find that the majority of the services can be placed at one of the layers 1, 2, or 7. Additionally, placement of such services above layer 7 is possible.

Integrity services can be placed at layers 3, 4, and 7 of the OSI stack, or — as with confidentiality services — above layer 7. Restriction to layers 1, 2, and 7, which will often be necessary in a FAN environment, limits the application of integrity services to layer 7 or above.

Taking into account that in a FAN environment we often find dedicated microcontrollers that are designed to handle a specific FAN interface and protocol, a security solution that is targeted above layer 7 appears to be a sensible choice in all cases where we try to secure an established FAN system. In FAN systems where we find an abstraction layer above layer 7, an inclusion of security services in this layer would be of special interest. Such a solution would have the special benefit that the user layer of a FAN system is typically targeted at the standardization of interoperable services or application profiles and the process of standardizing such services is carried out by a user group (usually comprising the companies that have an interest in the FAN), which leads to a broad acceptance in industry. Apart from the expected acceptance, this solution is also of interest as it provides end-to-end security in its narrowest sense as it secures all communication between two nodes of a FAN at the application level. In the absence of a (widely accepted) user layer into which security services could be integrated or where a specific user group does not see a necessity to add such services (as will presumably be often the case), a generic solution above layer 7 can still be devised with the drawback of losing interoperability with other solutions, which results in increased development efforts and consequently increased costs.

In both approaches, a prudent approach to providing security services could be to use a wrapping mechanism that takes an engineering value (which is a measured input value as it was sampled with a sensor or first sampled and then preprocessed at the node) and apply this value to either an integrity mechanism or to both an integrity and a confidentiality mechanism. Figure 55.3 shows an example of the second case where the field *Header* contains information about the security transformations applied. The *MAC* field contains integrity check information.

The integration of both integrity and confidentiality mechanisms could be prohibitive in most of today's FANs as they require processing power that might be out of range for the typical low-cost 8-bit microprocessors that can be found in typical FAN environments. Another drawback of solutions such as depicted in Figure 55.3 is that the (maximum) payload of FAN messages might not allow the message expansion that would be necessary to add confidentiality and/or encryption. This is a problem especially for integrity mechanisms as they always add additional data to the transmitted message, while for confidentiality only, we could think of just encrypting the engineering value and omitting the header of the message. In this case, two communicating nodes need to know in advance if the data to be sent/received will be in encrypted form or not.

When missing processing power in the nodes is a concern, one could also think of applying the necessary security services to the lower layers in the OSI stack. Although a first look at Table 55.1 shows us that only confidentiality services can be added at the lower level, it is still possible to add the required services at layer 2 if the necessity arises, as has been the case in Ethernet where [28] augments the services found

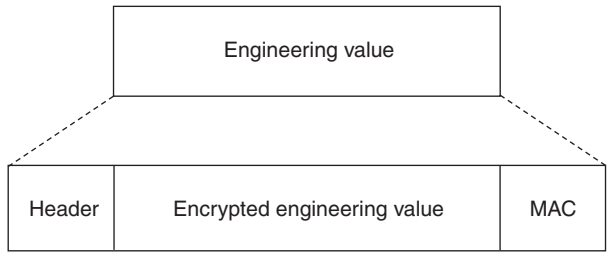

FIGURE 55.3 Wrapping an engineering value.

© 2005 by CRC Press LLC

in the OSI security model to also include integrity, authentication, and access control. While this could be a feasible solution, one has to keep in mind that the resulting protocol will also need to support non-layer 2 management functionalities that handle, for example, key exchange.

A solution for providing confidentiality and/or integrity would still leave a major security threat unanswered: *network management*. In today's FANs, this functionality is typically achieved in an unauthenticated manner; such an approach is synonymous to an invitation to a knowing attacker who has gained access to the FAN. Management functionality might even include the possibility to totally reprogram a node, for example, by directly overwriting parts of the memory of a node as well as to gain complete knowledge about the programming of the node by reading out configuration and application data from the memory. It is easy to imagine situations where such behavior is not acceptable. The least functionality that is needed to achieve security in this area is the provision of an *access control* mechanism. This task can be supported by integrity mechanisms that allow to authenticate configuration communication messages. The implementation of access control for network management should pose little problems. While the data transmitted might be larger than usual FAN messages and even multipart messages might be needed, such operations are usually not time-critical and the restrictions to the acceptable maximum length of a message and the maximum time a transmission may take are usually very relaxed.

Security for Uncontrolled FANs

An *uncontrolled FAN* (*UFAN*) environment is a FAN installation where physical access to communication nodes that comprise the FAN as well as access to the underlying communication media is controlled by a user (or a group of users) who is not the owner of the system and has to be considered as an adversary. Such a situation is found, for example, if a remote metering device is deployed at the site of a customer by a utility company or if a FAN is deployed in a car. A comparable situation that has been well studied (but where neither security mechanism nor attack results are published in the open) is the transmission of secured pay-per-view programs via cable or satellite, which only entitled subscribers should be able to descramble. The examples make it clear that for a UFAN environment, we also need to distinguish between the kind of system access that the owner/manufacturer has after the FAN has been deployed.

In a *remotely maintainable FAN* (RMF), there exists a rightful system owner, which has the possibility to *regularly* communicate with the system. The communication may take place on a periodic basis or when the need arises. In the remote metering example, we could imagine regular communication between the utility company and the meter every month in the case of a contract between the user and the company. On the other hand, if the user has to prepay his/her energy communication could be on a per-payment basis.

Nonmaintainable FANs (NMF) are those systems where the rightful system owner has no *regular* possibility to communicate with the system after its deployment (although some communication could become possible in the unforeseeable future, e.g., in the case of a system failure). This is, for example, the case if a FAN is deployed in a car.

If we compare the RMF and the NMF scenarios as above by looking at the set of possible STSs, we easily see that both scenarios are different in that they overlap in some parts (e.g., the adversary has access to the physical parts of the FAN), whereas neither is included in the other (e.g., the RMF is exposed to outside threats, which are adversarial third parties being neither the system owner nor the entity where the system is deployed). They are also not proper sub- or supersets of the SAF, LIF, and IIF scenarios described in the Security for controlled FANs section, mainly because the whole FAN infrastructure is accessible by the adversary. But we can see again that the sets are highly dependent on the underlying security policy and security assumptions. On the whole, UFAN systems seem to be more at risk than CFAN systems, because the adversary has more possibilities to circumvent possible security measures as well as because of the fact that analysis and results of security issues for such configurations have not been extensively dealt with yet.

As far as ways and means to secure UFANs are concerned, one natural train of thought leads to the investigation of physical measures to secure the different nodes of a FAN as well as the sensors and actuators connected to them. Depending on the security policy, this can lead to simple solutions where plumbs are attached to the devices (today, this is often done to prevent manipulation of power meters) in which case it is the legal implications associated with the removing of the seal that act as a deterrent. A (technologically) stronger

© 2005 by CRC Press LLC

solution are attempts to construct tamper-proof devices that either notify the system owner if they are tampered with in the case of an RMF system or that (permanently) deactivate themselves in the case of an NMF system. In the latter case — apart from trying to prevent (physical) access to the nodes — we usually find special security modules such as smart cards that are useful to protect sensitive data as well as to recognize attempted tampering. If it is not possible or feasible to physically protect the nodes, their programs, and their memory; security considerations regarding lower layers of the network stack become in vain as the protection possibly achievable at those layers does nothing to prevent the possible attacks at higher levels. Together with physical node protection, lower layer security is of course of interest again and might — as in the CFAN scenario — help to remedy problems that could arise with the use of integrity services.

Continuing considerations regarding physical security and automatic deactivation of nodes in case of tampering, the possibility of including intrusion detection mechanisms in a node seems to be an interesting topic of research for the future. Such a mechanism could become feasible in UFANs that — after deployment — remain unchanged, meaning that no nodes are added or removed as well as that the communication patterns between the nodes do not change or change in a way that can be anticipated. If such an analysis is possible, a node that detects an intrusion can either contact the system owner or deactivate itself, depending on the actual system configuration (in case of an RMF, a failure to contact the system owner after detection of an intrusion must also result in deactivation).

Regarding the different reasons that might lead to the deactivation of a system, it is also necessary to determine the right point at the time of deactivation. To give an example, it would be quite inconvenient and adverse to any safety considerations if a UFAN in a car would stop working during car operation.

Finally, a critical point in UFAN security is again the network management. In an RMF scenario, it is easy to see that a point-to-point security solution is indispensable. Here, it is conceivable that the same mechanisms that may be utilized in a CFAN are helpful. Conversely, in the NMF scenario we would like to prevent any management activities that concern the configuration of the nodes as well as the programs that are executed on the nodes. While in this case configuration data that reside in a ROM (or maybe in a once writeable WORM) and are therefore not changeable at all would be the easiest solution, such an approach might be prohibitive in the case where due to maintenance reasons single nodes might need to be exchanged or updated.

55.4 Security for External FAN Connections — An Example

If a FAN is connected to either an intranet or to the Internet (or any other public internet for that matter) or to the Internet via a connection to an intranet, we find ourselves in a situation as shown in Figure 55.4.

Access to the FAN is typically achieved via a central access point, in many cases, a gateway translating between the FAN protocol and the protocol used to access the gateway, which we subsequently assume to be part of the TCP/IP protocol suite. A common implementation is a web-based solution, that is, the gateway translates FAN data to accommodate a transport format such as, for example, XML over HTTP (see [29] for a thorough description of XML). Yet this structure also allows for implementations other than the pure gateway approach. Actually, other solutions are possible where FAN data are tunneled over the external network or where the IP protocol is tunneled over the FAN and handled in the node that is the

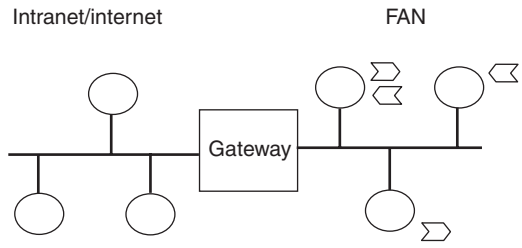

FIGURE 55.4 External connection to a FAN.

© 2005 by CRC Press LLC

sender/recipient of a message (although this last possibility seems to be very awkward if we compare the size of IP messages to that of typical FAN messages).

Access to the gateway will usually be achieved either through a firewall (which might be incorporated into the gateway itself) or via a dial-up connection. For more information about the different possibilities of where to place a firewall (and accompanying IDS system) and how to possibly configure it, which heavily depends on the IT environment at hand, see the references of Section 55.2.

It is important to note (and to recognize) that the secure connection of a FAN to an external IP network is more than just the application of any IP security protocol that we find on the Internet, as can be seen in the example presented below. Contrary to common conceptions, there is no need to rely on any of the very time-consuming asymmetric security primitives that are often assumed when Internet–FAN connections are considered. The reason for this lies in the fact that all parties involved in the communication are previously known to each other. This is a very typical property of Internet–FAN connections, often alleviating system design.

The rest of this section gives an example of a security architecture for a gateway with a need for a very high level of security and a limited demand for high bandwidth. The target application is a residential gateway primarily used for remote access to energy meters and consequently for simplified and automatic billing, may be including the application of flexible (time- and consumption-dependent) tariff schemes. For add-on services, the gateway could be connected to a home automation network. A detailed description of such a gateway can be found in [30]. In the light of the different scenarios described before, such an application is a UFAN, specifically the RMF subtype. From the security point of view, the configuration is a kind of worst case. The owner of the home has some interest to pay as little as possible for the energy consumed; therefore, he has to be considered as an adversary. Even worse, he has unlimited physical access to the entire installation, unless gateway and energy meter are locked in a sealed cabinet and there is no in-home network at all. Therefore, security demands are high.

Overview of the Security Architecture

An important point to note in this example is that the relationship between gateway and a client in the Internet is not just one-to-one. In fact, the utility company desiring remote access to the energy meters has numerous customers as well as more than one data acquisition client. In addition, the whole concept must take into account that the communication infrastructure can be used by third-party service providers who need to be granted access to the gateway as well, albeit to different sets of data. The security architecture therefore becomes rather complicated and consists of an off-line and an on-line part as shown in Figure 55.5. As can be seen, the key distribution center that operates off-line for security reasons generates the necessary keys that securely reside on tamper-proof smart cards [31], which are also used for the execution of cryptographic algorithms.

The on-line participants are the security clients and administrators (which can also be one entity) that access a remote FAN over the gateway using the smart cards to provide the necessary keys and security algorithms. While the clients are only entitled to access the FAN for monitoring and configuration purposes, administrators may additionally change access control settings or the configuration of the security server. On the gateway itself, the security server accepts and handles connections from the Internet using an access control component to enforce access restrictions to the FAN. For the actual FAN access, a FAN-specific module translates between the different protocols.

Implementation

The secure communication between clients/administrators and the gateway requires a minimal set of information to be carried in a message. In the example, the message format shown in Figure 55.6 was chosen providing integrity as well as confidentiality. The particular choice is arbitrary but illustrates the typical elements found in secure communication. Apart from the UID that indicates the sender of the message, the MODE field allows to implement and use different security primitives, should the need arise,

© 2005 by CRC Press LLC

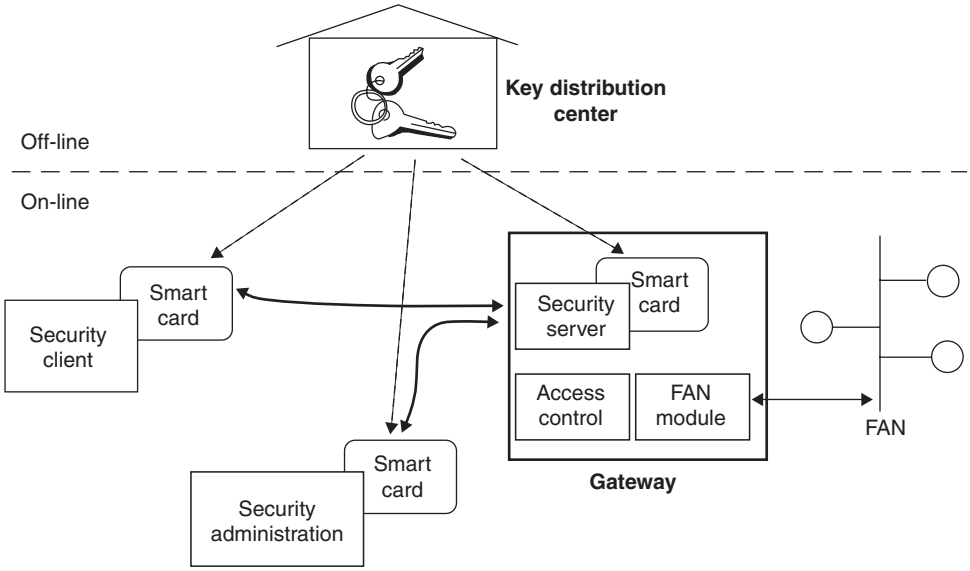

FIGURE 55.5 Architecture of the secure FAN–Internet gateway.

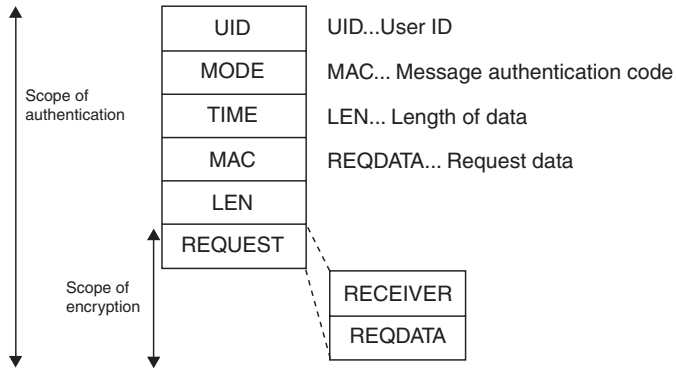

FIGURE 55.6 The communication message format.

because, for example, the security of one of the used primitives is broken. The inclusion of a time field (TIME) that contains the (notion of) time at the gateway involved in the communication allows to define a time window of validity for a message and prevents replay attacks of previously sent messages. In messages from the gateway, the field is used to update the local notion of the gateway's time. The MAC protects the integrity of the message and is calculated over the whole message. Finally, the LEN field indicates the length of the following encrypted REQUEST that is split into the actual request data and the receiver of the data, which is either the security server in case of configuration messages or the underlying FAN. The RECEIVER field also facilitates the support of more than one FAN connected to the gateway, which could be realized by incorporating more than one FAN module.

The security mechanism used to provide data encryption is the *remotely keyed encryption scheme* (RKES) described in [32], which utilizes the secret keys of the smart card to initialize the encryption, while the bulk work is done afterwards by the gateway processor, which calculates faster than the smart card and is also able to cope with larger messages. The authentication mechanism uses secure hash function *SHA-1* [33] and sends the resulting data to the smart card where they are encrypted using 3-DES. The result of this operation is then used as the MAC of the message.

© 2005 by CRC Press LLC

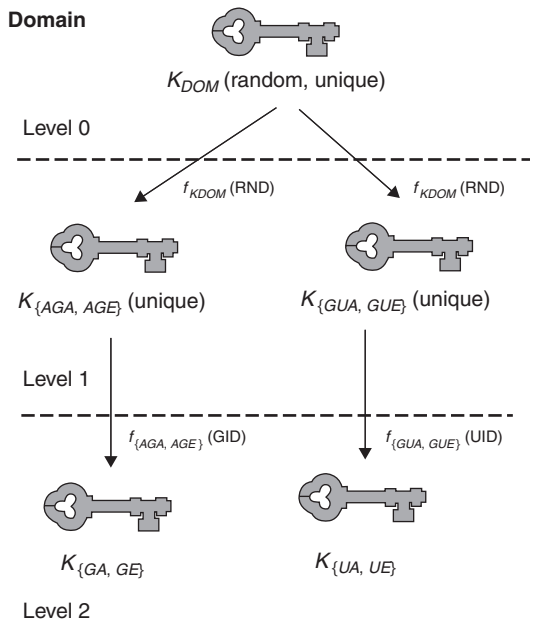

FIGURE 55.7 Key hierarchy.

Figure 55.7 shows the key hierarchy needed in the system. As we foresee that more than one gateway will be needed, we use a domain system where users and administrators of a domain can exchange messages with all gateways of the domain.

To achieve this functionality, a random and unique key K_{DOM} is generated in the key distribution center for each domain. This key is subsequently used to derive all other keys of that domain. Looking at the left portion of Figure 55.7, we see that we derive the keys K_{AGA} and K_{AGE} from the master key using a randomly chosen input at level 1 of the key hierarchy. Those keys are the master keys for authentication and encryption of administrator-to-gateway messages, respectively. They are used to derive the keys K_{GA} and K_{GE} of the gateways of the domain from the unique gateway identifiers (GID) of a gateway. This scheme allows an administrator to communicate with every gateway because she/he can derive every gateway key of level 2 by applying the key derivation function f to the GID of the requested gateway using the master keys of level one. Additionally, if the secret keys of a gateway are compromised, the system can continue to work because every gateway has its unique set of keys. The right portion of Figure 55.7 shows the same procedure for the generation of keys that are used in the communication between a gateway and a user.

Function f, which is used to derive the keys of levels 1 and 2 in Figure 55.7, is the application of SHA-1 to the argument followed by an application of 3-DES in EDE (encrypt–decrypt–encrypt) mode,

$$f_{KEY}(\cdot) = 3\text{-}DES - EDE_{KEY}(SHA\text{-}1(\cdot)) \tag{55.1}$$

which finally yields the key. The index *KEY* in (1) designates the master key used as a parameter in the DES algorithm. To derive, for example, the secret encryption key of a user with the UID X at a gateway, we need to calculate

$$K_{UE} = f_{KGUE}(X) = 3\text{-}DES - EDE_{KGUE}(SHA\text{-}1(X)) \tag{55.2}$$

The final functionality needed in the system is an access control mechanism. The easiest way to realize this functionality is the implementation of an access matrix, which operates on the FAN node level, and allows either *read access*, *write access,* or *create access* to data. Depending on the access rights of the user, and in the case where memory is a limited resource, it is possible to assign a Boolean flag to each

© 2005 by CRC Press LLC

entry that indicates if the following access modifiers constitute an *allowance* or *forbiddance* list for the specific user, where the latter would typically be applied for an administrator to keep the list short.

55.5 Conclusion

The necessity for security at the FAN level still has to be brought to the attention of the larger part of the FAN community. While the awareness for security issues in the connection of FANs to the Internet is starting to grow — mainly because of the frightening security record of the Internet — it will be of utmost importance to incorporate security considerations into the next generation of FAN systems themselves. The ultimate goal is to alert the community to the fact that security provisions should be an important factor in the decision about which FAN system to use for a specific task. It is to be hoped that contrary to the Internet, where it took more than 20 years (and the commercialization of the Internet) until people realized this fact, this process will be faster — especially if we consider safety-critical applications where FAN systems are deployed in increasing numbers.

While the pure realization of FAN–Internet connections profits immensely from the experience gained in attempts to secure the Internet — thanks to the gateway approach — we must realize that FAN-level security needs different and new approaches. This is due to the different specialized protocols as well as the very low-end processors typically used in this area. Another large field for further research and development where approaches are not very mature can be found in the UFAN scenarios.

We have discussed some potential security solutions (and pitfalls) for today's FAN systems that are worth a try where the need for security arises. However, the discussion also shows that this can only be an intermediate solution. Applying reasonable security strategies to nonsecurity-aware systems has to overcome significant obstacles, up to an extent where a meaningful operation is no longer practical. It seems that there is no way around the design of a *really* secure FAN infrastructure including all necessary security services as well as the necessary administration framework. The ultimate aim of such efforts has to be a standardized framework that is widely accepted.

56.1 Why do we Need Safety in Automation?

Any active industrial process is more or less associated with the risk

- To injure or kill people
- To destroy nature
- To damage investments.

With most of the processes, it is quite easy to avoid risk without special requirements imposed on automation systems. However, there are typical applications associated with high risk, for example presses,

© 2005 by CRC Press LLC

saws, tooling machines, robots, conveying and packing systems, chemical processes, high-pressure operations, off-shore technology, fire and gas sensing, burners, cable cars, etc. These applications need special care and technology.

Over time, the market balances out the reliability and availability of standard automation technology to a certain economic cost level. This means the failure or error rate of standard automation technology under normal circumstances is just acceptable for normal operations but not sufficient for the above-mentioned applications.

The situation may be compared with a public mail system. While normal letter expedition is expected to be as affordable as possible at certain reliability, everybody will use special mail for important messages.

56.2 Dichotomy of Standard and Safety Automation

In the past, microcontrollers, software, personal computers, and communication networks dramatically influenced the standard automation means and thus led to cost reduction, higher flexibility, and availability. With respect to safety, existing standards and regulations prohibited any usage of those means. Safety automation had to be "hard-wired" and based on "relay" technology. This dichotomy or gap is quite natural due to the fact that safety relies on trusted technology or material, trust on experience, and experience on time. But adding "classical" safety to modern automation solutions always led to inadequate cost due to additional wiring and engineering, due to less flexibility and availability than expected, and due to other disadvantages. In the meantime, the situation has changed dramatically. Microcontrollers and software have proved useful in millions of applications. And the preconditions for their usage in safety applications have been given since the introduction of the international standard IEC 61508 [1].

56.3 Motivation and Objectives for PROFIBUS

During its lifetime of more than 10 years, PROFIBUS has been emerging as one of the most important fieldbus systems in the world and just got standardized within IEC 61158 and IEC 61784 [2], respectively. It is enabling decentralized applications in factory and process automation with its variety of appropriate transmission technologies like RS485, MBP-IS,[1] and fiber optics. Thus, it was merely a matter of time to integrate the necessary means for safety applications into PROFIBUS DP in a seamless manner and provide a similar flexibility and availability also for powerful safety devices like remote I/O, laser scanners, light curtains, level switches, shutdown valves, drives, robots, and the like.

Back in 1998, when the PROFIBUS organization started its project "safe communication across PROFIBUS DP," more than 25 renowned companies on safety decided to follow the vision of connecting the above safety devices to the same transmission line as the standard devices and let them communicate with an additional programmable safety-related controller (F-Host in Figure 56.1). No cables, ASICs, layer stack software, or other communication devices like repeaters, links, and couplers should have been changed. Configuration, parameterization, programming, and diagnostic means should be as familiar to the user as possible in order to simplify the usage of safety: "what he/she is using, he/she will not be losing." Fortunately, the working group was able to base its design and development efforts on the new IEC 61508 and on the spadework of the EN 50159-1, now IEC 62280-1 [3], entitled "Railway applications — Communication, signalling and processing systems — Part 1: Safety related communication in closed transmission systems." PROFIBUS is such a closed transmission system as it only allows communication between configured and well-known participants. Open transmission systems in contrast are, for example, the public phone system or the Internet.

Already during the first sessions of the working group in 1998, it became apparent that the pure definition of the safe transmission of messages via the standard PROFIBUS cable would not prove sufficient for the new generation of safety devices that had to be connected to it. What sense would it make to a sensor

[1] MBP-IS = "Manchester Coded — Bus Powered and Intrinsically Safe" replaces the previous PROFIBUS name "IEC 1158-2." Further development has listed additional procedures in the corresponding IEC standard, so that creating an unambiguous designation has become necessary.

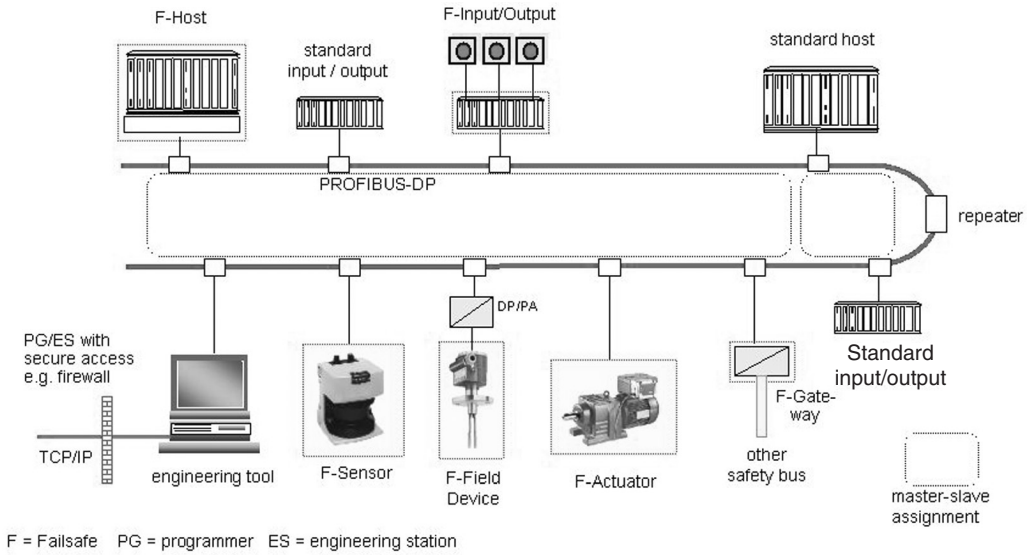

FIGURE 56.1 The PROFIsafe vision.

manufacturer, for example, if merely the shutdown signals could be transported via the bus, while parameter value assignment or diagnosis in the event of a failure still requires a time-consuming PC connection on site via the RS232 interface? The request for the system manufacturers to support the scenario of the rapid device replacement and the integration of the commissioning and diagnosis software of the field device into the engineering software of the system manufacturer for a joint utilization of the communication paths and the project storage was pending (Figure 56.2). Only such integration permits the requests of customers for more production flexibility (e.g., program-controlled parameter value assignment) and for increased availability (predicting and/or faster diagnosis and preventive maintenance) to be satisfied. However, the working group agreed to strive for solutions that keep the device manufacturers as independent as possible from the system manufacturers.

From the very beginning, it was planned to add safety gateways to other safety bus systems like ASi-Safety-at-Work.

Safe communication could be achieved by using redundant transmission lines. However, the working group decided to look for a "single channel" solution for safety applications such that redundancy can still be added to the system as an option to provide additional higher availability/reliability(Table 56.1). Eventually, the safety solution for PROFIBUS was called PROFIsafe and a sign was created.

56.4 PROFIsafe, The Solution

As we know, PROFIBUS DP, like most fieldbus systems, only uses layers 1, 2, and 7 of the ISO/OSI model [4]. No changes to any of these layers means to add the safety measures as a safety layer on top of the PROFIBUS layer 7, thus increasing the size of the OSI application layer. Since this safety layer is merely responsible for the transport of safety-relevant "user" or process data, it takes the rest of the application layer to look after the acquisition and processing of this data. These higher layers can be provided, for example, in a safe field device (e.g., light curtain) by the technology firmware of this device. Usually, parts of this firmware are of a safety-oriented design anyway — typically a redundant hardware/software structure, in which the PROFIsafe functionality can be embedded (Figure 56.1). Like in standard mode, the process data (signals and/or process values) are packed in the processing data unit (PDU) of a PROFIBUS message frame. In case of PROFIsafe, the raw process data are just supplemented by additional information, as we will see in the following sections. The so-completed safety-relevant process data are called a "PROFIsafe frame." Ideally, a "PROFIsafe frame" shall be passed completely unmodified from a (safety)

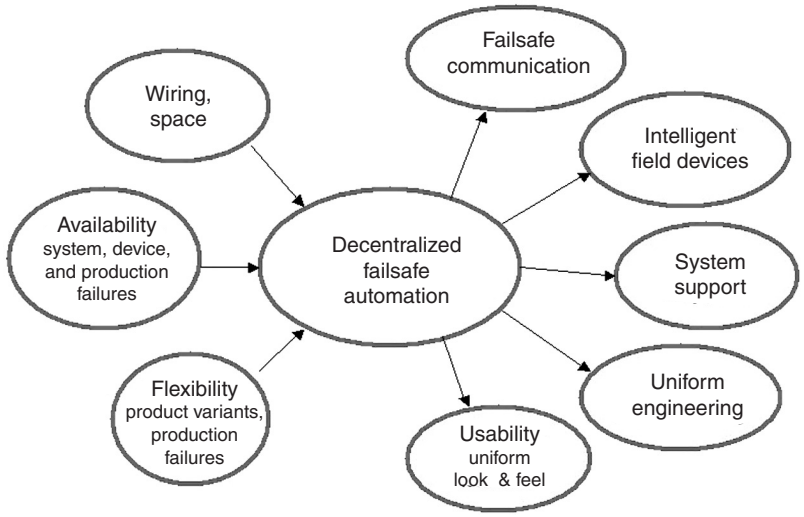

FIGURE 56.2 Requirements and tasks for distributed safety technology.

sender to a (safety) receiver no matter what kind of transmission system both had been using. Thus, the safety measures are *encapsulated* in the communicating end devices.

56.5 Black Channel

Such a communication system is called a "Black Channel" analogical to a "black box." This means first, that the chosen communication technology does not matter except for a few basic constraints to be defined later on in this document. Second, none of the error detection mechanisms of the chosen communication technology are taken into account to guarantee the integrity of the transferred process data. Basically, there are no restrictions with respect to transmission rate, number of bus devices, or transmission technology — as long as its parameters are tolerated by the required reaction times of a given safety application. The following example (Figure 56.3) shows that PROFIsafe also uses the "Black Channel" principle for complex PROFIBUS structures.

Safety-related sensor signals from a modular slave (F-Slave), that is, a PROFIBUS device that can be equipped with several safety-related modules with input/output (I/O) channels, are routed via the

TABLE 56.1 Safety and redundancy options

	PROFIBUS DP	PROFIsafe	Redundancy	PROFIsafe and Redundancy
Application	Suitable for all kinds of distributed automation	Factory and process automation. FIGURE 56.3 Complete communication paths for PROFIsafe frames.

PROFIBUS slave node to one of the two DP master nodes of a controller. From here, they proceed via a local backbone bus to the F-Host, the programmable safety-related system (e.g., Safety-PLC or F-Host). After the safe logic operation, a corresponding output signal is routed via the local bus to a second DP master node and to a second PROFIBUS segment. The transmission rate is reduced there in a DP– PA link, and the intrinsically safe transmission technology (MBP-IS) is used for routing the signal to the safety-related PA (process automation) slave. At no point on its communication path has the signal used a redundant communication path. In other words, this is a *single-channel* transfer.

Up to now, we simply dealt with the communication paths for safety-related message frames. Thus, it is still open who is responsible for the transfer, and when the transfer will take place. Here too, a PROFIBUS standard mechanism is used — the master–slave operation. A master, which may be assigned here to an F-Host, *cyclically* exchanges PROFIBUS messages with all its configured slaves one after the other. This means that there is always a *1:1 relationship* between master and slave. The polling operation has the advantage that any failed device will be detected immediately — one of the basic principles of safety technology. Now we are able to identify the basic constraints for the "Black Channel" for PROFIsafe operations: the polling principle and the 1:1 relationship.

56.6 Possible Transmission Errors and Their Remedies

Various errors may occur when messages are transferred in network topologies of the described complexity, be it due to hardware failures, or due to extraordinary electromagnetic interference, or other influences. A message can be lost, occur repeatedly, be inserted from somewhere else, appear delayed or in an incorrect sequence, and/or show corrupted data. In the case of safety-related communication, there may also be incorrect addressing — that means, a standard message erroneously appears at a safety device and pretends to be a safety message. Different transmission rates may additionally cause storage effects to occur. Out of the numerous remedies known from the literature, PROFIsafe concentrates on those presented in the matrix shown in Figure 56.4.

© 2005 by CRC Press LLC

Measure: / Error:	Consecutive number (sign of life)	Time-out (with acknowledgement)	Codename (for sender and receiver)	Data integrity (CRC)
Repetition	X			
Loss	X	X		
Insertion	X	X	X	
Incorrect sequence	X			
Data Corruption				X
Delay		X		
Masquerade (standard message mimics failsafe)		X	X	X
FIFO errors in intermediate routers		X[1)]		

1) no acknowledgement from routers

FIGURE 56.4 Transmission error types and remedies.

These include:

- the consecutive numbering of the PROFIsafe frames ("sign-of-life"),
- a time expectation with acknowledgement ("watch-dog"),
- a codename between sender and receiver ("password"), and
- data integrity checks (CRC = cyclic redundancy check).

Using the consecutive number, a receiver can see whether or not it received the PROFIsafe frames completely and within the correct sequence. When it returns a PROFIsafe frame with the consecutive number only as an acknowledgement to the sender, the sender, too, will be assured. Basically, a simple "toggle bit" would have proven sufficient. Due to the storing bus elements (e.g., routers), however, a counter from 0 to 255 has been selected for PROFIsafe. Zero is an exception in this procedure reserved for the startup transitions.

In safety technology, it not only matters that a message transfers the correct process signals or values. In addition, updated actual values must arrive within a fault tolerance time, thus enabling the respective device to automatically initiate safety reactions on-site, if necessary (e.g., stop of movement). For this purpose, the devices are using a watch-dog timer that is restarted whenever new PROFIsafe frames with incremented consecutive numbers arrive.

The 1:1 relationship between the master and a slave facilitates the detection of misdirected message frames. Master and slave must simply have an identification (password) that is unique in the network, and can be used for verifying the authenticity of a PROFIsafe frame.

Detecting corrupted data bits through an additional cyclic redundancy check (CRC) plays a key role. The necessary probabilistic examination can benefit from the definitions within the IEC 61508 [1] that considers the probability of failure of entire safety functions. PROFIsafe is following this approach (Figure 56.5).

Accordingly, a safety circuit includes all sensors, actuators, transfer elements, and logic processes that are involved in a safety function. IEC 61508 defines overall values for the probability of failures for different safety integrity levels. For SIL3, for example, this is 10^{-7}/h. For the transmission, PROFIsafe merely takes up 1%. This means that the permissible probability of failure is 10^{-9}/h. This permits suitable CRC polynomials to be determined for the intended PROFIsafe frame lengths. The resulting residual error probabilities of undetected corrupted PROFIsafe frames guarantee the required order of magnitude (see the following sections for details). The quality of the chosen CRC polynomials are such that in the case of PROFIsafe, we no longer depend on the basic error detection of standard PROFIBUS DP using frame checking sequence (FCS) and parity check. Thus, proof is not required that the error detection probability of the basic PROFIBUS DP mechanisms is independent of one of the additional PROFIsafe CRC mechanisms.

© 2005 by CRC Press LLC

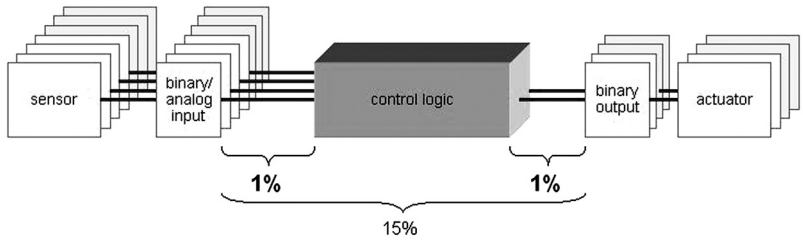

FIGURE 56.5 Safety function acc. IEC 61508.

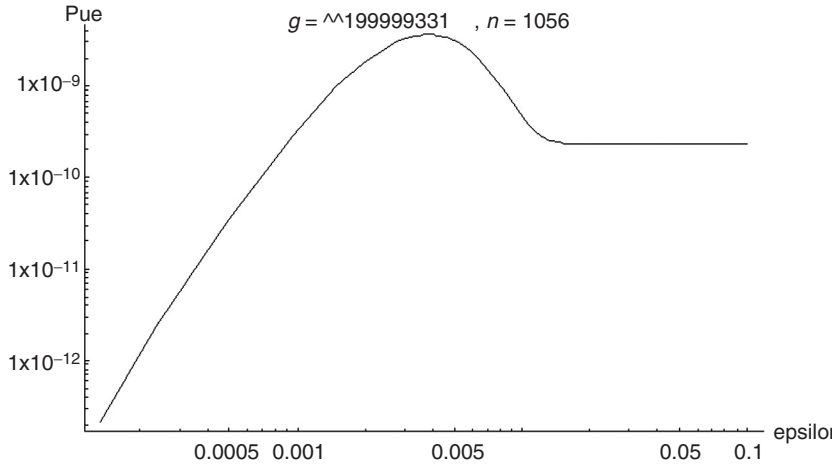

FIGURE 56.6 Example of an improper polynomial.

Besides other things, we need so-called "proper" polynomials. A polynomial is called "proper" when the residual error rate over an increasing bit error rate does not show a curve with pronounced peaks (i.e., when the curve rises continuously monotonic). This has been proven mathematically for the polynomials used for PROFIsafe [5].

16 Bit: 1**4EAB**h 32 Bit: 1**F4ACFB13**h

Figure 56.6 shows an example of an *improper* polynomial. Epsilon on the *x*-axis stands here for the bit error probability.

The residual error probability (*y* -axis) becomes problematic with a high bit error probability (i.e., with a very large number of corrupted bits in a PROFIsafe frame). In order to avoid any insecurity, PROFIsafe uses a patented procedure — the SIL Monitor.

56.7 The SIL Monitor

As mentioned before, PROFIsafe is not relying on the basic data integrity checks of PROFIBUS DP. The entire error detection that is necessary for attaining the required category and/or SIL is advantageously implemented in the additional PROFIsafe protocol. Being dependent on the basic safety structure would require complex verifications for all possible bus configurations. Thus, a mechanism was created that guarantees the compliance with SIL levels over the service life of a distributed safety-related automation solution, irrespective of the components and the configuration used.

© 2005 by CRC Press LLC

Here, all influences that may corrupt the PROFIsafe frames are looked at as a frequency f_w, whatever the cause of the corruption may be: hardware failures, electromagnetic interference (EMI), etc. For each safety function, the F-Host collects the number of detected corrupted PROFIsafe frames reported to it from the associated F-Slaves via the status byte (see Figure 56.7). It also sums up the number of detected corrupted PROFIsafe frames it received on its side. Once the frequency of corrupted PROFIsafe frames exceeds a certain limit (e.g., high bit error rate), the F-Host causes the safe state in the safety function to be activated. This requires monitoring intervals whose lengths depend on the SIL level. For example: T = 5 h for SIL3 and T = 0.5 h for SIL2. The values are calculated such that a maximum of *one* corrupted PROFIsafe frame is tolerated inside the monitoring interval T. The basis for the calculation is the following formula:

$$\Lambda_{HW+EMI+other} = f_W \{P_{UB(typ)} P_{US} + P_{US(typ)}\} = 1/T \{P_{UB(typ)} P_{US} + P_{US(typ)}\} < 10^{-9}/\text{h}$$

P_{US} = maximum residual error probability for 16/32-bit CRC, at a bit error rate of 0 ...0.5.

The SIL monitor is no separate component. It is implemented as a part of the PROFIsafe driver software within the F-Host.

There are two groups of safety-related parameters. The "F" parameters are associated with the PROFIsafe layer and the "i" (= individual) parameters with the individual safety-related technology firmware of a safety slave. The above-mentioned CRC protection is not only used for cyclically ensuring the data integrity of the process signals and process values but also for ensuring the data integrity of the safety-related parameters stored in the individual slaves (such as codename, watch-dog time, etc.). For this purpose, a separate CRC value of these parameters is generated at longer time intervals (≤8 h). This CRC value is then the new start value of the cyclic CRC generation. The same procedure is executed in the F-Host, where the parameters of the slaves are stored.

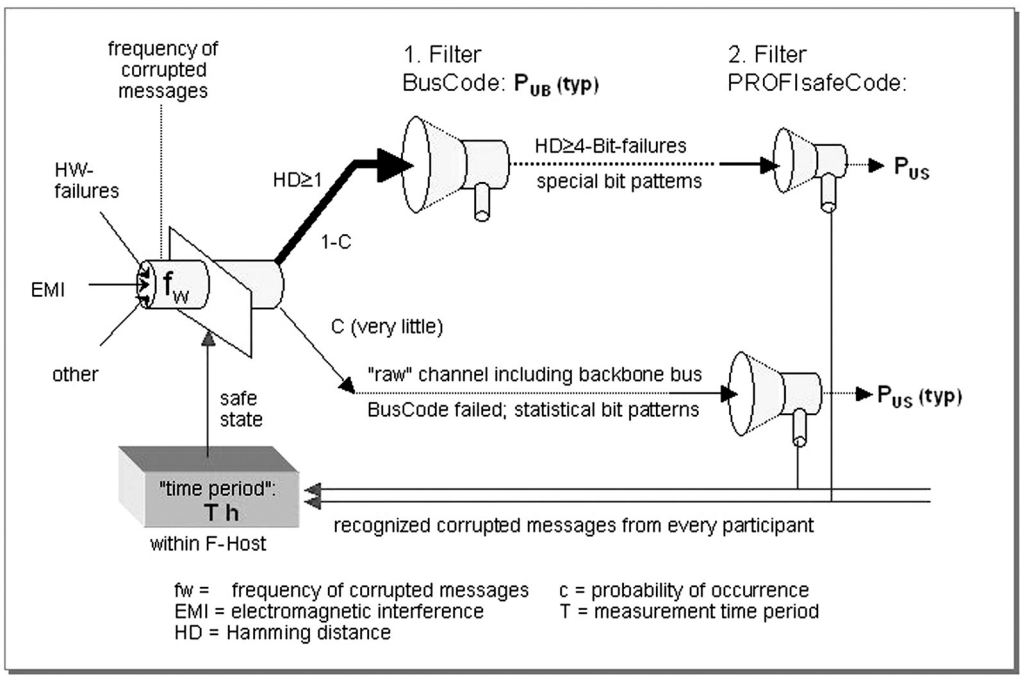

FIGURE 56.7 The SIL monitor.

56.8 PROFIBUS Messages with PROFIsafe Frames

Up to now, we have discussed the processes that PROFIsafe uses for safely transporting the PROFIsafe frames. This section now deals with the concrete mapping onto the PROFIBUS DP communication. Figure 56.8 shows the structure of a PROFIBUS DP message frame.

In this case, only the data unit, the parity bit (PB), and the frame checking sequence (FCS) are of interest. The configuration part of an engineering tool uses the electronic Generic Station Description (GSD) of a particular slave device to arrange for the format of the net process data to be transferred within the data unit of a message between a PROFIBUS DP master and its slave device. The same occurs in the safety case.

Due to the encapsulation via PROFIsafe layers, control and status information must be exchanged between an F-Host and an F-Slave to synchronize the sequences of the state machines. This is necessary, for example, in case an F-Slave requires i-Parameter sets or if the user program within the F-Host wants to change i-Parameter values. Furthermore, the F-Slave can report the detection of an incorrect PROFIsafe frame to the F-Host in order to support the SIL monitor function (Figure 56.8). For the described information exchange, PROFIsafe features a byte that follows the F-process data (Figure 56.9). Another additional byte contains the above-mentioned consecutive number. This number, which is entered by the sender of a PROFIsafe frame ("source-based counter"), is verified by the receiver and returned to the sender in the acknowledgement PROFIsafe frame. Counting is performed in a cycle from 1 to 255. 0 is reserved for the system start.

We have already discussed the fact that factory automation and process automation place different requirements upon a safety system. The former deals with short ("bit") signals that must be processed at a very high speed; the latter involves longer ("floating point") process values that may take slightly more time. PROFIsafe therefore offers two different "F" process data lengths that require CRC protection of different complexity. One length is limited to a maximum of 12 bytes; it requires a 2-byte CRC following the consecutive number. The other length is limited to a maximum of 122 bytes; it requires a 4-byte CRC. The remaining space in the PDU of the message may be used for standard data or other PROFIsafe frames. This results in a very efficient communication with modular F-Slaves or F-Gateways to other safety busses, for example (Figure 56.9).

The consecutive number enables the receiver to monitor the vitality of sender and communication link. Using the acknowledgement mechanism, it is also used for monitoring the propagation times between sender and receiver (Figure 56.10).

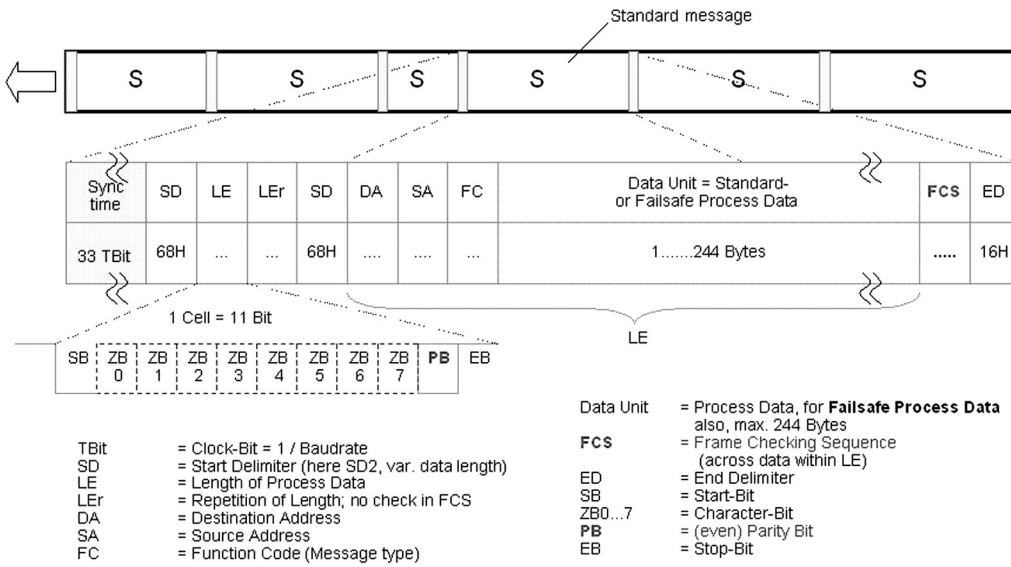

FIGURE 56.8 PROFIBUS DP message structure.

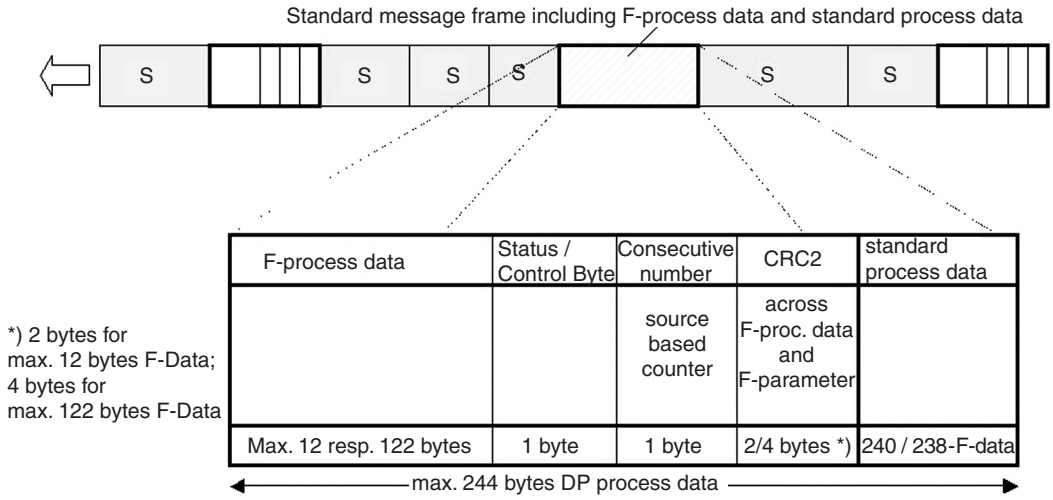

FIGURE 56.9 PROFIsafe frame structure.

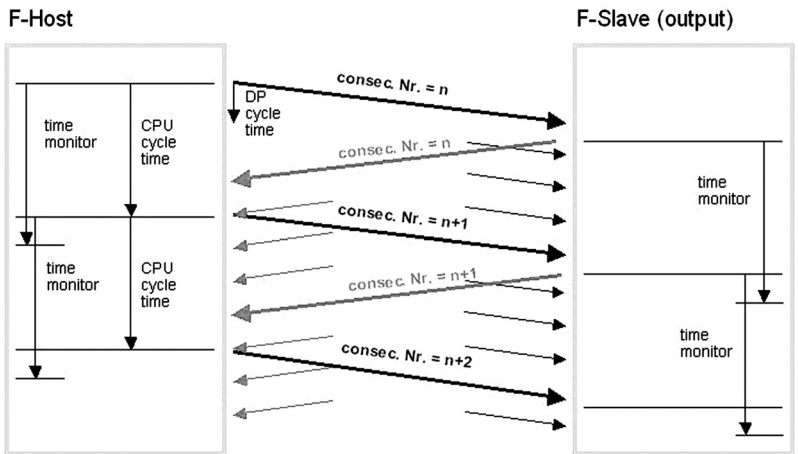

FIGURE 56.10 Monitoring propagation times.

56.9 Synchronization Means (Finite State Machines)

In distributed systems, a potential failure of the supply voltage of the devices and their subsequent restart are of particular importance. This hazard potential has been covered using detailed state diagrams and interaction diagrams in the PROFIsafe guidelines [5].

56.10 Safety-Related Programmable Control Logic

The PROFIsafe guidelines specify how to connect any type of F-Host to PROFIsafe communications. But it does not dictate how safety-related signals and process values are to be processed within an F-Host. It turned out, however, that programming safety circuits in graphic languages, such as ladder diagram (LAD) or function block diagram (FBD) according IEC 61131-3, should be preferred to any textual language. In the process world, the representation in continuous function chart (CFC) has proved to be helpful. Approved relay-based safety circuits now can be offered as a standard certified software library [6].

© 2005 by CRC Press LLC

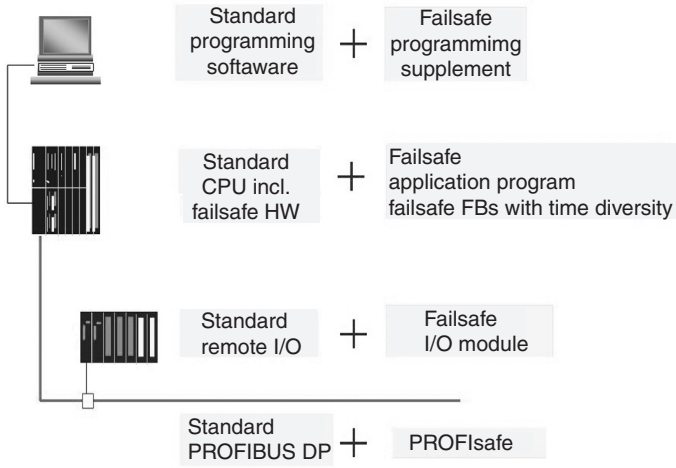

FIGURE 56.11 Combined standard and safety controls.

There are manufacturers offering the option of retrofitting safety-related user programs for some of their standard programmable logic controllers, which fulfill the necessary requirements for safety-related applications. The safety software is of a time diversity structure; it is executed in protected areas where it cannot be influenced by the standard application program. Special F I/O modules can supplement the associated standard remote I/O field devices (see Figure 56.11). CNC control systems, too, provide the connection for PROFIsafe field devices.

56.11 Commissioning and Repair

In order to be able to "address" the individual signals and/or process values during programming, the fieldbus must be *configured* using an engineering tool. In this configuration, the fieldbus participants arrange for their network address, the input signals, the output signals, the data formats, the transmission rate, etc. In case of F-Slaves, additional steps are required that supply parameters to the PROFIsafe layer: Codename, watch-dog time, etc. For the computer-aided calculation of total reaction times, in particular, and, consequently, the determination of watch-dog times, the device manufacturers specify the processing time of sensors and actuators in their electronic data sheets (GSD). During startup of the fieldbus network, the host/master sequentially provides all slaves with the necessary parameters including F-Parameters before it starts cyclic operation [7].

Due to the wide acceptance of microcontrollers, various new devices such as laser scanners and light curtains have turned up in the past even for safety applications that feature a certain complexity and require system support to be able to develop their full functionality. These are, for example, teach-in, rapid device replacement in the event of a malfunction, predictive diagnostics, self-testing and trend analysis, and more.

In its profile guidelines, PROFIsafe has shown ways for mastering these tasks — the so-called 3-component model that separates the responsibilities of device manufacturers and system manufacturers by using suitable interfaces. In the simplest case of an F-Slave that does not require any individual ("*i*") parameter, providing the safety device with PROFIsafe connection and a corresponding electronic data sheet (GSD file) proves sufficient. A possible example is a level switch. Slightly more effort is required in the case of a safety device. It can be connected to a laptop via a separate RS-232 interface. In order to perform diagnostics, for example, it uses a special parameterization and diagnostics program. In this case, the laptop or PC communication can also be routed via the PROFIBUS, using acyclic services that are accessible via the new PNO standard *FDT/DTM* interface technology [8]. Typical representatives of such devices are ESD (electronic shutdown) valves. A device manufacturer would have to provide the safety

© 2005 by CRC Press LLC

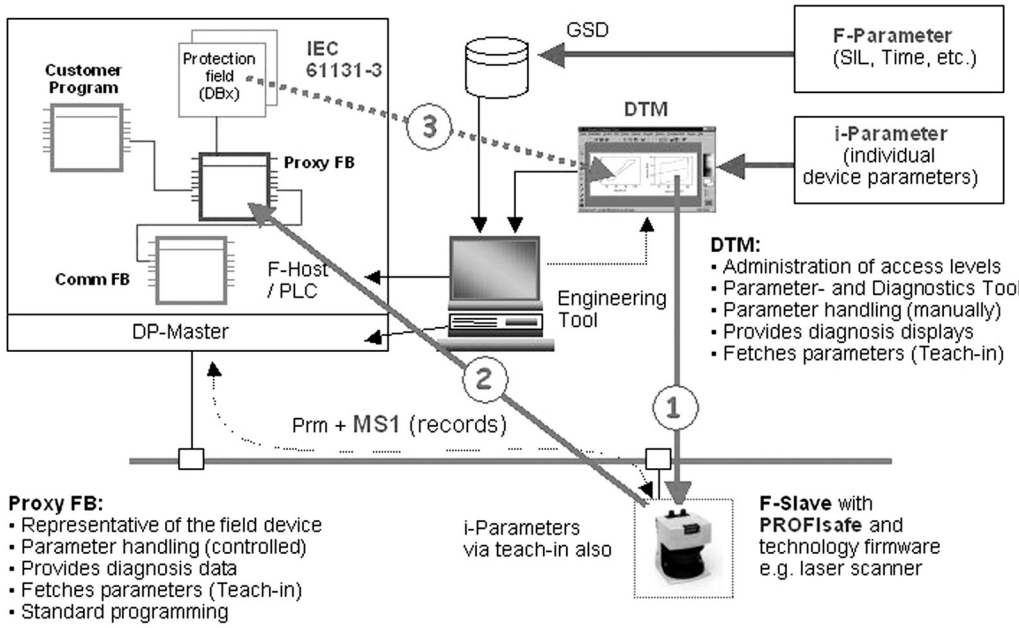

FIGURE 56.12 Parameter handling with powerful safety devices.

device, a GSD file, and a DTM program. The DTM program corresponds to the special parameterization and diagnostics program but it uses the standard FDT interface instead.

The most demanding devices are the ones that require user-program-controlled parameter value assignment in addition to the above-mentioned features. This requires an additional so-called proxy function block (FB) in the controller (e.g., F-Host). Typical representatives of this device class are the laser scanners for which we want to "play" a user scenario (Figure 56.12). DTM represents the parameterization and diagnostic program of the laser scanner manufacturer.

The FDT framework of the engineering tool arranges for the acyclic connection between the DTM and the safety field device. A user can carry out the parameter value assignment of the laser scanner (configuration of the protection field, e.g.) as he/she used to do it via the previously used RS-232 interface. The safety measures in the software, such as divers representations and various authenticity mechanisms, can remain the same. During each upload or download, the "i" (individual safety-related)-Parameters are CRC-protected block wise.

There are new steps now. With the help of the DTM, the user triggers the upload of the i-Parameters from the device into the F-Host. To do this, the proxy FB generates instant data for accommodating the i-Parameters. To ensure correct addressing and correct i-Parameters, the DTM — with the help of the engineering tool — reads the instance data of the proxy FB, and compares it with the i-Parameters directly read from the safety device. From here on, the proxy FB would be able to load the i-Parameters automatically into the laser scanner in the event of a device replacement. By checking its device type and its production number, the proxy FB finds out whether the device is correct or is a different one.

56.12 Availability

The availability plays a significant role in safety technology. It is simply a precondition. There is too much of a risk that a frequent — and apparently groundless — trip of the safety devices causes the system to shut down ("Bhopal" effect) [9]. There are mainly five areas that influence the availability of a system:

© 2005 by CRC Press LLC

- Design/construction of the components
- Facility layout
- Operating conditions
- MTBF of the components (bathtub curve)
- Requirements for operator actions.

In the meantime, most standard automation components and systems on the market have reached a design and construction quality standard that ensures high reliability (high meantime between failures). Among the causes that led to this situation are standards, test institutes, and certifications. However, the availability (up-time in relation to down-time plus up-time) may deteriorate in safety systems that are based on standard systems. Redundant standard components (e.g., two or three controllers) that require synchronization can cause this. The safety device trips if one component takes longer than the other one due to an external event. This risk is also in the redundant implementation of sensors whose measured values diverge briefly (discrepancy). PROFIsafe therefore endeavors to support certified safe integrated F-Slaves that take the risk away from the user as much as possible. Standard fieldbus systems, even proven-in-use, without additional mechanisms like PROFIsafe or special overall risk assessments of an application may not be considered safe.

In order to prevent electromagnetic interference from affecting the operation of a system, the PROFIBUS User Organization has published installation guidelines [10] whose utilization in bidding procedures is recommended, thus creating a clear situation right from the outset. They specify aspects like grounding, shielding, lightning protection, etc. PROFIsafe makes the satisfaction of these installation guidelines a prerequisite for the operation.

An additional redundant structure of the entire system provides a significant increase of the availability. PROFIsafe has taken this mode of operation into account right from the outset.

The operating conditions of a system have a strong influence on the reliability/availability. As we all know, a temperature rise of 10 K reduces the service life of an electronic device by 50 percent. Here, PROFIsafe can merely give recommendations. Devices should be designed for the usage in one of the following zones: Office environment, "enclosed-type" operation within racks, process participation inside and outside a building.

The means of the *predictive diagnosis* is used in order to avoid unexpected late failures toward the end of the service life of a field device. The proxy FBs are provided in the PROFIsafe concept. These proxy FBs can execute, automatically and periodically, test programs in the field device in order to determine its states and the trend. This enables risky units to be replaced at a time when the process is stopped anyway.

The availability of a system is also reduced if the user is unable to handle it properly due to complexity or variety. PROFIsafe therefore currently strives in the PROFIBUS User Organization to support all activities of standardizing the device performance characteristics and the software user interfaces [11].

56.13 Status of Profile Guidelines

At Hanover Fair 1999, the PROFIBUS User Organization had published version 1.0 of the PROFIsafe guidelines. It has been confirmed by positive reports from the German Institute for Occupational Safety and Health (BIA) and the worldwide operating Safety-Assessment Organization (TÜV). In the meantime, these guidelines have been enhanced by the requirements for the integration of any given safety-related control system (e.g., computerized numerical controls). Since most F-Host manufacturers currently use diversity hardware, the PROFIsafe working group also dealt with possible connections to these systems. The most common data types and rules for its arrangement have been defined. Via the information within a GSD file of a field device, the corresponding PROFIsafe layer driver in the F-Host can now be set up. Version 1.20 of the PROFIsafe guidelines was published in the fall of 2002. The guidelines and current notes can be found in the Internet under http://www.profibus.com.

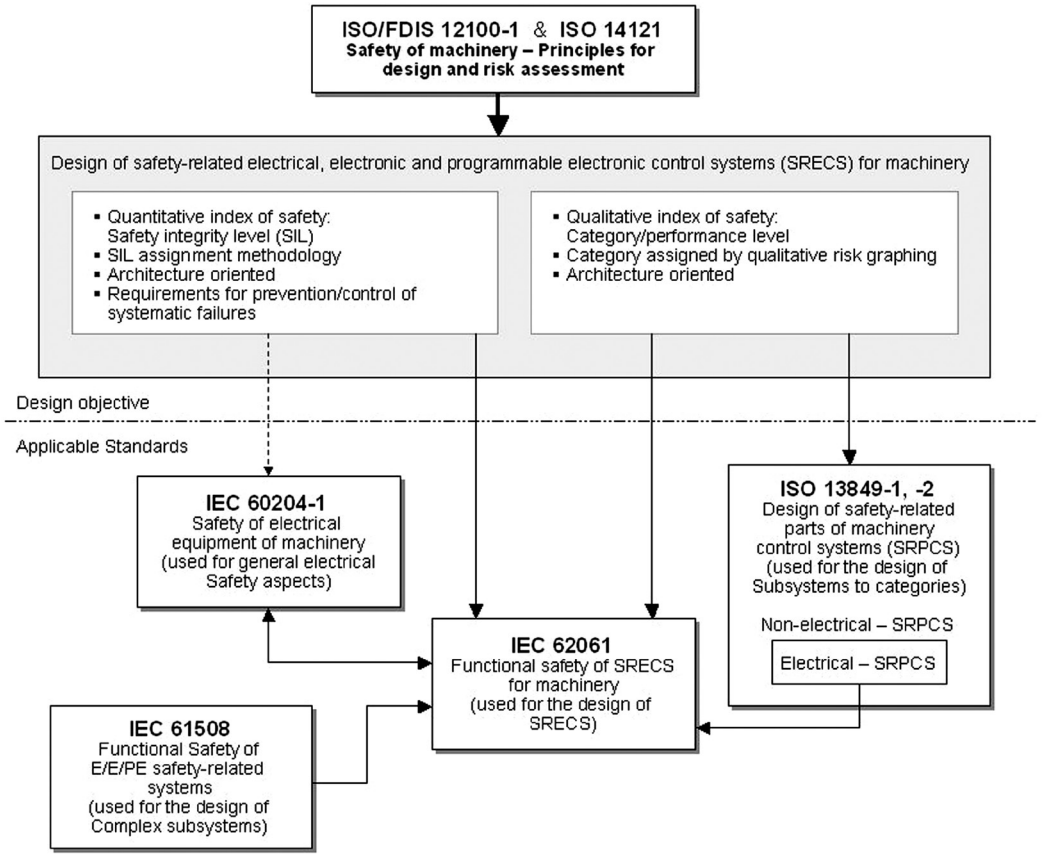

FIGURE 56.13 Relationship between relevant standards for machinery.

56.14 Standards Catching Up

The development of PROFIsafe was based on the new IEC 61508, which recently became European standard and mainly deals with the software development procedures. Up to now, various standards do not go yet into the new possible solutions and are therefore revised and/or newly created. This includes IEC 61511, which deals with the particular problems of process safety on the basis of IEC 61508.

For safety-relevant machine controls with programmable electronics, IEC 62061 also refers to IEC 61508. Figure 56.13 shows how this standard is embedded within other safety-relevant standards. In the U.S.A., existing restrictions against programmable electronics for emergency stop functions disappeared with the new NFPA 79 version that was published by the end of 2002.

56.15 Peculiarities for Different Industries

Within factory automation, the discussion about the need of using a separate safety bus in addition to the standard fieldbus for the implementation of distributed safety technology comes up time and again. For PROFIBUS and PROFIsafe, this vexatious second bus is not a problem. The single-cable solution with a combined standard and safety-related control in one CPU and the solution with separate transmission lines and separate CPUs can both be implemented using the same means. However, compared to a heterogeneous solution with two different bus systems, this "homogenous" solution

© 2005 by CRC Press LLC

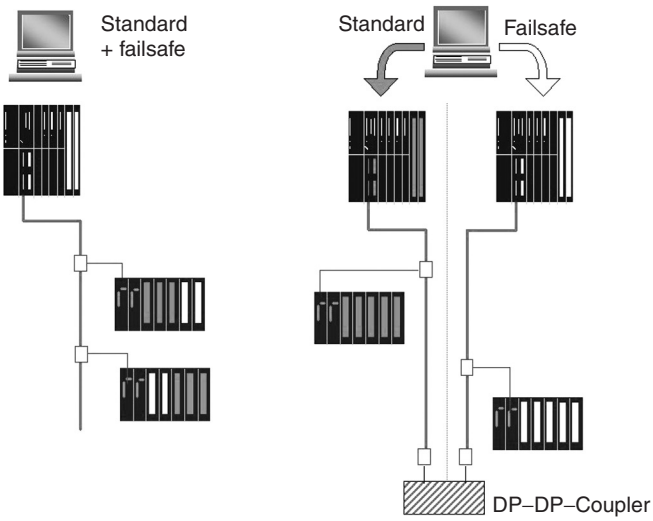

FIGURE 56.14 Safety on one transmission line or separately.

provides advantages through the same technique and engineering tools of uniform handling (Figure 56.14). Many users are following a migration strategy. First, within existing facilities, the new PROFIsafe technology will replace the relay-based safety technology via a second fieldbus segment. At the next opportunity and after some experience, it is planned to go with the combined solution due to the many obvious advantages.

In the meantime, several activities have taken place at the process automation side. As we know, safety applications in process engineering require a consideration that exceeds the functional safety. Pressure and temperature in a process, for example, cannot always be "monitored" independent of each other. A high availability of sensor functions requires a large degree of design skill and experience. To a large degree, the topic of "proven-in-use" plays a large role.

Up to now, the part of the protection equipment — which mostly represents cases similar to SIL2 — has been solved with standard field devices and 4–20-mA transmission technique. Communication faults, such as line interruptions or short circuit, were recognizable, the devices were proven-in-use, and safety monitoring was performed in the F-Host system by interpreting redundant signals and voters. In the case of microprocessor-equipped equipment, guidelines like the NAMUR recommendation NE79 defined the necessary prerequisites. These include the proof that the software/firmware has been developed according to generally recognized quality standards. Furthermore, the user expects facilities such as watch-dog timer, memory test, and protection against inadvertent parameter changes. The new recommendation NE97, which NAMUR published at the end of 2002, deals with the subject "Fieldbus for Safety Tasks." Among other things, this recommendation shows two possible solutions that can easily be implemented with PROFIsafe.

A proven-in-use field device, developed according to NE79 that is connected to PROFIBUS, could actually be used for applications up to SIL2 if the possible communication faults that are known in bus operation: Address corruption, loss, delay, etc., could be eliminated. As we already know, this is possible if we use a PROFIsafe protocol that is implemented in a single channel manner. In the future, this solution permits proven-in-use standard PROFIBUS field devices to be operated in standard operation mode or optionally in safety mode, just by changing a single parameter. The user is at liberty to use certified products (see Figure 56.15).

In many systems, the installed proven-in-use field devices are retained, and an additional fieldbus wiring is installed via a so-called remote I/O. For this operating mode, too, NE97 provides for a solution.

© 2005 by CRC Press LLC

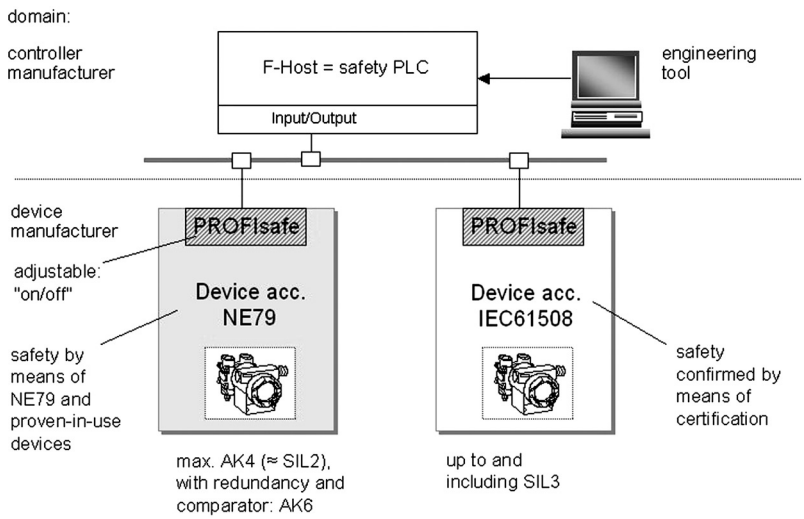

FIGURE 56.15 PROFIsafe in field devices for process automation.

The process automation field devices are usually subject to a strong standardization of device model and device parameters. Parameter value assignment, too, is expected to be as uniform and consistent as possible. To take this into account, the PROFIBUS User Organization has started to integrate PROFIsafe communication compatibly into the existing "PA device model" [12]. The related specification [13] especially deals with the following topics:

- switching between standard/safety mode,
- preparation and commissioning phases,
- new parameters in the "Physical Block" of the PA device model,
- safety-related data structures for the cyclic data exchange, and
- configuration data.

As already mentioned, the field devices should be usable in standard mode and in safety mode. Thus, it is planned to achieve this switch by corresponding parameter settings in the related GSD file, and thus, during the start-up of the field device. The required safety integrity level (SIL) is then communicated via an F-Parameter (F_SIL).

Due to the contingency that parameters have to be edited during operation, a state machine has been designed for the individual commissioning phases. The three states are: "None Safety Mode — S1," Safe Commissioning — S2," and "Safe Operation — S3."

This extended state machine provides the option of using additional states that permit existing parameter assignment tools based on Electronic Device Descriptions (EDD) to be used [14]. In this case, the parameter assignment usually is performed offline and the device is sealed by soldering or similar procedures.

The use of safe parameter value assignment procedures also permits i-Parameter value assignment according to the PROFIsafe Profile Guidelines [5] to be performed at runtime directly in the safe state S3 using FDT/DTM.

Additional parameters are required in such a safety-related field device for mastering the new tasks. Currently, there is one parameter for setting the SIL level, one parameter for displaying the operating states S1 – S3, and a device-individual password for write protection.

Additional data formats for the PROFIsafe frame have been supplemented with the standardized data formats for the PA device model for cyclic data exchanges. The corresponding configuration identifiers have been defined.

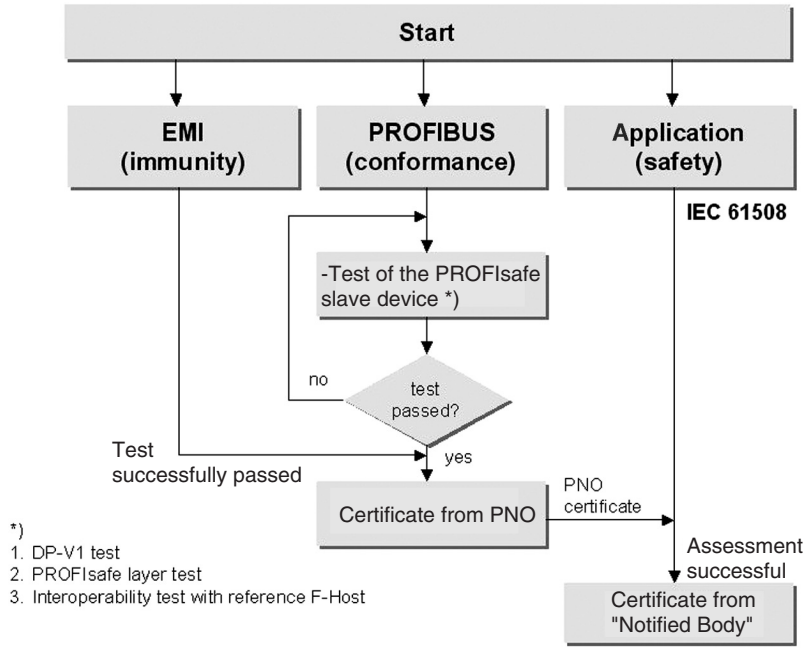

FIGURE 56.16 The PROFIsafe certification procedure.

56.16 Environmental Conditions

In the meantime, the PROFIBUS User Organization has published further specifications since most safety standards ignore bus operations. One of these is defining the boundary conditions for safe communication [15]. It deals with the topics of installation guidelines, electrical safety (overvoltage shock protection — SELV/PELV), power supply units, and immunity to electromagnetic interference. The other is describing a policy for all PROFIBUS member companies and providers of safety-related devices dealing with responsibilities and the quality of products and services [16].

56.17 Test and Certification

The PROFIsafe mechanisms are based on finite state machines. Thus, it was possible via a validation tool for finite state machines to mathematically prove that PROFIsafe is working correctly even in cases where more than two independent errors or failures may occur. This was achieved systematically by generating all possible cases for "test-to-pass" and "test-to-fail" situations. They have been extracted as test cases for a fully automated PROFIsafe layer tester, which is used to check the PROFIsafe conformance of safety-related devices. It is part of a three-step procedure within the overall certification process (Figure 56.16) [17].

56.18 Development Tools and Support

Using PROFIBUS/PROFIsafe in factory automation with short reaction times, and — on the other hand — in hazardous areas in process automation with lowest power dissipation places contradictory tasks. Since most modern devices use microprocessors, implementing the PROFIsafe procedure in software is an obvious solution. The operating conditions determine the selection of the microprocessor with respect to high performance or low power dissipation. PROFIsafe automatically adapts ideally; it requires merely some Kbytes of free memory: no additional power supply and no additional space in the confined enclosures. PROFIsafe becomes a part of the device-specific safety software.

© 2005 by CRC Press LLC

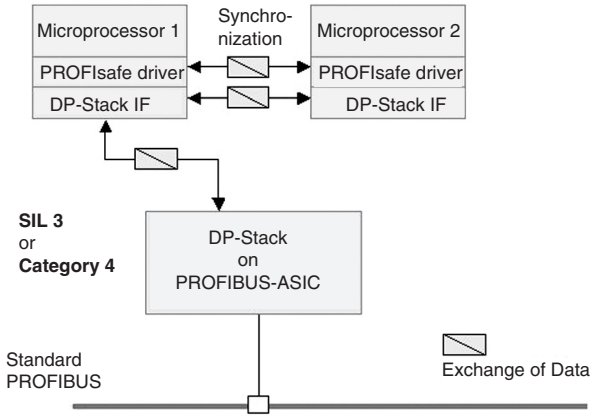

FIGURE 56.17 Generic PROFIsafe driver for slaves.

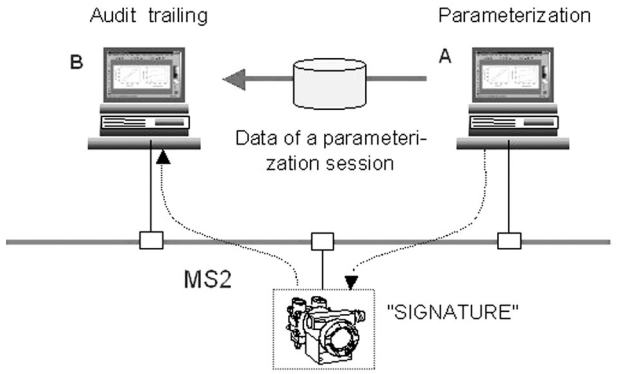

FIGURE 56.18 Audit trailing for secured safety parameters.

Immediately after completion of the specification, a company consortium started a joint development of a "generic PROFIsafe driver software" for slaves. Generic in this context means that the driver has been implemented in ANSI-C, and according to the encoding rules for safety technology for different microprocessors and C compilers. Although it should preferably be used in dual-channel mode (see Figure 56.17), it may also be used in single-channel mode (see Figure 56.15).

For the specifications, the approval authorities merely issue so-called "positive technical reports." With the acceptance of the software in a concrete hardware, we now have a TÜV certificate with the number: Z2 01 12 20411 008.

Without the help of simplifying step-by-step development equipment, the development of safety-related fieldbus devices turned out to be difficult due to the safety measures (consecutive numbering, watch-dog timers, etc.) that have to be fulfilled at any time in a real environment. The members of the PROFIBUS User Organization are now providing development boards and PC Software (PROFIsafe Monitor) to develop step by step from PROFIBUS DP to the PROFIsafe communication level.

56.19 Products

Currently available products are safety-related programmable controllers and numerical controllers, remote-I/O for IP20 and IP67, laser scanners, light curtains, motor starters, frequency converters, drives, gas and fire sensors, etc.

For further actual details, see www.profibus.com.

© 2005 by CRC Press LLC

56.20 Prospects

The sophisticated safety-related devices mentioned in this chapter with its many possibilities to use i-Parameters to adapt to all kinds of safety applications in a flexible manner are leading to the requirement for continuous automatic monitoring of security, safety, and data integrity. Thus, regulations like 21 CFR 11 [18] are defining

> Rules for the use of secure, computer-generated, time-stamped audit trails to independently record the date and time of operator entries and actions that create, modify, or delete electronic records. Record changes shall not obscure previously recorded information. Such audit trail documentation shall be retained for a period at least as long as that required for the subject electronic records and shall be available for agency review and copying.

PROFIBUS suggests in its device-independent Profile Guideline, Part 1 "Identification & Maintenance Functions" [19] the use of asset identification parameters and the parameter SIGNATURE to allow parameterization tools to store a "security" code as a reference for a particular parameterization session. Audit trailing tools may retrieve the code for integrity checks at any time. Together with the "asset identification parameters" consisting of MANUFACTURER_ID, ORDER_ID, and SERIAL_NUMBER, the SIGNATURE parameter allows unambiguity of the session data.

PROFINET: Due to its "Black Channel" approach, the PROFIsafe principle will be easily portable to PROFINET once this new technology is well established on the market. In the meantime, safety device manufacturers are well advised to start with a PROFIBUS DP/PROFIsafe version and find an already existing, fast-growing market that is receptive to the new safety technologies of PROFIsafe.

57.1 Introduction

One of the initial driving forces for the introduction of communication networks in automotive vehicles was to replace the numerous cables and harnesses and thereby reduce the number of connection points, cost, and weight. Moreover, *multiplexing*, as vehicle networking is traditionally referred to in the automotive industry, is an important enabler of new and increasingly complex functions. Today, using software and networking, it is possible to create new functionality, such as an antiskid system, that was considered unfeasible, both with respect to cost and functionality, some ten years ago.

The vehicle industry strives to enable cost-effective implementation of new functionality. A network enables reuse of sensor data and other calculated values. Moreover, distributed functions can be facilitated for truly distributed problems like coordination and synchronization of brakes.

© 2005 by CRC Press LLC

Another driving force is the demand for increasingly efficient diagnostics, service, and production functionality. The network in a vehicle should provide functionality not only during normal operation of the vehicle but also in the after market and during production. It should also provide communication for diagnostic functions in control units, and provide a single point interface to service tools to meet goals on more efficient service.

There is a wide span of requirements on the communication infrastructure in today's vehicles. The vehicle industry works with demands on functionality, reliability, and safety, but also with demands related to product variation, extendability and maintenance of delivered products, and integration of supplier components. This implies high requirements on network flexibility in terms of adding or removing nodes or other components. Moreover, part of the functionality has stringent requirements on real-time performance and safety, for example, safety-critical control applications. Other parts of the functionality, such as the infotainment applications, have high demands on network throughput. Yet, other parts require only lightweight networks, as, for example, locally interconnected lights and switches. All of these varying requirements in vehicle networks are reflected in the architecture, implementation, and operation of a modern in-vehicle network.

In this chapter, we try to describe the context in which today's vehicle industry work and develop distributed systems. This is uncovered in three case studies covering passenger cars, trucks, and construction equipment. Although the three different vehicle domains have much in common, there are also distinct differences, for example, in production volume and the number of different models. In fact, these differences are so important that they result in three quite different network architectures.

The contributions of this chapter are (1) the presentation of three case studies and (2) an analysis of the relation between business needs and architectural design issues of networking in automotive vehicles. The three case studies cover much of automotive industry and describe the business context and demands for automotive networking.

The rest of this chapter is organized as follows: Section 57.2 provides a structuring and presentation of important issues and challenges in automotive networking. An introduction to automotive network technologies is provided in Section 57.3. Section 57.4 presents the three case studies and in Section 57.5, we analyze the architectures with respect to the different business needs. Finally, in Section 57.6, we draw some conclusions; in Section 57.7, links to relevant web sites are provided.

57.2 Challenges

In this section, we present some current trends in vehicle networking, together with descriptions of some of the context in which vehicle networks are developed today. The presentation is structured into sections on the main aspects of vehicle networks, namely functionality, cost, standards, and architecture.

Functionality

Functionality in a vehicle is not limited to end-user functions, but also includes functions to support, for instance, production and service. In this section, we will outline some important groups of functionality, both supportive and end-user functions that are often addressed in vehicle development.

Feedback control includes functions that control mechanical systems in the vehicle, for example, engine control and anti-lock-brake-systems. Feedback control systems can be combined to achieve advanced control functions for vehicle dynamics. Examples are electronic stabilizer programs, ESP, and other chassis control systems like antiroll systems. Furthermore, the vehicle manufacturers strive to achieve cheaper and more flexible functionality by going toward x-by-wire solutions. X-by-wire solutions, such as steer-by-wire, are achieved by replacing, for example, mechanical or hydraulic solutions by computer-controlled electrical systems.

Discrete control, in this context, includes simple functions to switch on or off devices, for example, control of lamps or wipers. The challenges for this group of functions often relate to the sheer number of

© 2005 by CRC Press LLC

such simple devices and thereby the amount of traffic on the network. Another problem is that these functions often interact logically in nontrivial ways.

Diagnostics and service: Functions in this group are used in vehicles to support the maintenance of delivered products. Diagnostic functions provide means to diagnose physical components, such as sensors, as well as software properties, such as version number and network load. Service functions provide means for updating the electronic system by downloading new software and to test vehicle operation. Because of the large amount of retrievable information, solutions are needed for automatic, or at least tool-supported, diagnoses, and service.

Infotainment refers to in-vehicle systems not related to driving the vehicle, but more related to information and entertainment. Examples are Internet connection and video consoles. This leads to requirements on high bandwidth for vehicle networks. Components like network controllers and software are often purchased off-the-shelf, and must be integrated in a harsh physical environment. Components must also be integrated without impacting safety-critical functionality in the vehicle.

Telematics [1] is a name of the set of functions that uses wireless communication networks outside the vehicle to perform their task. This includes functions in the vehicle and outside the vehicle. There is a strong trend in the vehicle industry to increase the use of telematics. Examples include fleet management systems for commercial vehicles, maintenance systems, and antitheft systems.

Cost

Providing cost-efficient network architectures is a challenge in several respects. The architecture should exhibit properties that support a variety of business needs. Business needs in the context of vehicle network systems often include lifecycle aspects of development, production, maintenance, and service.

Fixed and variable cost: Building a vehicle is a process of finding the best compromise between conflicting aspects, and one of the most important trade-offs is to find the balance between cost, performance, and functionality that provides the best business case. The cost can be divided into variable cost (the cost of purchasing the physical components that go into the vehicle and the resources consumed during production) and fixed cost (the investments made in development, production facilities, tooling, after market support, etc.). There is always a trade-off to be made between the two, which depends heavily on the production volumes, and the relations between various cost factors[2].

Maintenance and service: To reduce the lifecycle cost of the product, it is often important to consider various aspects of maintenance. To facilitate maintenance, it is desirable to develop architectures that allow future upgrades and extensions to the delivered product. Servicing delivered products requires the ability to upgrade both software and physical components. Configuration management and distribution is then a crucial issue, for example, to determine the compatibility of new components in an existing configuration.

Standards

The use of standards is motivated by the need to meet goals related to:

- Cost reduction,
- Integration of supplier components,
- Increased reliability of components, and
- Commonality in tools used in, for example, development, diagnostics, and service.

One example is the Controller Area Network (CAN) standard that has provided the vehicle industry with cheap network controllers. Due to the large volumes of these controllers, they are tested to a great extent (in the field) under diverse conditions, which increases reliability. A challenge is to standardize properties of software in similar ways, to accommodate reuse of software components, and to allow for common development tools. Although there are great benefits in using standards, they should also allow for proprietary solutions in key areas of a domain in order not to hinder competitive and brand-specific solutions.

© 2005 by CRC Press LLC

Architecture

The IEEE has the following definition of architecture[3]:

> *Architecture: the fundamental organization of a system embodied in its components, their relationships to each other and to the environment and the principles guiding its design and evolution.*

For automotive electronic architectures, the components are mainly the electronic control units (ECU), and the relationships between them are the communication networks. The environment is the vehicle itself, as well as the lifecycle processes that must support it. An important aspect when designing the architecture is the physical packing of the ECUs. A guideline is to place them as close as possible to their inputs and outputs, to reduce the wiring length (and thereby the cost and weight). At the same time, the architecture must be easy to assemble on the manufacturing line, and the overall architecture of the car puts restrictions on the possible locations, since space is generally very limited. Aspects of maintenance must also be considered when designing the architecture in order to facilitate aftermarket service of ECUs and software. Also, environmental factors like temperature and EMC influence the location of the ECUs. As the product development is increasingly focused on platforms and commonality, the ability to create many variants from the same overall structure is important.

57.3 Network Technologies

In this section, we will introduce present and emergent network technologies in the automotive industry. The network technologies in focus are different types of field busses that meet the requirements of automotive applications and communication software and high-level protocols. Throughout the section, we will give an overview of automotive network technologies in general and provide more details about technologies covered in the case studies of Section 57.4.

Automotive Field Busses

Control Busses

The dominant bus technology for power train and body electronics in vehicles is the CAN standard[4]. The protocol has gained widespread acceptance because of the relatively high bandwidth (at the time of introduction) in conjunction with its predictability and reliability. Due to the extensive use of the protocol, dedicated controllers for CAN are cheap and, moreover, integrated in many microcontrollers. The CAN specification is divided into standard CAN (CAN 2.0A) and extended CAN (CAN 2.0B), where the length of the message frame differs. The wide use has made processors available with integrated CAN controllers. CAN is a broadcast bus designed to operate at speeds of up to 1 Mbps. Data are transmitted in messages (frames) containing between 0 and 8 bytes of data. An identifier is associated with each message. The identifier serves two purposes: (1) assigning a priority to the message and (2) enabling receivers to filter messages.

CAN is a collision-detect broadcast bus, which uses deterministic collision resolution to control access to the bus. During arbitration, competing stations are simultaneously putting their identifiers, one bit at the time, on the bus. By monitoring the resulting bus value, a station detects if there is a competing higher priority message and stops transmission if this is the case. Because identifiers are unique within the system, a station transmitting the last bit of the identifier without detecting a higher priority message must be transmitting the highest priority queued message, and hence can start transmitting the body of the message.

Low-Cost Busses

Low-cost busses have been introduced in automotive applications in order to facilitate cost-effective integration of components such as smart sensors and actuators into the vehicle network. Smart sensors and actuators have some ability to process (typically filter, or translate) measurements and send signals on the network, whereas nonintelligent ones are wired to the I/O of an ECU that handles processing. The

© 2005 by CRC Press LLC

introduction of low-cost controllers and single-wire networks is made at the expense of bandwidth, which is relatively low for these busses. Besides being a low-cost alternative to adding a full featured ECU, the low-cost busses present a way of reducing the complexity of the master node and facilitate differently equipped product variants with only one ECU configuration.

One bus in this category is the Local Interconnect Network (LIN)[5], which is a serial bus based on the Universal Asynchronous Receiver Transmitter (UART) present in most microcontrollers. LIN implements a time-triggered protocol, where a master node handles synchronization on the bus. By letting a master node handle all synchronization on the network, temporal predictability is achieved without the need for arbitration by slave nodes. LIN provides low bandwidth (up to about 20 kbit/sec) and data packages can be of the size 2, 4, and 8 bytes. The performance, in terms of bandwidth and network services, of a LIN network is limited compared to CAN; but the LIN concept provides for simple inexpensive slave nodes making it possible to also connect very simple components to a network. The LIN standard provides not only the protocol specification but also an application interface and a network configuration description that conforms to the LIN configuration language description. The application interface provides a software-level abstraction for interfacing the network, whereas the configuration description holds information on the composition of the complete LIN network.

Other busses included in this category are the TTP/A bus[6], which is also a time-triggered bus based on UART, and the SAE 1850[7], an asynchronous serial protocol.

Infotainment Busses

Since vehicles are becoming equipped with more and more multimedia and telematics applications, the need for dedicated infotainment busses has arisen. A network in this category is MOST (Media Oriented Systems Transport)[8], which is based on optical fiber technology, and provides bandwidth up to about 20 Mbit/sec. MOST have services optimized for infotainment applications. The topology supported is ring, star, and daisy chain. The network is synchronous with a timing master, making it possible for devices to synchronize their operation; this is suitable for streaming of audio and video. MOST also has defined mechanisms for asynchronous, packet-based data, which can be found in, for example, Internet traffic.

Other infotainment busses relevant to automotive applications are the IEEE1394 [9] and the wireless Bluetooth [10], and IEEE 802.11b [11] protocols. (Bluetooth and IEEE 802.11b are used mainly to connect external devices.)

Time-triggered Safety-Critical Busses

Emergent safety-critical functions, such as x-by-wire applications, where x may be, for example, steer or brake, have forced the development of bus technologies for use in automotive vehicles that meet demands of very high reliability and timeliness. A group of busses that meet this demand are evaluated by the automotive industry. These busses are all based on the time-triggered paradigm where the progression of time initiates data transfers greater than asynchronous events. The time-triggered busses provide synchronous communication without the need for arbitration. Moreover, they offer mechanisms for redundant networks and have built-in support for a global time base. Therefore, the time -triggered protocols are suitable for implementing safety-critical control functions with stringent demands on low latency and low jitter. Three time-triggered protocols developed for automotive use are FlexRay, TTP/C, and TTCAN. All these protocols offer services, such as global time and time-triggered communication enabling pre-runtime scheduling of communication. Moreover, all three protocols also make it possible for event-triggered traffic to coexist with time-triggered communication.

The FlexRay communication protocol [12] supports bandwidth up to 10 Mbit/sec with the possible topologies bus, star, and multiple star. Available communication controllers for the TTP/C [13] protocol support 25 Mbit/sec for time-triggered transmission and 5 Mbit/sec for event-triggered transmission. TTP networks can contain up to 64 nodes and the cabling topology can be bus, star, or any combination of the two. Finally, TTCAN [14] is a further development of Extended CAN (version 2.0B), which like Extended CAN is limited to 1 Mbit/sec.

© 2005 by CRC Press LLC

Summary

Table 57.1 shows the typical use of some different busses in automotive industry. As indicated, CAN is used in many different application areas. However, for safety-critical control, CAN does not have the same abilities as Flexray, TTP/C, and TTCAN, which offers global time base and redundant networks. Furthermore, for simple nodes the CAN solution is more expensive than LIN.

High-level Protocols and Communication Software

High-level protocols and communication software have been introduced in automotive industry to address problems related to integration, configuration, and timing properties. The high-level protocols span from proprietary representation of a given type of engineering data by a specific CAN identifier to powerful methods and tool sets automating large parts of the network configuration. Depending on application area, both proprietary and standardized protocols are in use.

In this section, we will describe three different high-level protocols; Volcano, SAE J1939, and MOST. These protocols are intended for different areas of application within the automotive domain.

Volcano [15] is a communication concept used throughout the Volvo Car Corporation for managing network traffic. Currently, Volcano supports the CAN and LIN busses. The basic concept in Volcano for communication between software components is signals, where a signal typically represents some engineering data. Through the Volcano API, the underlying network technology is hidden from the application engineer. Moreover, the engineer is not concerned with issues regarding assignment of signals to network frames. Instead, this is done automatically ensuring signal timing requirements.

The Volcano concept also addresses vehicle manufacturer-controlled integration of components developed by suppliers. This is done through the use of the Volcano API and by separate specification of the signals used by a component and the network configuration. The network configuration is provided by the integrator and specifies how signals are to be transferred over the network.

In the domain of heavy vehicles, the J1939 standard [16] for communication between components has been created by a number of vehicle manufacturers and subsuppliers. SAE J1939 uses standard CAN 2.0B for communication and communicates with 250 kbit/sec. J1939 defines a transport service in the network layer. In the application layer, the protocol defines data (signals, e.g., vehicle speed) and the packaging of signals in frames. Moreover, J1939 also defines the interaction between components, for example, the interaction between engine and transmission during gear shifting. To provide for vehicle manufacturer-specific functionality, the protocol also allows some proprietary messages.

Both Volcano and J1939 address integration of supplier components; but the approaches differ. Volcano does not, as J1939, explicitly define assignment of specific signals to given frames. Instead, the assignment is resolved in the implementation phase. This makes is possible to do application specific network configurations that are optimal with respect to, for example, timing and bandwidth usage.

For vehicle infotainment systems, MOST, in addition to defining the low-level communication protocol, also defines architecture at the application level of a component connected to a MOST network. At

TABLE 57.1 Primary Use and Key Characteristics of Different Busses in Automotive Applications

	Primary Use					Key Characteristics	
	Feedback Control	Fault-tolerant Control	Discrete Control	Diagnostics and Service	Infotainment and Telematics	Node Cost	Maximum Speed (Mbits/sec)
CAN	x		x	x		Medium	1
LIN			x			Low	20
MOST					x	High	20
FLEXRAY		x				High	10
TTP/C		x				High	25
TTCAN		x				Medium–High	1

© 2005 by CRC Press LLC

the application level, a MOST application such as, for example, an audio system is represented by a *device*. Devices are supported by the system services, which provide a standard interface to network management functions and services for sending and receiving data. A MOST device on the top level can logically be described by a set of function blocks, where a function block represents an application in the device, for example, a CD player or tuner. Moreover, each function block contains a set of functions, for example, play and stop, which are visible to the rest of the MOST system. Function blocks interface other function blocks on the same device or devices connected to the network through services constructed from the system services.

By the definition of the application architecture, devices connected to a MOST system are logically constructed in the same manner and can be interfaced in a consistent way.

57.4 Case Studies

Volvo Car Corporation

The Car Industry

Volvo Car Corporation (VCC) is a subsidiary of the Ford Motor Company, where it is one of the premium brands aimed at the upper end of the car market. The European premium car brands are driving the development of vehicle electronics, having both the demand for advanced functionality and the production volumes to support the costs associated with the introduction of new technology. The components developed for cars are often later used in other parts of the automotive industry. Cars are consumer products, and the customers tend to be sensitive not only to the functionality of the car but also to how it feels and its visual appearance.

Cars are typically manufactured in volumes in the order of millions per year. To achieve these volumes, and still offer the customer a wide range of choices, the products are built on platforms that contain common technology that has the flexibility to adapt to different kinds of cars. As an example, the Volvo XC90, which appeared in 2002, is based on the same platform as four previous Volvos launched since 1998. This reduces the development cost, but also makes it possible to reuse the same manufacturing facilities and strengthens the brand image through an increased similarity between the models.

The component technology is, to a large extent, provided by external suppliers, who work with many different car companies (or OEMs, original equipment manufacturers), providing similar parts. The role of the OEM is thus to provide specifications for the suppliers, so that the component will fit a particular car, and to integrate the components into a product. Traditionally, suppliers have developed physical parts; but in modern cars, they also provide software. As the computational power of the electronic control units (ECUs) increases, it will be more common to include software from several suppliers in the same nodes, which increases the complexity of integration.

Functionality

The driving factor behind the development is increasing demands on functionality. There are several classes of functionality, and in the following paragraphs we provide examples in each of them, which represent some of the largest future challenges for VCC.

Feedback control systems were one of the earliest uses for electronics in cars, and the early applications were engine control, ABS brakes, and vehicle dynamics. These areas are still developing, and one of the main challenges is to cope with new environmental constraints, in particular, related to the reduction of the level of CO_2 emissions. The systems are refined in the sense that more and more sensors are added, and new modes of interaction are included, thereby increasing the overall complexity of the functionality.

Discrete control systems are also common in current cars, in particular, in body electronics. Applications include driver information, security (locks and alarms), and lights. Due to the fact that the overall functionality increases, as well as the abilities of the owner to configure the car through various parameter settings, the complexity of the driver interface becomes a bottleneck. This is caused both by the physical space around the driver seat, and the ability of the driver to process information while driving the car.

© 2005 by CRC Press LLC

Novel ways of interaction are thus needed, in addition to more intelligent systems that, in most cases, can make correct decisions without driver intervention.

Safety-critical control systems become more common as traditional mechanical solutions are replaced by electronics. For the functions currently implemented, there is always a natural fall-back solution if the electronics fail, but future by-wire systems may not have that possibility, which increases the need for fault-tolerance in the electronics and communication. The first such application is likely to be brake-by-wire, and later steer-by-wire will follow. The driving factors behind this development are that the cost and weight could be reduced, and also that it enables new control systems to support the driver, for example to enhance safety. Again, this means a considerable increase in system complexity.

Diagnostic systems provide information about the status of the vehicle. Initially, this was driven by legal requirements that mandated monitoring of emission-related components, but it is also an important factor in increasing the perceived quality of the system. The diagnostic system consists of an in-car part and a workshop tool. The former is usually distributed to all the nodes of the on-board network, and consists of fault detection routines and diagnostic kernels that interact with the workshop tool. As the number of sensors increase, so does the need for diagnostics, and there is also a wish to increase the intelligence of the on-board system, to, for example, detect the need for preventive maintenance so that the customer never experiences critical problems, and thereby gains a perception of high quality.

Infotainment systems implement entertainment functionality, extending from traditional radios to multimedia applications such as TV, video, and gaming, and also contains information functions such as navigation systems. As the number of devices for audio and video data increase in cars, sharing of input and output is essential to bring down cost and conserve space, and this means that complexity moves from hardware to software and communication.

Telematic systems are used in cars for wireless data communication with the world outside via a built-in mobile phone. The applications range from automatic emergency calls in case of an accident to Internet access, and many ideas exist for services that the car owner could be interested in. The area is still in its infancy, and the business cases are currently unclear; but the underlying technology is being developed rapidly.

As can be seen above, complexity is a keyword that must be handled in the development. (For an introduction to the nature of complexity in technical systems, see [17].)

Cost

In the car industry, the development cost is huge in absolute numbers, but still comparatively small in relation to the total variable cost of the production, or the investment in tooling. This means that it is usually profitable to invest in development cost to optimize the components, or to increase commonality between car models on the same platform. Since the cost of development is closely related to the complexity (i.e., the information that needs to be processed to describe the product), it is thus profitable to increase complexity to obtain more flexible components that can be used in many different cars.

For software, the cost relations are somewhat different. There is an indirect variable cost, in that the characteristics of the software influence the resource needs in terms of memory size and processing capability. This cost can, to some extent, be manipulated by optimizing the performance, but this makes the software more complex and thus the development more expensive. In the long term, Moore's law will make hardware increasingly cheap and thereby making it more profitable to optimize software development cost rather than hardware resource needs.

One way to decrease software development cost is to raise the level of abstraction when describing the functionality. At VCC, model-based system development is being introduced [18], where the system is described using a tool chain based on UML, Statecharts, and data flow models. Code generation is then used to reduce the cost of producing the final software. In a way, the complexity is moved from the specific applications to general tools that can be used over and over again. Another example is in network communication over the CAN buses. The Volcano system [15] provides tools for packing data into network frames, and for verifying the end-to-end communication timing to ensure the control performance.

© 2005 by CRC Press LLC

Standards

As indicated above, the OEM's role is to integrate systems from suppliers into a product. This means that it is important to have well-defined interfaces so that the various systems fit together. Also, standards are important as a means to reduce cost of components by sharing development, and allow competition between suppliers. One area where standardization has been particularly vivid is in communication protocols. The following protocols are now used or planned by VCC:

- *CAN* is used for backbone control-oriented peer-to-peer communication.
- *LIN* is a low-cost alternative for control-oriented master–slave communication. Originally developed at VCC, it is now an international standard.
- *MOST* is used for multimedia communication in the infotainment system.
- *Flexray* is expected to be used instead of CAN for safety-critical applications where fault-tolerance is needed.

Selecting a bus protocol is thus a trade-off mainly between cost, bandwidth, predictability, and fault-tolerance. Another area where standards are important is in diagnostics, where authorities mandate it so that they may check that a vehicle fulfills emission regulations, using a single tool.

The current development trends in automotive software also call for increasing standardization of the software structure in the nodes. In particular, the use of code generation requires a clear interface between the support software and the application, and the need to integrate software from different suppliers in the same node also calls for a well-defined structure. The node architecture (see Figure 57.1) includes several important components:

- *Operating systems* (RTOS) provide services for task scheduling and synchronization. Traditional real-time operating systems are usually too resource-consuming to be suitable for automotive applications, and do not provide the predictable timing that is needed. Therefore, the new standard OSEK has been developed. There are several suppliers of OSEK compliant operating systems.
- *Network communication software* provides a layer between the hardware and the application software, so that communication can be described at a high level of abstraction in the application, regardless of the low-level mechanisms used to send data between the nodes. At VCC, the Volcano concept [15] is used for both CAN and LIN communication.
- *Diagnostic kernels* provide an implementation of the diagnostic services that each node must implement to act as a client toward the off-board diagnostic tool. It relies on the communication software to access the networks and on the operating system to schedule diagnostic activities so that it does not interfere with the application functionality.

All these components interact with each other and with the application, and must therefore have standardized interfaces, and at the same time provide the required flexibility. To conserve hardware resources, the components are configurable to only include the parts that are really necessary in each particular instantiation.

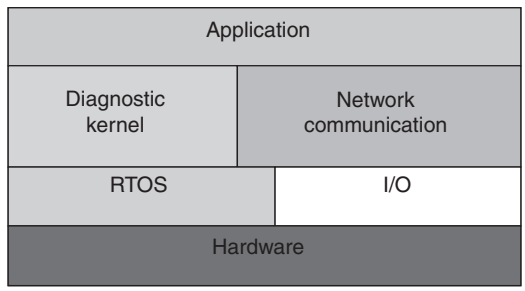

FIGURE 57.1 The node architecture.

© 2005 by CRC Press LLC

Architecture

An example of a contemporary car electronic architecture is that of the Volvo XC90 (see Figure 57.2). The boxes in Figure 57.2 represent ECUs and the lines represent communication buses. The intent of the figure is to show the complexity rather than the details. The maximum configuration contains about 40 ECUs. They are connected mainly by two CAN networks: one for powertrain and one for body functionality. From some of the nodes, LIN subnetworks are used to connect slave nodes into a subsystem. The other main structure is the MOST ring, connecting the infotainment nodes together, with a gateway to the CAN network for limited data exchange. Through this separation, the critical powertrain functions on the CAN network are protected from possible disturbances from the infotainment system. The diagnostics access to the entire car is via a single connection to one ECU. The figure shows approximately how the ECUs are placed in various locations in the car. The partitioning of functionality is decided by the location of the sensors and actuators used, but also by the combinations of optional variants that are possible. If a car is sold with only a subset of the full functionality, the amount of physical hardware installed should be limited to the minimum necessary.

In the future, when safety-critical functionality is introduced, the architecture will be extended with a Flexray-based network, and this will again be isolated from the less critical parts using a gateway. Another important aspect is to create a more flexible partitioning. The main use for this is probably not to find the optimal partitioning for each car on a given platform, since that would create too much work on the verification side, but to allow parts of the software to be reused from one platform to the next. This places even higher demands on the node architecture, since the application must be totally independent of the hardware, through a standardized interface that is stable over time. Therefore, further standardization work is needed, in particular, for sensor and actuator interfaces.

Volvo Trucks

The Trucking Industry

The functionality in trucks has grown dramatically during the past 10 years. Earlier, there was a separate stand-alone system for handling each function; today, all these subsystems are integrated into a single complete system. The development time has decreased and the vehicles are much more complex.

There are different demands depending on market in the truck industry. One example is the system voltage, which is 12 V in the North American market and 24 V in the rest of the world. Moreover, it is

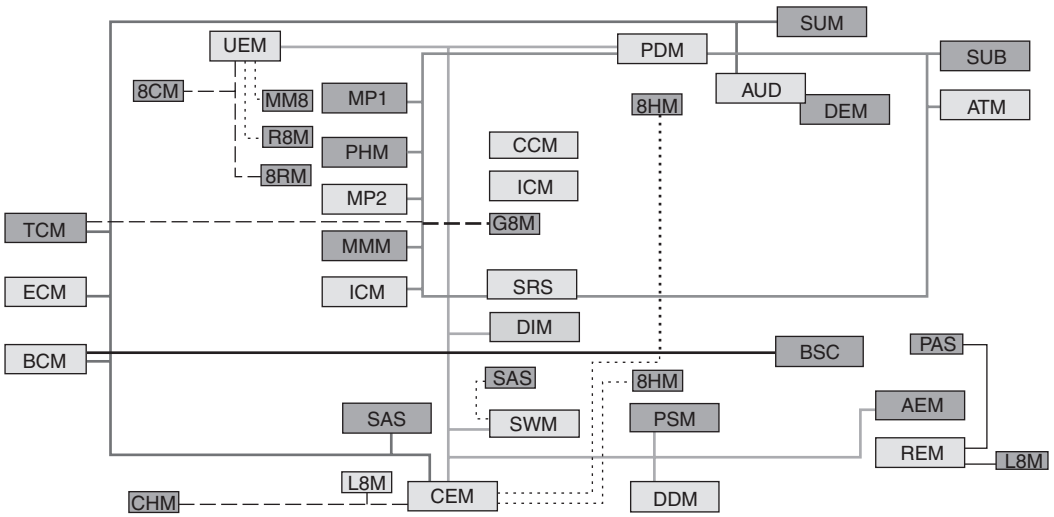

FIGURE 57.2 The electronic architecture of Volvo XC90.

very common for the customers to choose their own driveline in the U.S., which puts special demands on OEMs to integrate engines and transmissions from various suppliers.

One way to obtain cost-effective solutions is to use a common platform covering both mechanical, electrical, and software systems. The challenge is to have a shared platform and yet maintain the unique truck brands.

The truck market has changed from delivering vehicles, to providing a complete transport solution, which may include several different types of services, for example, "around the clock" support and on-line fleet management, etc. A complete transport solution could mean providing the full logistic routing system for a town.

Functionality

Trucks have many areas of use. The requirement on functionality can be split into three different segments.

- Goods transportation and logistics,
- Building and construction, and
- City distribution and waste handling.

"Goods transportation and logistics" means transportation of goods over long distances, for example, food from southern Europe to Sweden. "Building and construction," for example, concrete trucks, crane trucks, or gravel trucks operate under rougher conditions such as on a construction site, in mines or in roadworks. "City distribution and waste" refers to local transport, for instance, a garbage truck.

Feedback control systems were among the first electronic systems introduced in the beginning of the 1980s (e.g., electronic motor control and antilock braking system, ABS). These systems were complete stand-alone systems. Over time, the systems became more complex and integrated. For example, the ABS system can command the engine not to apply the exhaust brake when ABS is activated. Furthermore, some sensors are shared between the systems and data can be exchanged through the vehicle network.

Discrete control systems include functions such as driver information, but also systems like climate control, exterior light, central locking, tachograph, etc. With increasing amount of functionality and information on the network, the requirements on the Human Machine Interface (HMI) are getting increasingly complex. It becomes a challenge to support the driver in deploying the functionality the right way.

Superstructures: Trucks can be supplemented with superstructures, such as concrete aggregates, tipping devices, refrigerator units, etc. One way to decrease the total cost of the vehicle is to have a well-defined interface between the electrical system and the superstructure, to allow, for example, the crane equipment to control the engine speed to facilitate the right flow in the hydraulic pump.

Safety-critical control systems: The increase in safety-critical systems has been striking in the last few years. One driving factor for this is to prevent personal and property damage in case of accident. Earlier mechanical systems are being replaced or supplemented. Many systems are common with the car industry, for instance, ABS and airbags. One difference is that the gross combination weight (weight of vehicle and trailer) is much greater. Trucks also have many variants and it is common that they have more than four wheels.

Recently, the Electronically Controlled Brake System (EBS) and Electronic Stability Program (ESP) were introduced. In the EBS, an electronically controlled valve located close to each wheel applies individual braking force to each wheel. There is also a centrally positioned ECU that controls the vehicle's braking effect, both in the disk brakes and the engine brake. There is a back-up system using pressurized air.

The ESP system is a supplement to EBS. By means of a yaw rate sensor, a lateral accelerator sensor and a steering wheel sensor the new functionally can be added. ESP is an active safety-enhancement system whose task is to stabilize the vehicle, for example, prevent jack-knifing when the driver makes a rapid avoidance maneuver.

Diagnostic system: An increasing part of the vehicle electronics has demands on efficient built-in diagnostics not only for the aftermarket but also to check the mounting of components in production. The goal is to be able to check all components, not only ECUs but also very simple components like switches and bulbs.[1]

[1] Compare to the semiconductor industry where diagnostics is included in the chips for production tests only.

© 2005 by CRC Press LLC

There is an aftermarket tool that communicates with the control units. Through this tool, it is possible to read out fault codes, sensor values, etc. The tool is also able to run tests in the control units and download new software and parameters. Since the North American market requires support for third-party components, it must also be possible for the suppliers' aftermarket tools to coexist.

Infotainment has not been very common in trucks, but because many drivers that are transporting goods far away are living in their trucks, the need has increased. Because of the low product volumes compared to the car industry, it is likely that the truck industry for cost reasons will inherit from the car industry.

Telematics in trucks is mainly used for traffic information and tracking of goods. Volvo has its own telematics system called Dynafleet. Tracking of goods gives the possibility to enhance logistics. This type of system becomes more and more common due to the demand for just-in-time transports. Because of the growth of the Internet, the telematics systems will become more integrated in all business systems. By using the information on the truck location and data about the goods (e.g., the temperature in a cold transport), the transports can be planned with a positive effect both on economy and the environment.

Cost

Reducing costs is becoming increasingly important. The vehicles offer more and more functionality but the cost per function is decreasing. Because the truck industry has lower volumes compared to passenger cars, it is important to get the right trade-off between development cost and product cost. Systems that are fitted in all truck models, like the Vehicle Control Unit (VECU), must have a low product cost. But the systems that are only available in some variants produced in a couple of 1000s/year are less sensitive for product cost. Instead, here, a gain is to be made by using "general-purpose" components that realize more than one variant.

To get the best trade-off between development cost and product cost, the architecture design is crucial. The architecture should identify which components are convenient to share with respect to cost. During the life cycle of a platform, the development cost for software is higher than the development cost for hardware; but hardware costs have a more direct effect on the product cost.

Standards

A truck is essentially built by integrating systems from many suppliers. Volvo Trucks has some in-house development of core control units that is important to give the truck the characteristic "feeling." Still, there are several systems that are not profitable to develop in-house. One such system is the ABS brakes. In this area, there are a few big suppliers that have key-knowledge and their own development of systems. But still, Volvo Trucks is deeply involved in formulating requirements on the system and adding unique Volvo functionality. It is, however, important to use as much standard as possible to make the integration in different brands as simple as possible.

For heavy vehicle, there are two standard protocols that are used in today's production:

- SAE J1939 [16] and
- SAE J1708/J1587 [19], an older protocol. It uses RS485 as base and communicates with 9600 bit/sec, and is mainly used in the vehicles for diagnostics and for some fall-back for J1939.

Other protocols that will be used or are under investigation at Volvo trucks include:

- LIN [5] will be used for sensor networks but also for sub-busses.
- MOST [8] is the optical ring bus that is used for infotainment by some manufacturers in the car industry.
- Flexray [12] is under evaluation for safety-critical systems.
- TTCAN [14]. Because TTCAN is built on the well used CAN protocol, TTCAN might be very interesting for control-intensive vehicle systems.

Architecture

The market pull in the U.S. for selecting truck components from different vendors introduces additional complexity, when more and more electronics is integrated in the trucks. To handle the electrical

© 2005 by CRC Press LLC

integration, Volvo Trucks uses the standardized protocol J1939. Since J1939 not only defines network and application layer services but also the interaction between vehicle components it partly acts as architecture; see Figure 57.3. Volvo trucks have also added some in-house strategies and guidelines to J1939 and for other electrical installations. Together with the standard, this defines the architecture.

The advantage of using a standard is the relatively straightforward integration of components from different vendor suppliers. On the other hand, there are some disadvantages, for example, development or changes to the protocol can only be made through standardization work.

J1708/J1587 is also used. It is used in parallel with J1939 for diagnostic, information sharing, and as a backup for J1939.

These standards, strategies, and guidelines have been a good support when all stand-alone systems have been integrated to a distributed system. With software and communication, it is now possible to create functionality that was not possible 20 years ago. Nonetheless, it also introduces some new problems. One example is startup and shutdown of the systems, where all systems must synchronize through the network.

Despite the added complexity, the demand for reduced product development time has increased, and at the same time the demands on decreased product cost have also increased. To be able to reduce the development time, it is important to find new solutions. One way is to use a reference architecture that covers all products and include both software and hardware. This will also set demand on new tools that can handle complex system models in real time, real time because there will be a lot of persons working in parallel with the model. Because Volvo Trucks is a global organization with product development on four sites, it is also important that the tools support this way of work. A common misunderstanding is that the high product development cost is related to HW. This is usually wrong. It is therefore very important to have an architecture that supports both hardware and software. This gives the possibility to have a high degree of reuse between the products. This saves both product development time and cost. Of course, this will also give a profit in higher quality.

To enable reduction of the number of physical control units, it is important to have a system view instead of considering each control unit separately. Thereby, software functions can be deployed in the control unit that is closest to the necessary sensors and actuators.

The superstructure interface must also be included in the architecture. A well-defined interface is believed to decrease the cost and time for adding superstructures. This is believed to increase customer satisfaction and thereby profit for the company (Figure 57.4).

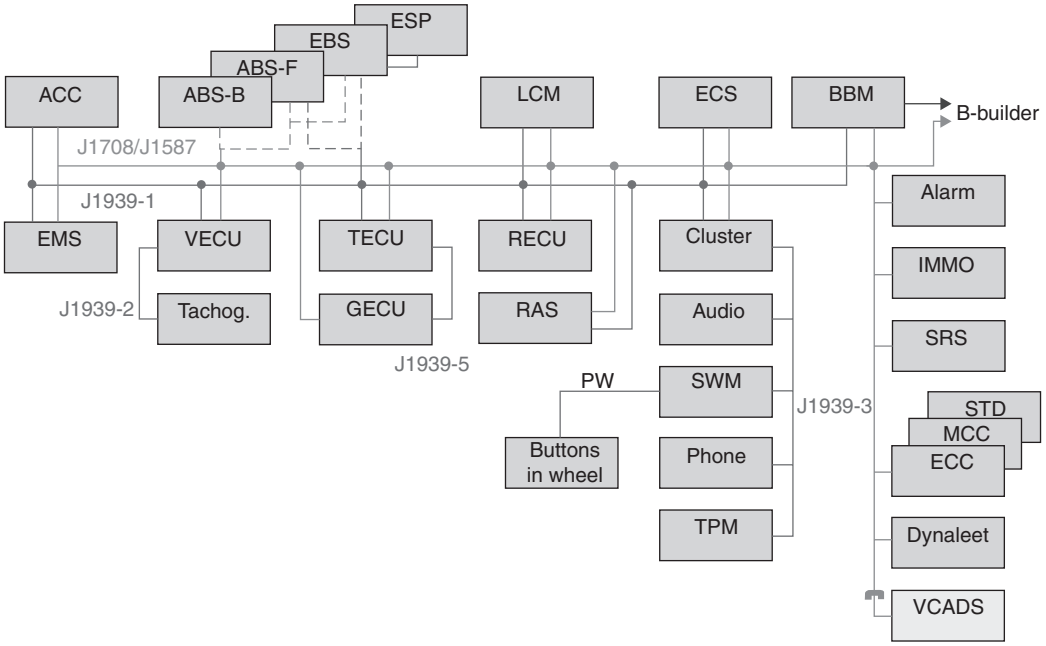

FIGURE 57.4 Volvo FH electronic architecture.

Conclusion

The progress in the last ten years has moved VTC vehicles from centralized computer systems to distributed systems, and much functionality has been added. This has of course increased the complexity and together with demands on a shortened product development time and increased quality, there is a need not to reinvent the wheel. One way to handle this situation is to use reference architectures supported by tools and better methods for product development.

Volvo Construction Equipment

Volvo Construction Equipment (VCE) develops and manufactures a wide variety of construction equipment vehicles, such as articulated haulers, excavators, graders, backhoe loaders, and wheel loaders. The products range from relatively small compact equipment (1.4 t), to large construction equipment (52 t). VCE is divided into product companies with focus on one type of equipment, and that typically manufactures product lines of similar products, for example, excavators or wheel loaders.

Compared with passenger cars and trucks, construction equipment vehicles are equipped with less complex electronic systems and networks. Also, the focus in product development is somewhat different. The products are to be used in construction sites, and the most important aspect of the vehicle is to provide a reliable machine to increase production. A customer of passenger cars, on the other hand, may be interested in a number of styling attributes related to the look and feel of the car, whereas the dominant requirements for customers of construction equipment are related to production goals. The requirements for reliability and robustness are equally high in both cases, but styling requirements are typically low for construction site machinery.

In-vehicle electronic systems and networks are an important part of the construction equipment product and are crucial to provide end-user functionality, such as automatic gearbox, as well as providing diagnostic and service functions. The use of a distributed electronic system also accommodates functions that reduce the cost of the vehicle, for example, reuse of sensors and displays, and adaptive solutions to accommodate cheaper mechanical parts.

© 2005 by CRC Press LLC

Functionality

Here, we describe today's situation in functionality requirements for construction equipment at VCE. To each class of functionality, we present some major drivers and examples.

Feedback Control: The main feedback control functionality in VCE products includes control of engine, gearbox, retarder brake, differential lock, and engine cooling fan. Besides engine control, the automatic gearbox is a complex feedback control system that can include control of clutches and brakes for the gear pinions as well as converter, lockup, and drop box. The functionality for an automatic gearbox includes logics for when to shift gears, minimization of slip, avoidance of hunting, various efficiency optimizations, and self-adapting solutions to accommodate a variance of mechanical properties. There are also distributed control functions that synchronize engine speed for good comfort in shifting gears. Feedback control systems also include the cooperation of brakes to minimize wear, for xample, the cutin of a retarder brake, or exhaust brake.

Discrete Control: Like in the truck case, discrete control systems include control of driver information, wipers, lamps, and other on—off-type devices. The challenges arise due to configuration issues rather than constructing a functional system.

Diagnostics and service: Diagnostic functions are used to determine status and operational history of electronic components. Some diagnostic functions reside in the on-board software and some in service tools. On-board diagnostic functions implement criteria for faults, and can send fault codes via the network. Diagnostic functions also include logging functions to store operational data, for example, fault history or general operation statistics on buffers, network load, or sensor input. A service tool (a PC with service applications) can be connected to the vehicle network via a service connector. The service tool can run tests to diagnose faults either by invoking on-board functions, or by running test programs to verify functionality.

The service tool can, thus, extract diagnostic data for a service technician, but also download new software or parameters into the vehicle control units. The tool can be connected to a central configuration database that holds information on compatibility between versions and configurations. When downloading software or parameters, the central system is updated to reflect the current configuration. Also, the operational data can give valuable feedback to the development department.

Infotainment: As mentioned, customers of construction equipment purchase products with the intent of increasing production at construction sites. There is little incentive to pay for entertainment systems and therefore VCE does not provide any such systems today. There are demands for information systems; but this does not usually include general systems such as Internet connection and video. Instead, tailored applications to increase production are requested.

Telematics: In the field of construction equipment, telematics can be used to achieve the increased production in several ways. The challenge is to accommodate telematic functions in a cost-efficient way. Construction sites could be located in remote regions and wireless technology like satellite or radio communication must be considered as opposed to the car industry where mobile phone communication seems to be sufficient. Fitted equipment and cost for communicating over commercial networks are expensive and may not be crucial to every customer.

Applications running on an office desktop computer can be developed to access information in a fleet of vehicles and to present and analyze data far away from the actual vehicles. Examples are fleet management systems, maintenance systems, and antitheft systems. A fleet management system can provide information to increase the efficiency of a fleet of vehicles. A maintenance system could, for instance, report on status of mechanically worn components like brakes and thereby reduce maintenance cost.

The trend toward telematic systems is very strong and a variety of systems are expected to be available in a few years.

Cost

The electronic systems in VCE products are, in total, less complex and are sold in smaller volumes compared to cars or trucks. The final products are also much more expensive than passenger cars; but the

© 2005 by CRC Press LLC

electronic content is a much lower percentage of the total product cost. Therefore, the cost for developing electronic systems in VCE is relatively large compared to the variable costs for production, at least compared to VCC and VTC. This implies that it is usually not profitable to optimize hardware to a large extent since it would generate increased complexity of the system and increased development cost, for example, the need for configuration handling.

Accommodating commonality is considered very beneficial because VCE has a large number of products (although sold in smaller volumes). Reuse is beneficial for both hardware and software as it directly affects development cost. This results in VCE focusing heavily on commonality, even though it may mean that a lower-end product is produced with some spare resources in terms of electronics.

Compared to both cars and trucks, VCE builds on-board electronic systems that have a lower development cost, smaller volumes, and lower overall complexity.

Trends indicate that the electronic content (and complexity) will increase quite rapidly in construction equipment over the coming years. The situation for construction equipment is likely to resemble the situation of trucks today and later may be the situation for cars. However, the volumes will not equal those of trucks or cars. VCE have fewer products with a higher price and will thereby not focus as much on optimizations, but rather at handling complexity and commonality. Commonality can also help in reducing development time.

To customers of construction equipment, providing efficient maintenance and service is probably as important as providing a functional product. This is because of the long-term service contracts where 80% of the vehicles are in use after 20 years.

VCE, like VCC and VTC, also anticipate a trend of increasingly cheap hardware and will focus on optimizing software development cost rather than optimizing hardware content in products, that is, designing electronic systems for a minimum slack of hardware such as memory and processing power.

Standards

VCE uses the same standards for communication protocols as VTC, that is, SAE J1939 / CAN and SAE J1587 / J1708 (see the High-level protocols and communication software, and standards sections for details).

Architecture

The focus of VCE's electronic architecture effort is mainly concerned with assuring system properties that are judged essential to provide the "right" product (a good business case) and to have an architecture that supports working with platforms. System properties include scalability to support product variation, reusability and partitioning of SW components to lower development cost, as well as safety and reliability issues.

This means that methods for designing SW in control units and handling communication are also considered architectural issues. The goal is to have an architecture that helps in designing on-board electronic systems with respect to the wanted system properties that are identified as the most important for the VCE business case.

As temporal behavior is considered very important, VCE uses a design process [20] that focuses on high-level design and temporal attributes of the system. VCE uses the operating system Rubus, which provides a configuration tool allowing specification of temporal constraints, communication, and synchronization. This method separates the design of timing characteristics from the design of functionality, and enables early verification of temporal behavior.

Partitioning, scalability, and commonality: VCE has a setting different from VCC and VTC, in that there is almost no use of externally developed vendor control units. This leads to the possibility of using the same software component model, operating system, and reusing software components. By doing this, the partitioning of functionality is likely to be easier than in the case of a network with many differently developed control units. Easy partitioning provides the possibility to scale the system with respect to hardware and optimize hardware content in a specific product. For instance, a low-end product with fewer features requires less hardware resources, and can be realized by placing software components on

© 2005 by CRC Press LLC

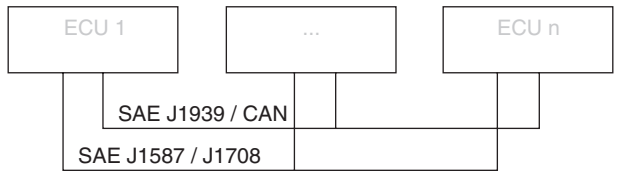

FIGURE 57.5 VCE Network Architecture.

other nodes and thereby reduce the number of control units. This means that the number of control units can be chosen according to resource needs for a given configuration of a product. Thus, the architecture is reused; but the numbers of ECUs differ between products (see Figure 57.5).

To have a situation with a large degree of in-house developed control units also gives benefits in terms of commonality. The use of common design methods for control units in itself leads to reduced cost, but also helps in decreasing the complexity of the system. (The overall information that must be processed during development is decreased.) Reusing infrastructure like drivers, communication components, and other software components is a goal in commonality that can be met as long as common design methods are used.

On the other hand, VCE platforms are used in a wider variety of different products. Facilitating commonality in very different products, such as an excavator and an articulated hauler, presents a different situation compared to VTC or VCC.

The different situation in VCE is caused by lower demands for many variants. While trucks are delivered in numerous configurations, construction equipment often provides quite few. Examples are an optional tachograph, or an optional enhanced suspension system.

In the car and truck industry, there are several vendors that specialize in certain systems, deliver in large numbers, and can provide competitive prices. VCE is likely to move toward the VTC situation with products including external vendor nodes. This will likely generate a need for new methods for accommodating scalability partitioning commonality.

Furthermore, the trend toward supplying services rather than vehicles could be relevant to VCE. Currently, the trend of increasing rental products can be seen as a step toward providing services, as VCE accepts responsibility for up time of products.

57.5 Analysis

The different business demands on cars, trucks, and construction equipment led to different focus in the design effort of the respective vehicles. In this section, we present analysis of the correlation between different business and product characteristics and key properties of the resulting network architectures. In Table 57.2 below, the business and product characteristics are given for the three different organizations.

The case study has shown that the product volumes are different for the three organizations, and thereby also the focus on fixed cost and hardware optimization. The willingness to reduce fixed cost at the expense of variable cost increases with the product volume. One way of achieving a reduced fixed cost is to optimize vehicle hardware content to include a minimum of resources. Software components are not subject to the optimization profit, due to an increase in variable cost but almost no gain in fixed cost. VCC that produces vehicles in the range of 10^6 can benefit to a larger extent by reducing fixed cost, and therefore an increased cost for the design of optimal hardware is more profitable than for VCE that has volumes in the range of 10^4.

The number of vehicle models sold for the respective organizations is indicated in the table by "Number of products." The number of products and the product volume directly affect the profitability of reusing components, that is, commonality, and this also includes software components. VCE has a high number of products, but smaller volumes, while VCC and VTC have high volumes. Thus, the effort to achieve commonality is emphasized in all the three organizations.

© 2005 by CRC Press LLC

TABLE 57.2 Business Characteristics for Each Organization

	Organization		
Characteristics	VCC Volvo Car Corporation	VTC Volvo Truck Corporation	VCE Volvo Construction Equipment
Annual production volume (Order of magnitude)	10^6	10^5	10^4
Products	~8 products	~8 products	>50 products
Platforms	3	3	8
Number of physical configurations per product	Many	Very many	Few
Amount of information	Huge	Very large	Moderate
Standards application level	Proprietary (Volcano)	J1587–J1939	J1587–J1939
Number of network Technologies	~4	2	2
Hardware optimization	High	Medium	Low
Openness	None	High	Some
Safety-critical	Yes	Yes	Yes
Advanced control	Yes	Yes	Yes
Infotainment	Much	Some	None

The "Number of physical configurations" means the different options of network topologies that can be fitted in a certain product. VTC products, which may be configured in many ways, achieve a high extendability and can facilitate change of configuration in the aftermarket or adding superstructures by other vehicle developing organizations. The large amount of data and the many configurations place high requirements on the management of different components, for example, ECUs, connected to the network in different variants.

The large amount of information together with the requirements for optimization in the VCC case imply that using several tailored networks for specific needs can be profitable. The use of LIN networks provides a cost-effective network for handling locally interconnected lights and switches, and a high bandwidth MOST network serves the needs of infotainment applications. Especially for VCE, the increase in development cost for designing tailored networks for a certain purpose is deemed unprofitable and this is reflected in the small number of network technologies.

The use of in-vehicle networks opens up the possibility for efficient diagnostics and service, by the ability to extract information via the bus. Although the amount of information varies in the three cases, the needs for diagnose and service are emphasized in all three organizations. The reason for this is that there is sufficient information in all systems to substantially ease analysis of the distributed system.

As mentioned, VTC needs to facilitate superstructures, and this is reflected in the large number of physical configurations. In order to support extensions to the network by other parties, standardized communication interfaces like SAE J1939 and J1708/J1587 are used. VCE uses the same standards, since both VTC and VCE belong to the Volvo group and there is commonality in service tools.

Safety aspects on networking require that messages be transferred with correct timing and without being corrupted. One step toward guaranteeing the real-time properties and integrity of messages related to safety-critical functionality is to use communication protocols with support for deterministic and analyzable timing behavior. Examples are CAN and LIN and the coming protocols Flexray and TTCAN, which are all used or evaluated by the three considered organizations. Another step is to use several networks that are interconnected through gateways. Safety-critical communication can thereby be separated from communication that is not trusted to the same degree.

57.6 Conclusion

In recent years, networking issues have become more and more important in the design of vehicle control systems. One of the initial driving forces for introduction of communication networks in automotive

© 2005 by CRC Press LLC

vehicles was to replace the numerous cables and harnesses and thereby reduce cost and weight. Today, it is possible using software and networking to create new functionality that was considered unfeasible some ten years ago.

We have presented case studies of the context, use, and requirements of networking in construction equipments, trucks, and passenger cars. Furthermore, we have identified challenges with respect to functionality, cost, standards, and architecture for development of vehicles. Based on these case studies with different business and functionality demands, we have provided analysis of the design principles used for the communication architectures in these domains. Despite a common base of similar vehicle functionality, the resulting network architectures used by the three organizations are quite different. The reason for this becomes apparent when looking at different business and product characteristics and their effect on the network architecture. An important lesson from this is that one should be very careful to uncritically apply technical solutions from one industry to another, even when they are as closely related as the applications described in this paper.

58.1 Introduction

The international standard Manufacturing Message Specification (MMS) is an OSI application layer messaging protocol designed for the remote control and monitoring of devices such as Remote Terminal Units (RTU), Programmable Logic Controllers (PLC), Numerical Controllers (NC), or Robot Controllers (RC). It provides a set of services allowing the remote manipulation of variables, programs, semaphores, events, journals, etc. MMS offers a wide range of services satisfying both simple and complex applications.

For years, the automation of technical processes had been marked by increasing requirements with regard to flexible functionalities for the transparent control and visualization of any kind of processes. The mere cyclic data exchange will be increasingly replaced by systems that join together independent yet

© 2005 by CRC Press LLC

coordinated systems — like communication, processing, open- and closed-loop control, quality protection, monitoring, configuring, and archiving systems — to a whole. These individual systems are interconnected and work together. As a common component, they require a suitable real-time communication system with adequate functions.

The MMS standard defines common functions for distributed automation systems. The expression "manufacturing," which stands for the first M in MMS, has been inappropriately chosen. The MMS standard does not contain any manufacturing-specific definitions. The application of MMS is as general as the application of a personal computer. MMS offers a platform for a variety of applications.

The first versions of MMS documents were published in 1990 by ISO TC 184 (Industrial Automation) as an outcome of the GM initiative *Manufacturing Application Protocols* (MAP). The current version was published in 2003:

Part 1: ISO 9506-1 Service definition (2003) [1]: Describes the services that are provided to remotely manipulate the MMS objects. For each service, a description of the parameters carried by the service primitives is given. The services are described in an abstract way, which does not imply any particular implementation.

Part 2: ISO 9506-2 Protocol specification (2003) [2]: Specifies the MMS protocol in terms of messages. The messages are described with a notation ASN.1, which gives the syntax.

Today, MMS is being implemented — unlike the practice 15 years ago and unlike the supposition still partly found today — on all common communications networks that support a safe transport of data. These can be networks like TCP/IP or ISO/OSI on Ethernet, a fieldbus, or simple point-to-point connections like HDLC, RS 485, or RS 232. MMS is independent of a seven-layer stack. Since MMS was originally developed in the MAP environment, it was generally believed earlier that MMS could be used only in connection with MAP.

MMS is the basis of the international project *Utility Communication Architecture* (UCA™, IEEE TR 1550) [13], IEC 60870-6-TASE.2 [14,15] *(Inter control center communication)*, IEC 61850 [17–21] *(Communication networks and systems in substations),* and IEC 61400-25 [22] *(Communications for monitoring and control of wind power plants)*.

This chapter introduces the basic concepts of MMS applied in the above-mentioned standards.

58.2 The MMS Client/Server Model

MMS describes the behavior of two communicating devices by the client/server model (see Figure 58.1). The client can, for example, be an operating and monitoring system, a control center, or another intelligent device. The server represents one or several real devices or whole systems. MMS uses an object-oriented modeling

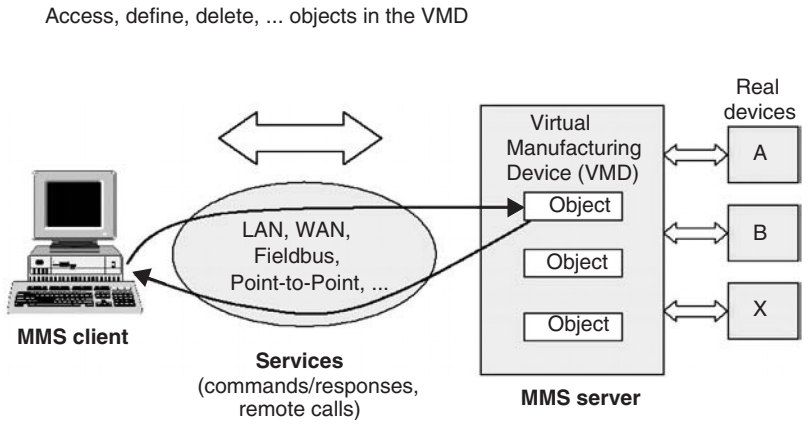

FIGURE 58.1 MMS client/server model.

© 2005 by CRC Press LLC

method with object classes (Named Variable, Domain, Named Variable List, Journal, etc.) and instances from the object classes and methods (services like read, write, information report, download, read Journal, etc.).

The standard is comprehensive. This does not mean that an MMS implementation must be complex or complicated. If only a simple subset is used, then the implementation can also be simple. Meanwhile, MMS implementations are available in the third generation. They allow the use of MMS both on PC platforms and embedded controllers.

The MMS server represents the objects that the MMS client can access. The Virtual Manufacturing Device (VMD) object represents the outermost "container" in which all other objects are contained.

Real devices can play both roles (client and server) simultaneously. A server in a control center for its part can be a client with respect to a substation. MMS basically describes the behavior of the server. The server contains the MMS objects and it also executes services. MMS can be regarded as "server centric." In principle, in a system, more devices are installed that function as server (e.g., controllers and field devices) than devices that perform the client role (e.g., PC and workstation).

The "calls" that the client sends to the server are described in the part ISO 9506-1 (services). These "calls" are processed and answered by the server. The services can also be referred to as remote calls, commands, or methods. Using these services, the client can access the objects in the server. It can, for example, browse through the server, that is, making visible all available objects and their definitions (configurations). The client can define, delete, change, or access objects via reading and writing.

An MMS server models real data (e.g., temperature measurement, counted measurand, or other data of a device). These real data and their implementation are concealed or hidden by the server. MMS does not define any implementation details of the servers. It is only defined as to how the objects behave and represent themselves to the outside (from the point of view of the wire) and how a client can access them.

MMS provides the very common classes. The Named Variable, for example, allows to structure any information provided for access by an application. The content (the semantic of the exchanged information) of the Named Variables is outside the MMS standard. Several other standards define common and domain-specific information models.

IEC 61850 defines the semantic of many "points" in electric substations. For example, "Atlanta26/XCBR3.Pos.stVal" is the position of the third (3rd) circuit breaker in substation "Atlanta26." The names "XCBR," "Pos," and "stVal" are standardized names.

The forth coming standard IEC 61400-25 (communication for wind power plants) defines a comprehensive list of named "points" specific for wind turbines. For example, "Tower24/WROT.RotSpd.mag" is the (deadbanded) measured value of the rotor position of Tower24. "RotSpd.avgVal" is the average value (calculated based on a configuration attribute "avgPer." These information models are based on common data classes like Measured value, 3-phase value (delta and Y), and single point status.

58.3 The VMD

According to Figure 58.2, the real data and devices are represented — in the direction of a client — by the VMD. In this regard, the server represents a "standard driver" that maps the real world to a virtual one. The following definition helps to clarify the modeling in the form of a virtual device:

If it's there and you can see it	It's REAL
If it's there and you can't see it	It's TRANSPARENT
If it's not there and you can see it	It's VIRTUAL
If it's not there and you can't see it	It's GONE

Roy Wills

The VMD can represent, for example, a variable "Measurement3," whose value may not permanently exist in reality; only when the variable is being read will a measurand transducer get started to determinate the value. All objects in a server can already be contained in a device before the delivery of a device. The objects are predefined in this case.

© 2005 by CRC Press LLC

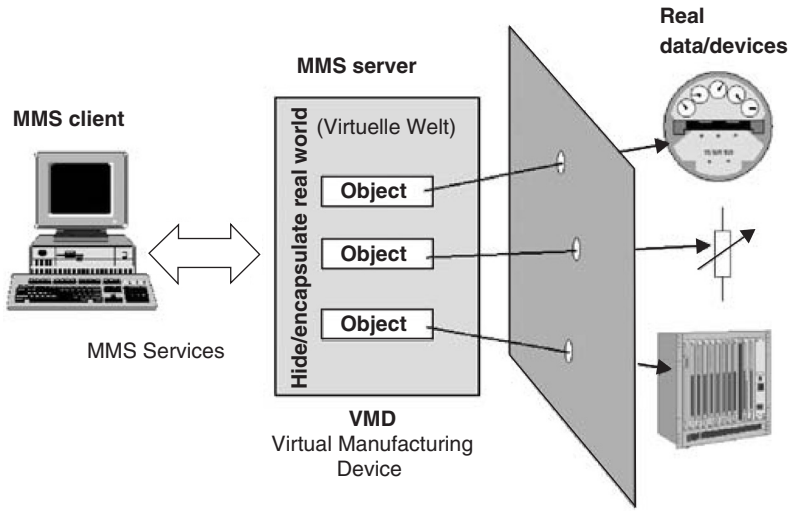

FIGURE 58.2 Hiding real devices in the VMD.

Independent of the implementation of a VMD, data and the access to data are always treated in the same way. This is completely independent of the operating system, the programming language, and memory management. Similar to how printer drivers for a standard operating system hide the various real printers, a VMD also hides real devices. The server can be understood as a communication driver that hides the specifics of real devices. From the point of view of the client, only the server with its objects and its behavior is visible. The real device is not visible directly.

MMS merely describes the server side of the communication (objects and services) and the messages that are exchanged between client and server.

The VMD describes a virtual manufacturing device completely. This virtual device represents the behavior of a real device as far as it is visible "over the wire." It contains, for example, an identification of manufacturer, device type, and version. The virtual device contains objects like variables, lists, programs and data areas, semaphores, events, journals, etc.

The client can read the attributes of the VMD (see Figure 58.3), that is, it can browse through a device. If the client does not have any information about the device, it can view all the objects of the VMD and their attributes by means of the different Get services. With this, the client can perform a first plausibility check on a just installed device by means of a Get(Object-Attribute)-Service. It learns whether the installed device is the ordered device with the right model number (Model Name) and the expected issue number (Revision). All other attributes can also be verified (e.g., variable names and types).

The attributes of all objects represent a self-description of the device. Since they are stored in the device itself, a VMD always has the currently valid and thus consistent configuration information of the respective device. This information can be requested on-line directly from the device. In this way, the client always receives up-to-date information.

MMS defines some 80 functions:

- browsing functions about the "contents" of the virtual device: "Which objects are available?",
- functions for reading, reporting, and writing of arbitrarily structured variable values, and
- functions for the transmission of data and programs, for the control of programs, and many other functions.

The individual groups of the MMS services and objects are shown in Figure 58.4. MMS describes such aspects of the real device that shall be open, that is, standardized. An open device must behave as described by the virtual device. How this behavior is achieved is not visible and also not relevant to the user who accesses the device externally. MMS does not define any local, specific interfaces in the real systems. The

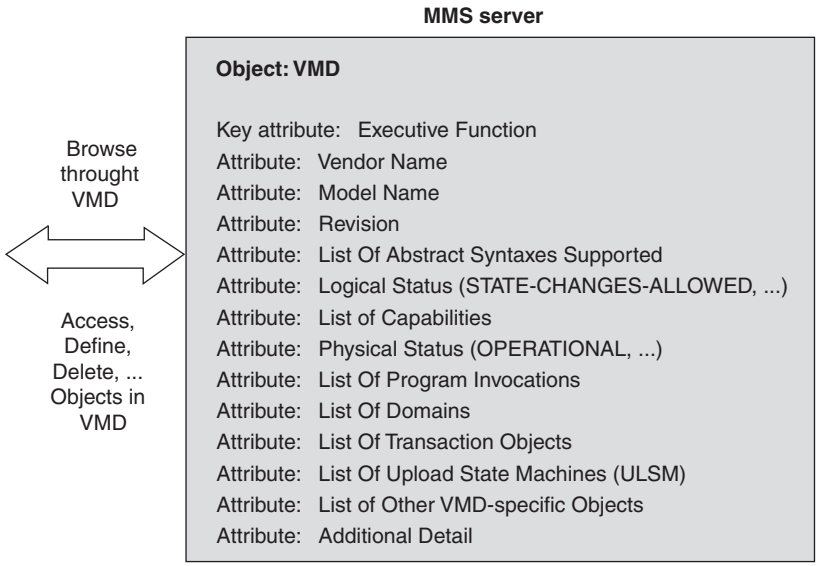

FIGURE 58.3 VMD attributes.

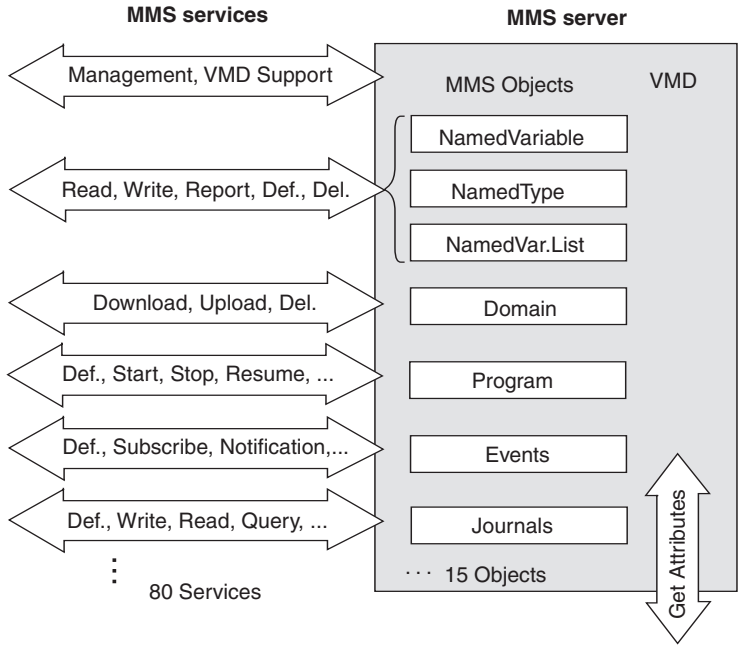

FIGURE 58.4 MMS objects and services.

interfaces are independent of the functions that shall be used remotely. Interfaces in connection with MMS are always understood in the sense that MMS quasi-represents an interface between the devices and not within the devices. This interface could be described as an external interface. Of course, interfaces are also needed for implementations of MMS functions in the individual real devices. These shall not and cannot be defined by a single standard. They are basically dependent on the real systems — and these vary to a great extent.

MMS Models and Services

ISO 9506-1 (part 1) — Service Specification

Environment and General Management Services.
Two applications that wish to communicate with each other can set up, maintain, and close a logical connection (initiate, conclude, abort).

VMD Support.
The client can thereby query the status of a VMD or the status is reported (Unsolicited Status); the client can query the different lists of the objects (Get Name List), query the attributes of the VMD (Identify), or change the names of objects (Rename).

Domain Management.
Using a simple flow control (Download, Upload, Delete Domains, ...), programs and data of arbitrary length can be transmitted between the client and server and also a third station (and vice versa). In the case of simple devices, the receiver of the data stream determines the speed of the transmission.

Program Invocation Management.
Services to create, start, stop, and delete modularly structured programs by the client (Start, Stop, Resume, Kill, Delete, ...).

Variable Access.
This service allows the client to read and write variables that are defined in the server or a server is enabled to report the contents to a client without being requested (Information Report). The structures of these data are simple (octet string) to arbitrarily complex (Structure of Array of ...). In addition, data types and arbitrary variables can be defined (Read, Write, Information Report, Define Variable, ...). The variables consitute the core functionality of every MMS application; therefore, the variable access model will be explained in detail below.

Event Management.
It allows an event-driven operation; that is, a given service (e.g., Read) is only carried out if a given event has occurred in the server. An alarm strategy is integrated. Alarms will be reported to one or more clients if certain events occur. These have the possibility to acknowledge the alarms later (Define, Alter Event Condition Monitoring, Get Alarm Summary, Event Notification, Acknowledge Event Notification, ...). This model is not explained further.

Semaphore Management.
The synchronization of several clients and the coordinated access to the resources of real devices is carried out hereby (Define Semaphore, Take/Relinquish Control, ...). This model is not explained further.

Operator Communication.
Simple services for the communication with operating consoles integrated in the VMD (Input and Output). This model is not explained further.

Journal Management.
Several clients can enter data into journals (archives, logbooks) that are defined in the server. Then these data can be selectively retrieved through filters (Write Journal, Read Journal, ...). This model is not explained further.

ISO9506-2 (Part 2) — Protocol Specification

If a client invokes a service, then the server must be informed about the requested type of the service. For a Read service, for example, the name of the variables must be sent to the server. This information that the server needs for the execution is exchanged in so-called Protocol Data Units (PDU). The sets of all the PDU that can be exchanged between client and server constitute the MMS protocol.

© 2005 by CRC Press LLC

In other words, the protocol specification — using the standards ISO 8824 (Abstract Syntax Notation One, ASN.1) and 8825 (ASN.1 Basic Encoding Rules, BER) — describes the abstract and concrete syntax of the functions defined in part 1. The syntax is explained below exemplarily.

58.4 Locality of the VMD

VMDs are virtual descriptions of real data and devices (e.g., protection devices, measurand transducers, wind turbine, and any other automation device or system). With respect to the implementation of a VMD, there are three very different possibilities where a VMD can be located (see Figure 58.5):

1. *In the end device*: One or several VMDs are in the real device that is represented by the VMD. The implementations of the VMD have direct access to the data in the device. The modeling can be carried out in such a way that each application field in the device is assigned to its own VMD. The individual VMDs are independent of each other.
2. *In the gateway*: One or several VMDs are implemented in a separate computer (a so-called gateway or agent). In this case, all MMS objects that describe the access to real data in the devices are at a central location. While being accessed, the data of a VMD can be in the memory of the gateway — or they must be retrieved from the end-device only after the request. The modeling can be carried out in such a way that for each device or application, a VMD of its own will be implemented. The VMD are independent of each other.
3. *In a file*: One or several VMDs are implemented in a database on a computer, on a FTP server, or on a CD ROM (the possibilities under 1. and 2. are also valid here). Thus, all VMDs and all included objects with all their configuration information can be entered directly in engineering systems. Such a CD ROM, which represents the device description, could also be used, for example, to provide a monitoring system with the configuration information: names, data types, object attributes, etc. Before devices are delivered, the engineering tools can already process the accompanying device configuration information (Electronic Data Sheet)! The configuration information can also be read later on-line from the respective VMD via corresponding MMS requests.

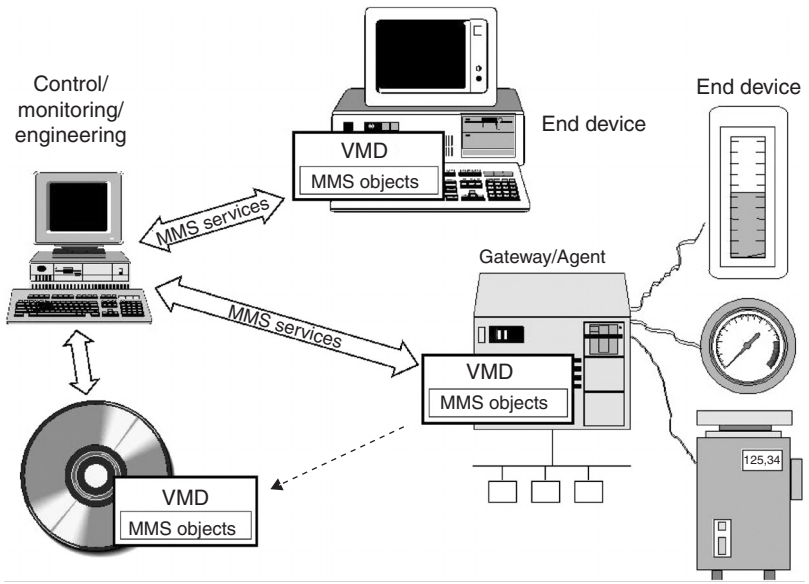

FIGURE 58.5 Location of VMDs.

© 2005 by CRC Press LLC

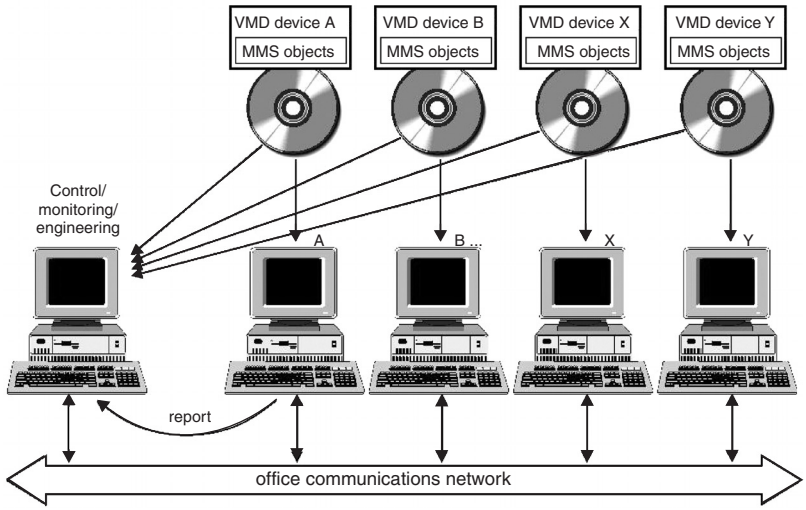

FIGURE 58.6 VMD testing using PC in an office environment.

The VMD is independent of the location. This also allows, for example — besides the support during configuration — that several VMD can be installed for testing purposes on a computer other than the final system (see Figure 58.6). Thus, the VMD of several large robots can be tested in the laboratory or office. The VMD will be installed on one or several computers (the computers emulate the real robots). Using a suitable communication (e.g., intranet or also a simple RS 232 connection — available on every PC), the original client (a control system that controls and supervises the robots) can now access and test the VMD in the laboratory. In this way, whole systems can be tested beforehand regarding the interaction of individual devices (e.g., monitoring and control system).

If the Internet is used instead of the intranet, global access is possible to any VMD that is connected to the Internet. The author himself tested the access from Germany to a VMD that was implemented on a PLC in the U.S.A. That is to say, through standards like MMS and open transmission systems, it has become possible to set up global communications networks for the real-time process data exchange.

The previous statements about the VMD are also valid in full extent for all standards that are based on MMS.

58.5 Interfaces

The increasing distribution of automation applications and the exploding amount of information require more and more and increasingly more complex interfaces for operation and monitoring. Complex interfaces turn into complicated interfaces very fast. Interfaces "cut" components into two pieces; through this, interactions between the emerged sub-components — which were hidden in one component before — become visible. An interface discloses as to which functions are carried out in the individual subcomponents and how they act in combination.

Transmitter and receiver of information must likewise be able to understand these definitions. The request "Read T142" must be formulated "understandably," transmitted correctly, and understood unambiguously (see Figure 58.7). The semantic (named terms that represent something) of the services and the service parameters are defined in MMS. The content, for example, of Named Variables is defined in domain-specific standards like IE 61850.

Interfaces occur in two forms:

- internal program–program interfaces or APIs and
- external interfaces over a network (WAN, LAN, fieldbus, …).

© 2005 by CRC Press LLC

Both interfaces affect each other. MMS defines an external interface. The necessity of complex interfaces (complex because of the necessary functionality, not because of an end in itself) is generally known and accepted. To keep the number of complex interfaces as small as possible, they are defined in standards or industry standards — mostly as open interfaces. Open interfaces are, in the meantime, integral components of every modern automation. In mid-1997, it was explained in Ref. [22] that the trend in automation engineering obviously leads away from the proprietary solutions to open, standardized interfaces — that is, to open systems.

The reason why open interfaces are complicated is not because they were standardized. Proprietary interfaces tend to be more complicated or even very complicated. The major reasons for the latter observation are found in the permanent "improvement" of the interfaces that express themselves in the quick changes of version and in the permanent development of new, apparently better, interfaces. Automation systems of one manufacturer often offer, for identical functions, a variety of complicated interfaces that are incompatible with each other.

At first, interfaces can be divided into two classes (see Figure 58.8): internal interfaces (e.g., in a computer) and external interfaces (over a communication network). The following consideration is strongly simplified because, for example, in reality both internally and externally several interfaces can lie one above the other. However, it nevertheless shows the differences in principle that require attention. MMS defines an external

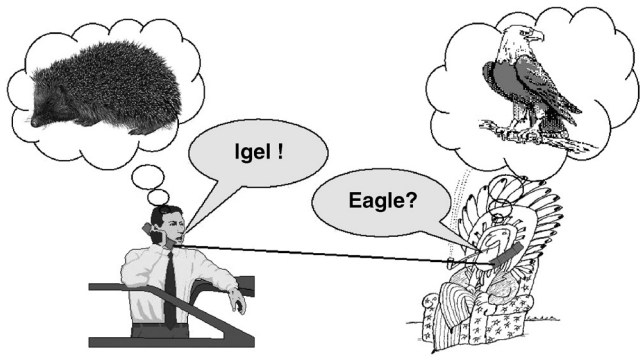

FIGURE 58.7 Sender and receiver of information.

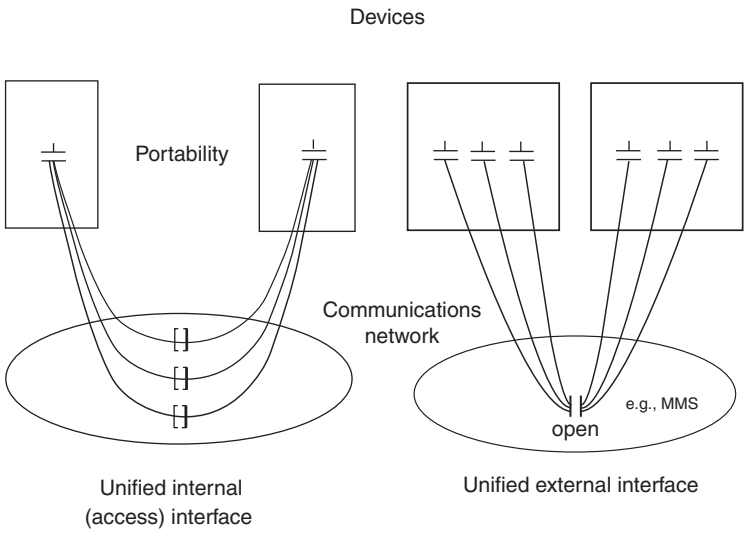

FIGURE 58.8 Internal and external interfaces.

© 2005 by CRC Press LLC

interface. Many understand MMS in such a way that it offers — or at least also offers — an internal interface. This notion results in completely false ideas. Therefore, the following consideration is very helpful.

The left-hand side of the figure shows the case with a uniform internal interface and varying external interfaces. This uniform internal interface allows many applications to access the same functions with the same parameters and perhaps the same programming language — independent of the external interface. Uniform internal interfaces basically allow the portability of the application programs over different external interfaces.

The right-hand side of the figure shows the case where the external interface is uniform. The internal interfaces are various (since the programming languages or the operating systems, e.g., are various). The uniform external interface is independent of the internal interface. The consequence of this is, for example, that devices whose local interfaces differ and are implemented in divers environments can communicate together. Differences can result, for example, from an interface being integrated into the application in a certain device, but being available explicitly in another device. The essential feature of this uniform external interface is the interoperability of different devices. The ISO/OSI reference model is aimed at exactly this feature.

The (internal) MMS interface, for example, in a client (perhaps: $READ (Par. 1, Par. 2, ... Par. N)) depends on the manufacturer, operating system, and programming language. MMS implementations are, for example, available for UNIX or Windows NT. On the one hand, this is a disadvantage because applications that wish to access an MMS server would have to support, depending on the environment, various real program interfaces. On the other hand, the MMS protocol is completely independent of the, fast-changing, operating system platforms. Standardized external interfaces like MMS offer a high degree on stability, because in the first place the communication can hardly be changed arbitrarily by a manufacturer and in the second place several design cycles of devices can survive.

Precisely the stability of the communication, as defined in MMS, also offers a stable basis for the development of internal interfaces on the various platforms such as under Windows 95, NT, or in UNIX environments.

In the ISO/OSI world, openness describes the interface on the "wire." The protocol of this external interface is executed according to defined standardized rules. For an interaction of two components, these rules have to be taken into account on the two sides; otherwise, the two will not understand each other.

58.6 Environment and General Management Services

MMS uses a connection-oriented mode of operation. That is to say, before, for example, a computer can read a value from a PLC for the first time, a connection must be set up between the two.

MMS connections have particular quality features such as:

- Exclusive allocation of computer and memory resources to a connection. This is necessary to guarantee that all services (e.g., five Read, …) that are allowed to be carried out simultaneously find sufficient resources on both sides of the connection.
- Flow control in order to avoid blockages and vain transmissions, if, for example, the receive buffers are full.
- Segmentation of long messages.
- Routing of messages over different networks.
- Supervision of the connection if no communication takes place.
- Acknowledgment of the transmitted data, and
- Authentication, access protection (password), and encoding of the messages.

Connections are generally established once and then remain established as long as a device is connected (at least during permanently necessary communication). If, for example, a device is only seldom accessed by a diagnostics system, a connection then does not need to be established permanently (waste of resources). It suffices to establish a connection and, later, to close it to release the needed resources again. The connection can remain established for rare but time-critical transmissions. The subordinate layers supervise the connection permanently. Through this, the interruption of a connection is quickly recognized.

© 2005 by CRC Press LLC

The MMS services for the connection management are:

- *initiate* (connection setup),
- *conclude* (orderly connection tear-down; waiting requests are still being answered), and
- *abort* (abrupt connection tear-down; waiting requests are deleted).

Besides these services that are all mapped to the subordinate layers, there are two further services:

- *cancel* and
- *reject*.

After the MMS client has sent a Read request to the MMS server, for example, it may happen that the server leaves the service in its request queue and — for whatever reason — does not process it. Using the Service Cancel, the client can now delete the request in the server. On the other hand, it may occur that the server shall carry out a service with "forbidden" parameters. Using Reject, it rejects the faulty request and reports this back to the client.

Although MMS was originally developed for ISO/OSI networks, a number of implementations are available in the meantime that also use other networks such as the known TCP/IP network. From the point of view of MMS, this is insignificant as long as the necessary quality of the connection is guaranteed.

58.7 VMD Support

The VMD object consists of 12 attributes. The Key Attribute identifies the "Executive Function." The Executive function corresponds directly with the entity of a VMD. A VMD is identified by a presentation address:

Object: VMD	
Key Attribute:	Executive Function
Attribute:	Vendor Name
Attribute:	Model Name
Attribute:	Revision
Attribute:	Logical Status (STATE-CHANGES-ALLOWED, NO-STATE- CHANGES-ALLOWED, LIMITED-SERVICES-SUPPORTED)
Attribute:	List of Capabilities
Attribute:	Physical Status (OPERATIONAL, PARTIALLY-OPERATIONAL, INOPERABLE NEEDS-COMMISSIONING)
Attribute:	List of Program Invocations
Attribute:	List of Domains
Attribute:	List of Transaction Objects
Attribute:	List of Upload State Machines (ULSM)
Attribute:	List of Other VMD-specific Objects

The attributes Vendor Name, Model Name, and Revision provide information about the manufacturer and the device.

The Logical status defines as to which services may be carried out. The status Limited-Services-Supported allows that only such services that have read access to the VMD be executed.

The Physical Status indicates whether or not the device works in principle.

The following two services:

- *Unsolicited Status* and
- *Status*

are used to get the status unsolicited (Unsolicited status) or explicitly requested (Status). Thus, a client can recognize whether a given server — from the point of view of the communication — works at all.

© 2005 by CRC Press LLC

The List of Capabilities offers clients and servers a possibility to define application-specific agreements in the form of features. The available memory of a device, for example, could be a capability. Through the Service Get Capability List, the current value can be queried. The remaining attributes contain the lists of all the MMS objects available in a VMD. The VMD therefore contains an Object Dictionary in which all objects of a VMD are recorded.

The following three services complete the services of the VMD:

- *Identify* supplies the VMD attributes Vendor Name, Model Name, and Revision. With this, a plausibility check can be carried out from the side of the client.
- *Get Name List* returns the names of all MMS objects. It can be selectively determined from which classes of objects (e.g., Named Variable or Event Condition) the names of the stored objects shall be queried. Let us assume a VMD is not yet known to the client till now (because it is, e.g., a maintenance device), the client can then browse through the VMD and systematically query all names of the objects. Using the Get services that are defined for every object class (e.g., Get Variable Access Attributes), the client can gain detailed knowledge about a given object (e.g., the Named Variable "T142").
- *Rename* allows a client to rename the name of an object.

58.8 Domain Management

Domains are to be viewed as containers that represent memory areas. Domain contents can be interchanged between different devices. The object type "domain" with its 12 attributes and 12 direct operations, which create, manipulate, ..., delete a domain, are part of the model.

The abstract structure of the domain object consists of the following attributes:

```
Object:    Domain
    Key Attribute:    Domain Name
    Attribute:        List of Capabilities
    Attribute:        State (LOADING, COMPLETE, INCOMPLETE,  READY, IN-USE)
    Constraint:       State = (LOADING, COMPLETE, INCOMPLETE)
        Attribute:        Assigned Application Association
        Attribute:        MMS Deletable
        Attribute:        Sharable (TRUE, FALSE)
        Attribute:        Domain Content
        Attribute :       List of Subordinate Objects
    Constraint:       State = (IN-USE)
        Attribute:        List of Program Invocation References
        Attribute:        Upload In Progress
        Attribute:        Additional Detail
```

The domain name is an identifier of a domain within a VMD.

Domain Content is a dummy for the information that is within a domain. The contents of the data to be transmitted can be coded transparently or according to certain rules agreed upon before. Using the MMS version (2003) [1, 2], the data stream can be coded per default in such a way that a VMD can be transmitted completely — including all MMS object definitions that it contains. This means, on the one hand, that the contents of a VMD can be loaded from a configuration tool into a device (or saved from a device), and on the other, that the contents can be stored on a disk per default.

Using a visible string, List of Capabilities describes which resources are to be provided — by the real device — for the domain of a VMD.

MMS Deletable indicates whether or not this domain may be deleted by means of a MMS operation.

Sharable indicates whether or not a domain may be used by more than one program invocation.

List of Program Invocation lists those Program Invocation Objects that use this domain.

© 2005 by CRC Press LLC

List of Subordinate Objects lists those MMS objects (no domains or program invocations) that are defined within this domain: objects that were (a) created by the domain loading, (b) created dynamically by a Program Invocation, (c) created dynamically by MMS operations, or (d) created locally.

State describes one of the ten states in which a domain can be.

Upload in Progress indicates whether or not the Domain Content of this domain is being copied to the client at the moment.

MMS defines loading in two directions:

- data transmission from the client to the server (download) and
- data transmission from the server to the client (Upload).

Three phases can be distinguished during loading:

- open transmission,
- segmented transmission, controlled by the data sink, and
- close transmission.

Transmission during download and upload is initiated by the client, respectively. If the server initiates, then it has the possibility to initiate the transmission indirectly (see Figure 58.9). For this purpose, the server informs the client that it (the client) shall initiate the loading. Even a third station can initiate the transmission by informing the server, which then informs the client.

What is the Domain Scope?

Further MMS objects can be defined within a domain: variable objects, event objects, and semaphore objects. That is to say, a domain forms a scope (validity range) in which named MMS objects are reversibly unambiguous.

MMS objects can be defined in three different scopes, as shown in Figure 58.10. Objects with VMD-specific scope (e.g., the variable "Status_125") can be addressed directly through this name by all clients. If an object has a domain-specific scope such as the object "Status_155," then it is identified by two identifiers:

Domain Identifier "Motor_2" and Object Identifier "Status_155."

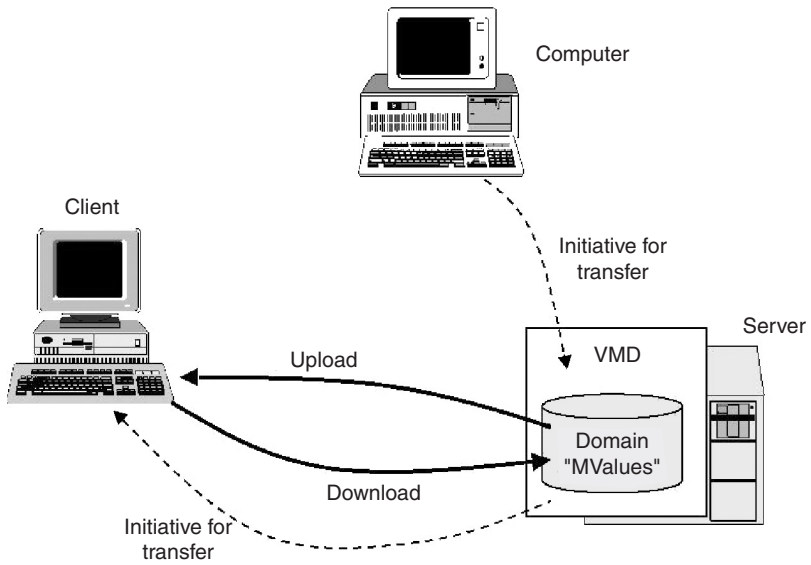

FIGURE 58.9 MMS domain transfer.

© 2005 by CRC Press LLC

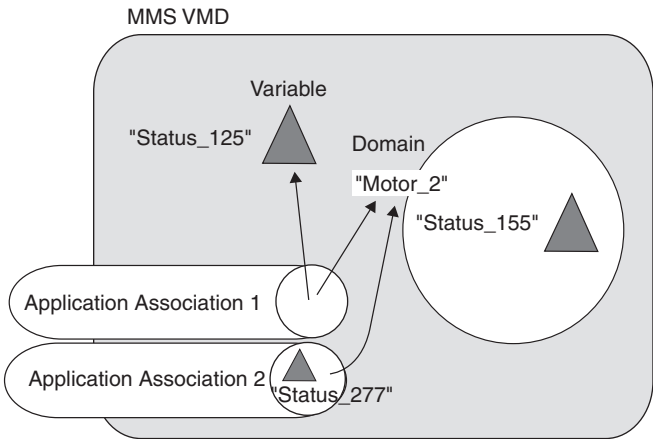

FIGURE 58.10 VMD- and Domain-scope.

A third scope is defined by the Application Association. The object "Status_277" is part of the corresponding connection. This object can only be accessed through this connection. When the connection is closed, all objects are deleted in this scope.

MMS objects can be organized using the different scopes. The object names (with or without domain scope) can be compounded from the following character set:

The identifiers can contain 1 to 32 characters and they must not start with a number.

The object names can be structured by agreement in a further standard or other specification. Many standards that reference MMS make considerable use of this possibility. This way, all named variables with the Prefix "RWE_" and similar prefixes, for example, could describe the membership of the data (in a trans-European information network) to a specific utility of an interconnected operation.

58.9 Program-Invocation-Management

A Program Invocation Object is a dynamic element that corresponds with the program executions in multitasking environments. Program Invocations are created by linking several domains. They are either predefined or created dynamically by MMS services or created locally.

A Program Invocation Object is defined by its name, its status (Idle, Starting, Running, Stopping, Stopped, Resuming, Unrunnable), the list of the domains to be used, and nine operations.

Object: Program Invocation
- Key Attribute: Program Invocation Name
- Attribute: State (IDLE, STARTING, RUNNING, STOPPING, STOPPED, RESUMING, RESETTING, UNRUNNABLE)
- Attribute: List of Domain References
- Attribute: MMS Deletable(TRUE, FALSE)
- Attribute: Reusable (TRUE, FALSE)
- Attribute: Monitor (TRUE, FALSE)
- Constraint: Monitor = TRUE
  - Attribute: Event Condition Reference
  - Attribute: Event Action Reference
  - Attribute: Event Enrollment Reference
  - Attribute: Execution Argument
  - Attribute: Additional Detail

© 2005 by CRC Press LLC

Program Invocations are structured flatly — although several Program Invocations can reference the same domains (Shared Domains). The contents of the individual domains are absolutely transparent from the point of view of both the domain and the Program Invocations. What is semantically connected with the Program Invocations is beyond the scope of MMS. The user of the MMS objects must therefore define the contents; the semantics result from this context. If a Program Invocation connects two domains, then the domain contents must define what these domains shall do together — MMS actually only provides a wrapper.

The Program Invocation Name is a clear identifier of a Program Invocation within a VMD.

State describes the status in which a Program Invocation can be. Altogether, seven states are defined.

List of Domains contains the names of the domains that are combined to a Program Invocation. This list also includes such domains that are created by the Program Invocation itself (this can be a domain in which some output is written).

MMS Deletable indicates whether or not this Program Invocation may be deleted by means of an MMS operation.

Reusable indicates whether or not a Program Invocation can be started again after the program execution. If it cannot be started again, then the program Invocation can only be deleted.

Monitor indicates whether or not the Program Invocation reports a transition to the client when exiting the Running status.

Start Argument contains an application-specific character string that was transferred to a Program Invocation during the last start operation; this string, for example, could indicate which function has started the program last.

Additional Detail allows the companion standards to give application-specific definitions.

Program Invocation Services

Create Program Invocations: This service arranges an operational program, which consists of the indicated domains, in the server. After installation, the Program Invocation is in the status Idle from where it can be started. The monitor and the monitor type indicate as to whether or not, and how the program invocation shall be monitored.

Delete Program Invocation: Deletable Program Invocations are deleted through this service. Primarily, that is to say that the resources bound to a Program Invocation are released again.

Start: The start service causes the server to transfer the specified Program Invocation from the Idle into the Running state. Further information can be transferred to the VMD through a character string in the start argument. A further parameter (Start Detail) once again contains additional information that can be defined by companion standards.

Stop: The stop service changes a specified Program Invocation from the Running into the Stopped state.

Resume: The Resume service changes a specified Program Invocation from the Stopped into the Running state.

Reset: The Reset service changes a specified Program Invocation from the Running or Stopped into the Idle state.

Kill: The Kill service changes a specified Program Invocation from arbitrary states into the Unrunnable state.

Get Program Invocation Attribute: Through this service, the client can read all attributes of a certain Program Invocation.

58.10 The MMS Variable Model

MMS Named Variables are addressed using identifiers composed of the domain name and the Named Variable name within the domain. Components of an MMS Named Variable may also be individually addressed using a scheme called Alternate Access. The Alternate Access address of a component consists of the domain name and the Named Variable name, along with a sequence of enclosing component names of the path down to the target component.

© 2005 by CRC Press LLC

The Variable Access Services contain an extensive variable model that offers the user a variety of advanced services for the description and offers access to arbitrary data of a distributed system.

A wide variety of process data are processed by automation systems. The data, their definition, and representation are usually oriented toward the technological requirements and the available automation equipment. The methods that the components use for the representation of their data and the access to them correspond to the way of thinking of their implementers. This has resulted in a wide variety of data representations and access procedures for one and the same technological datum in different components. If, for example, a certain temperature measurement shall be accessed to in different devices, then a huge quantity of internal details must generally be taken into account for every device (request, parameter, coding of the data, ...).

As shown in Figure 58.11, the number of the protocols for the access of a client (on the left in the figure) to the data from *n* servers (S1 – S*n*) can be reduced to a single protocol (on the right in the figure). Through this, the data rate required for the communication primarily in central devices can be reduced drastically.

In programs, variables are declared, that is, they get a name, a type, and a value. Described in a simplified way, both the name and the type are converted by the compiler into a memory location and into a reference that is only accessible to the compiled program. Without any further measures, the data of the variable are not identifiable outside the program. It is concealed for the user of the program how a compiler carries out the translation into the representation of a certain real machine.

The data are stored in different ways depending on the processor; that is, primarily that the data are stored in various memory locations. During the runtime of the program, only this representation is available.

These data are not visible from the outside. They must first be made visible for the access from the outside. To enable this, an entity must be provided in the implementation of the application. It is insignificant here whether or not this entity is separated from or integrated into the program. This entity is acting for all data that shall be accessible from the outside.

This consideration is helpful for the explanation of the MMS variable model: what do protocols through which process data are accessed have in common? Figure 58.12 shows the characteristics in principle. On the right is the memory with the real process data that shall be read. The client must be able to identify the data to be read (gray shade). For this purpose, pointer (start address) and length of the data must be known. By means of this information, the data can be identified in the memory.

Yet how can a client know the pointer of the data and what the length of the data is? It could have this information somehow and indicate it when reading. Yet if the data should move some time, then the pointer of the data is not correct any more. There can also be the case that the data do not exist at all at the time of reading but must be calculated first. In this case, there is no pointer. To avoid this, references

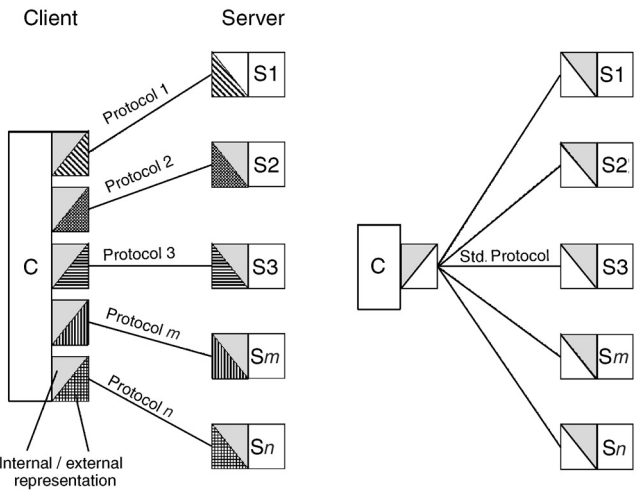

FIGURE 58.11 Unified protocols.

© 2005 by CRC Press LLC

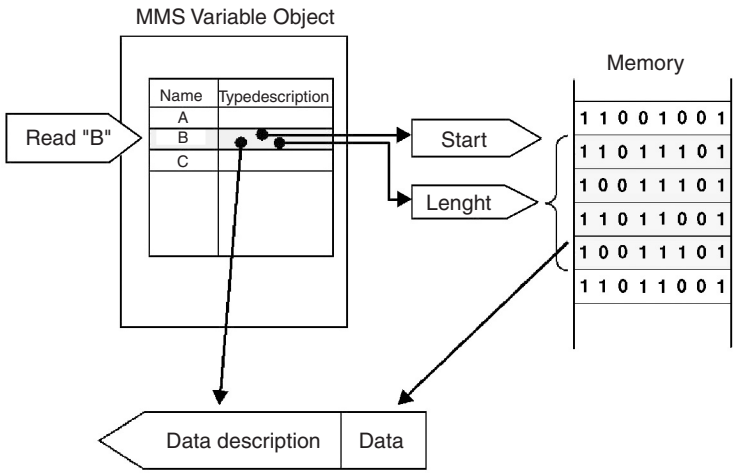

FIGURE 58.12 Data access principle.

to the data, which are mapped to the actual pointers (table or algorithm), are used in most cases. In our case, the reference "B" is mapped by table to the corresponding pointer and the length.

The pointer and the length are stored in the type description of the table. The pointer is a system-specific value, which is generally not visible on the outside. The length is dependent on the internal representation of the memory and on the type. An individual bit can, for example, be stored as an individual bit in the memory or also as a whole octet. However, this is not relevant from the point of view of the communication.

The data themselves and their description are important for the message response of the read service. The question of the external representation (is, e.g., an individual bit encoded as a bit or as an octet?) is — unlike the internal representation — of special importance here! The various receivers of the data must be able to interpret the data unambiguously. For this purpose, they need the representation that is a substantial component of the MMS variable model. The data description is therefore derived from the type description.

For a deeper understanding of the variable model, three aspects have to be explained more exactly:

- objects and their functions,
- services (read, write, …) that access the MMS variable objects, and
- data description for the transmission of the data.

The object model of an MMS variable object is conceptually different from a variable according to a programming language. The MMS objects describe the access path to structured data. In this sense, they do not have any variable value.

Access Paths

The access path represents an essential feature of the MMS variable model. Starting from a more complex hierarchical structure, we will consider the concept. The abstract and extremely simplified example are deliberately chosen. Here, we are merely concerned about the principle.

Certain data of a machine shall be modeled using MMS methods. The machine has a tool magazine with *n* similar tools. A tool is represented — according to Figure 58.13 — by three components (tool type, number of the blades, and remaining use time).

The machine with its tool magazine "M" is outlined in the figure on the right. The magazine contains three tools "A," "B," and "C." The appropriate data structure of the magazine is shown on the left. The structure is tree-like; the root "M" is drawn as the topmost small circle (node). "M" has three components (branches) "A," "B," and "C," which are also represented as circles. These components in turn also have three components (branches). In this case, the branches end in a leaf (represented in the form of a

© 2005 by CRC Press LLC

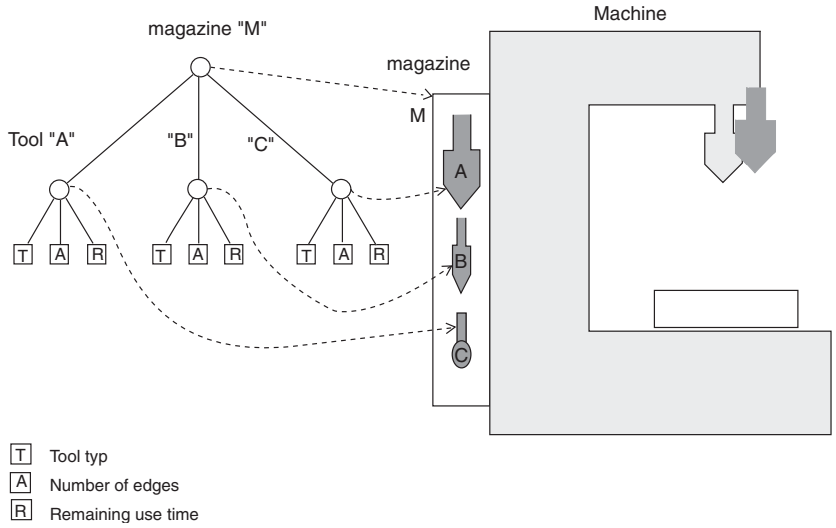

FIGURE 58.13 Data of a machine.

square). Leaves represent the end-points of the branches. For each tool, three leaves are shown: "T" (tool type), "A" (number of blades), and "R" (remaining use time). The leaves represent the real data. The nodes ordered hierarchically are merely introduced for reasons of clustering. Leaves can occur at all nodes. A leaf with the information "magazine full/not full" could, for example, be attached at the topmost node.

With this structure, the MMS features are explained in more detail. The most essential aspect is the definition of the access path. The access to the data (and their use) can be carried out according to various task definitions:

1. selecting all leaves for reading, writing …,
2. selecting certain leaves for reading, writing …, and,
3. selecting all leaves as component of a higher-level structure, for example, "machine" with the components magazine "M" and drilling machine, and
4. selecting certain leaves as component of a higher-level structure.

Examples of cases 1. and 2. are shown in Figure 58.14. The case that the complete structure is read is shown in the left top corner (the selected nodes, branches, and leaves are represented in bold lines or squares). All nine data are transmitted as response ($3 \times (T+A+R)$). At first, the representation during transmission is deliberately refrained from here and also in the following examples.

Only a part of the data is read in the top right corner of the figure: respectively only the leaf "R" of all three components "A," "B," and "C." The notation for the description of the subset M.A.R/.B.R/.C.R is chosen arbitrarily.

The subset M.A.R represents a (access) path that leads from a root to a leaf. It can also be said that one or several paths represent a part of a tree. The read message contains three paths that must be described in the request completely. A path, for example, can also end at "A." All three components of "A" will be transmitted in this case.

Besides the possibility to describe every conceivable subset, MMS also supports the possibility to read several objects "M1" and "M5" in a read request simultaneously (see the lower half of the figure). Of course, every object can only be partly read too (which is, however, not represented).

An example of case 4 is shown in Figure 58.15 (case 4 has to be understood as the generalization of case 3). Here, a new structure was defined using two substructures. The object "machine" contains only the "R" component of all six tools of the two magazines "M1" and "M5." The object "machine" shall not be mixed up with a list (Named Variable List). Read "machine" supplies the six individual "R" values.

© 2005 by CRC Press LLC

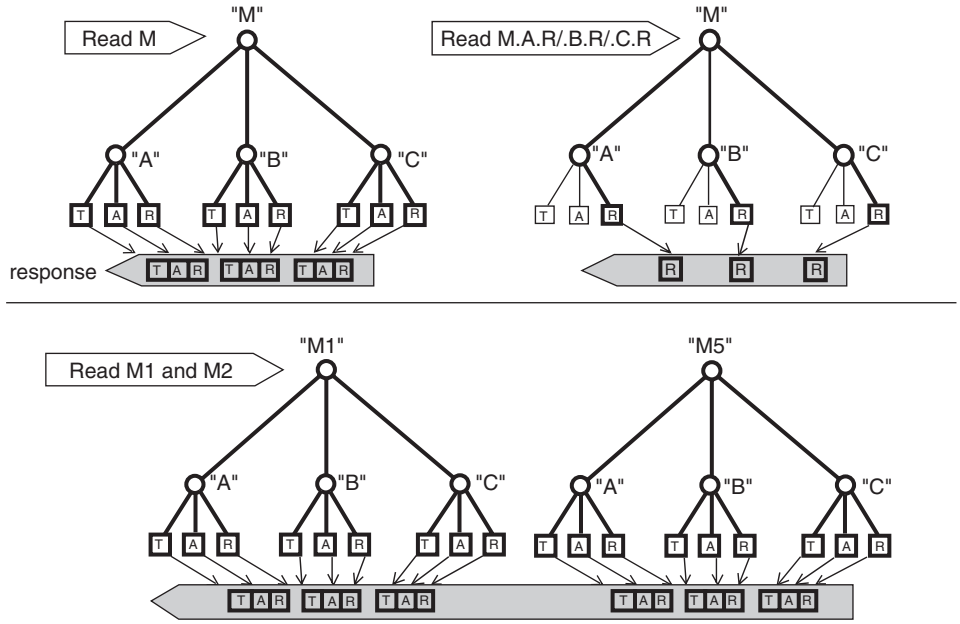

FIGURE 58.14 Access and partial access.

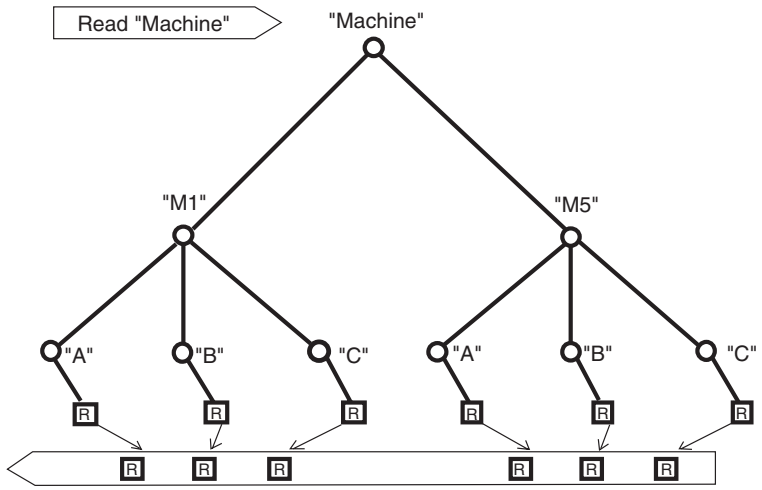

FIGURE 58.15 "Partial" trees.

The component names, such as "A," "B," or "C," need to be unambiguous only below a node — and only at the next lower level. Thus, "R" can always stand for the remaining lifetime. The position in the tree indicates the remaining lifetime of a particular tool. The new structure "machine" has all features that were described in the previous examples also for "M1" and "M5."

These features of the MMS variable objects can be applied to (1) the definition of new variable objects and (2) the access to existing variable objects. The second case is also interesting. As shown in Figure 58.16, the same result as in Figure 58.15 can be achieved by enclosing the description (only the "R" components of the tools shall be read from the two objects "M1" and "M5") in the read request every time. The results (read answer) are absolutely identical in the two cases.

© 2005 by CRC Press LLC

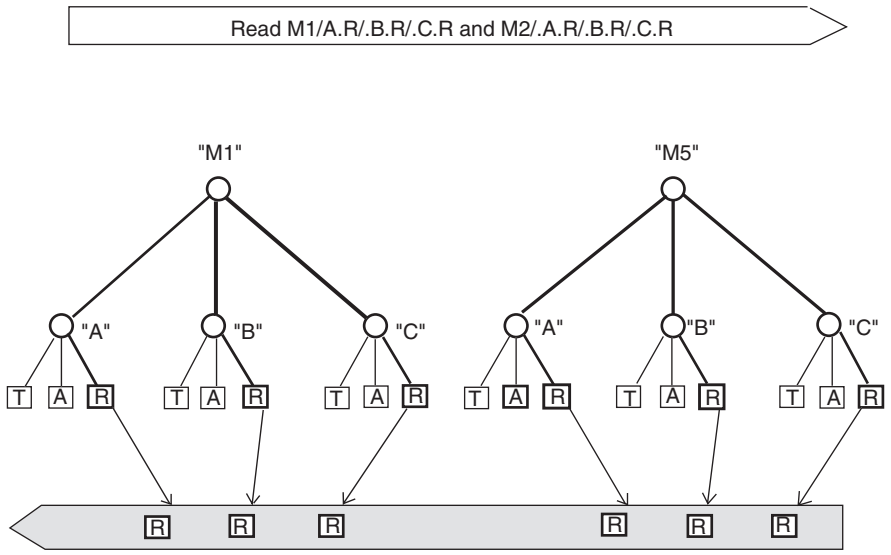

FIGURE 58.16 "Partial" trees used for read requests.

Every possibility, to assemble hierarchies from other hierarchies (1), or to, for example, read parts of a tree during the access (2), has its useful application. The first case is important in order to avoid enclosing the complete path description every time when reading an extensive part of tree. The second case offers the possibility to construct complex structures based on standardized basic structures (e.g., the structure of "tool data" consisting of the components "T," "A," and "R") and to use them for the definition of new objects.

Summarizing, it can be stated that the access paths accomplish two tasks:

- description of a subset of nodes, branches, and leaves of objects during reading, writing, …, and
- description of a subset of nodes, branches, and leaves of objects during the definition of new objects.

In conclusion, this may again be expressed in the following way: path descriptions describe the "way" or the "ways" to a single data (leaf) or to several data (leaves). A client can read the structure description (complete tree) through the MMS service Get Variable Access Attributes.

Another aspect is also of special importance. Till now, we have not considered the description of leaves. Every leaf has one of the following MMS basic data types:

- BOOLEAN,
- BIT,
- INTEGER,
- UNSIGNED,
- FLOATING POINT,
- REAL,
- OCTET STRING,
- VISIBLE,
- GENERALIZED TIME,
- BINARY, and
- BCD.

Every node in a tree is either an array or a structure. Arrays have n elements (0 to $n-1$) of the same type (this can be a basic type, an array or a structure). When describing a part of a tree, any number of array elements can be selected (e.g., one element, two adjacent elements, two arbitrary elements, …).

Structures consist of one or several components. Every component can be marked by its position and if necessary by an "Identifier" — the component name. This component name (e.g., "A") is used for the access to a component. Parts of trees can describe every subset of the structure.

© 2005 by CRC Press LLC

The path description contains the following three elements:

- All of the possibilities of the description of the structures (individual and composite paths in the type description of the MMS variables) are defined in the form of an extensive abstract syntax.
- For every leaf of a structure (these are MMS basic data types), the value range (size) is also defined besides the class. The value range of the class INTEGER can contain one, two, or more octets. The value range four (4) octets (often represented as Int32) for example, indicates that the value cannot exceed these four octets. On the other hand, with ASN.1 BER coding (explained later) and the value range Int32, the decimal value "5" will be transmitted in only one octet (not in 4 octets!). That is to say, only the length needed for the current value will be transmitted.
- The aspect of the representation of the data and their structuring during transmission on the line (communication in the original meaning) is dealt with below in the context of the encoding of messages.

The path description is used in a quintuple way (see Figure 58.17):

- during the access to and during the definition of variable objects,
- in the type description of variable objects,
- in the description of data during reading, for example,
- during the definition of Named Type Objects (an object name of its own is assigned to the type description – i.e., to one or several paths – of those objects), and
- when reading the attributes of variables and Named Type Objects.

Objects of the MMS Variable Model

The five objects of the MMS variable model are:
Description of simple or complex values:

- Unnamed Variable,
- Named Variable.

List of several unnamed variables or named variables:

- Named Variable List,
- Scattered Access (is not explained here).

Description of the structure by means of a user-defined name:

- Named Type.

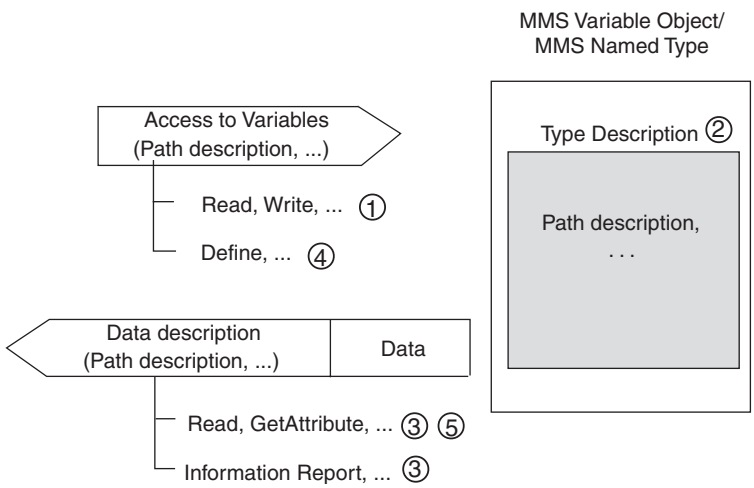

FIGURE 58.17 Application of path descriptions.

© 2005 by CRC Press LLC

The Unnamed Variable

The Unnamed Variable Object describes the assignment of an individual MMS variable to a real variable that is located at a definite address in the device. An Unnamed Variable Object can never be created or deleted. The Unnamed Variable has the attributes:

Object: Unnamed Variable
- Key Attribute: Address
- Attribute: MMS Deletable (FALSE)
- Attribute: Access Method (PUBLIC)
- Attribute: Type Description

Address: Address is used to reference the object. There are three different kinds:

1. Numeric Address (nonnegative integer values),
2. Symbolic Address (character string), and
3. Unconstrained Address (implementation specific format).

Even though in (2) the address is represented by character strings, this kind of addressing has absolutely to be distinguished from the Object Name of a Named Variable (see domain scope and explanations below).

MMS Deletable: The attribute is always FALSE here.
Access method: The attribute is always PUBLIC here.

Type Description: The attribute points to the inherent abstract type of the subordinate real variable as it is seen by MMS. It specifies the class (bitstring, integer, floating-point, etc.), the value range of the values, and the group formation of the real variable (arrays of structures). The attribute Type Description is completely independent of the addressing.

Figure 58.18 represents the Unnamed Variable roughly sketched. The Unnamed Variable with the address "62" (MMSString) has three components with the names: value, quality, and time. These component names are only required if individual components (specifying the path, for e.g., "62"/"Value") shall be accessed.

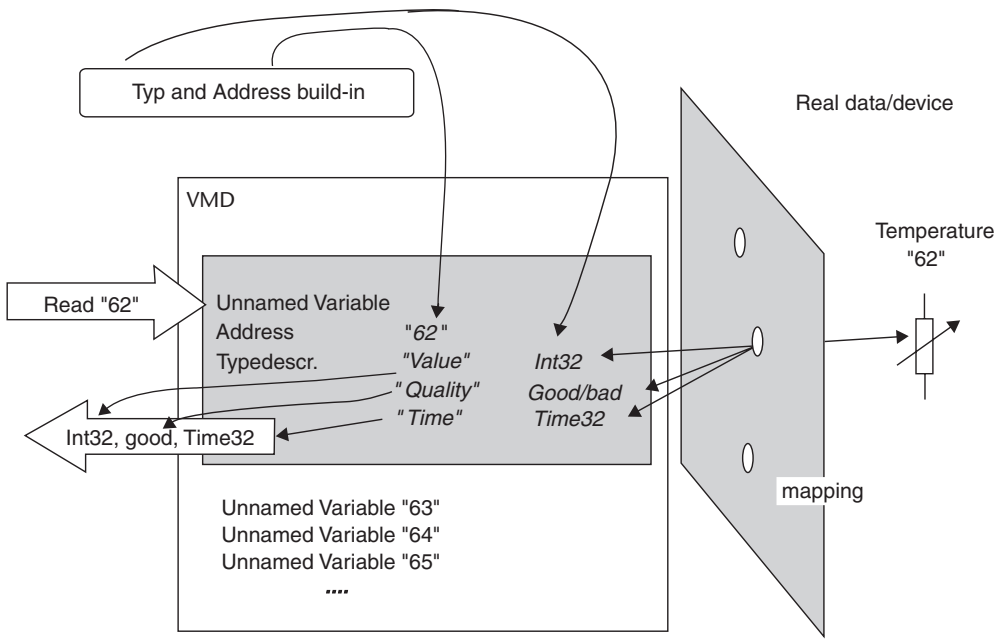

FIGURE 58.18 Unnamed Variable Object.

© 2005 by CRC Press LLC

MMS Address of the Unnamed Variable

The MMS Address is a system-specific reference that is used by the system for the internal addressing — it is quasi-released for the access via MMS. There, the address can assume one of three forms (here, the ASN.1 notation is deliberately used for the first time):

```
Address ::= CHOICE {
   numericAddress          [0] IMPLICIT Unsigned32,
   symbolicAddress         [1] MMSString,
   unconstrainedAddress    [2] IMPLICIT OCTET STRING
   }
```

The above definition has to be read as follows: address defines as (::=) a selection (keyword CHOICE) of three possibilities. The possibilities are numbered here from [0] to [2] to be able to distinguish them. The keyword IMPLICIT is discussed later.

The numeric address is defined as Unsigned32 (4 octet). Thus, the addresses can be defined as an index with a value range of up to 2**32. Since only the actual length (e.g., only one octet for the value 65) will be transmitted for an Unsigned32, the minimal length of the index, which can thus be used, is merely 1 octet. Already, 255 objects (of arbitrary complexity!) can be addressed with one octet.

The symbolic address can transmit an arbitrarily long MMSString (e.g., "DB5_DW6").

The Unconstrained Address represents an arbitrarily long octet string (e.g., 24FE23F2A1hex). The meaning and the structure of these addresses are beyond the scope of the standard.

These addresses can be used in MMS Unnamed Variable and Named Variable Objects and in the corresponding services. MMS can neither define nor change these addresses. The address offers a possibility to reference objects by short indexes.

The addresses can be structured arbitrarily. Unnamed Variables could, for example, contain measurements in the address range (1000 to 1999), status information in the address range (3000 to 3999), limit values in the address range (7000 to 7999), etc.

Services for the Unnamed Variable Object

Read: This service uses the V-Get function to transmit the current value of the real variable, which is described by the Unnamed Variable Object, from a server to a client. Variable Get represents the internal, system-specific function through which an implementation obtains the actual data and provides them for the communication.

Write: This service uses the V-Put function to replace the current value of the real variable, which is described by the Unnamed Variable Object, by the enclosed value.

Information Report: As Read, although without prior request by the client. Only the Read.response is sent by the server to the client without being asked. The Information Report corresponds to a spontaneous message. The application itself determines when the transmission is to be activated.

Get Variable Access Attributes: Through this operation, a client can query the attributes of an Unnamed Variable Object.

Explanation of the TypeDescription

Features of the structure description of MMS variable objects were explained in principle above. For those interested in the details, the formal definition of the MMS Type Specification is explained according to Figure 58.19.

The description in ASN.1 was deliberately also selected here. The type specification is a CHOICE (selection) of 15 possibilities (Tags [0] to [13] and [15]). Tags are qualifications of the selected possibility. The first possibility is the specification of an ObjectName, a Named Type Object. If we remember that one Named Type Object describes one or several paths, then the use is obvious. The path description referenced by the name can be used to define a Named Variable Object. Or, if during reading the path must be specified, it can be referenced by a Named Type Object in the server.

© 2005 by CRC Press LLC

```
TypeSpecification ::= CHOICE {
        typeName                [0] ObjectName,
        array                   [1] IMPLICIT SEQUENCE {
                packed                  [0] IMPLICIT BOOLEAN DEFAULT FALSE,
                numberOfElements        [1] IMPLICIT Unsigned32,
                elementType             [2] TypeSpecification },
        structure               [2] IMPLICIT SEQUENCE {
                packed                  [0] IMPLICIT BOOLEAN DEFAULT FALSE,
                components              [1] IMPLICIT SEQUENCE OF SEQUENCE {
                        componentName   [0] IMPLICIT Identifier OPTIONAL,
                        componentType           [1] TypeSpecification } },

        Simple                  Size                            Class
        boolean                 [3] IMPLICIT NULL,              - BOOLEAN
        bit-string              [4] IMPLICIT Integer32,         - BIT-STRING
        integer                 [5] IMPLICIT Unsigned8,         - INTEGER
        unsigned                [6] IMPLICIT Unsigned8,         - UNSIGNED
        floating-point          [7] IMPLICIT SEQUENCE {
                format-width            Unsigned8,      - # of bits in fraction plus sign
                exponent-width          Unsigned8       - size of exponent in bits },
        real                    [8] IMPLICIT SEQUENCE {
                base                    [0] IMPLICIT INTEGER(2|10),
                exponent                [1] IMPLICIT INTEGER,   - max number of octets
                mantissa                [2] IMPLICIT INTEGER    - max number of octets },
        octet-string            [9] IMPLICIT Integer32,         - OCTET-STRING
        visible-string          [10] IMPLICIT Integer32,        - VISIBLE-STRING
        generalized-time        [11] IMPLICIT NULL,             - GENERALIZED-TIME
        binary-time             [12] IMPLICIT BOOLEAN,          - BINARY-TIME
        bcd                     [13] IMPLICIT Unsigned8         - BCD
        objId                   [15] IMPLICIT NULL}
```

FIUGRE 58.19 MMS Typespecification.

Note that the ASN.1 definitions in MMS are comparable with XML schema. ASN.1 BER (Basic encoding rules) provide very efficient message encoding compared to XML documents. The forth coming standard IEC 61400-25 provides applies ASN.1 as well as an XML schema for the specification of messages.

The next two possibilities (array and structure) have a common feature. Both refer — through their element type or component type — back to the beginning of the complete definition (type specification). This recursive definition allows the definition of arbitrarily complex structures. Thus, an element of a structure can in turn be a structure or an array.

Arrays are defined by three features. Packed defines whether or not the data are stored optimized. Number-Of-Elements indicates the number of the elements of the array of equal type (Element Type).

The data of structures can also be saved as packed. Structures consist of a series of components (components [1] IMPLICIT SEQUENCE OF SEQUENCE). This series is marked by the keyword SEQUENCE OF ..., which describes a repetition of the following definition. Next in the list is SEQUENCE {component Name und component Type}, which describes the individual component. Since the SEQUENCE OF ... (repetition) can be arbitrarily long, the number of the components at a node is also arbitrary.

Then follow the "simple data types." They start at the tag [3]. The length of the types is typical for the simple data types. For example, integers of different lengths can be defined. The length (size) is defined as Unsigned8, which allows for an integer with the length of 255 octets.

It should be mentioned here that — in the ASN.1 description of the MMS syntax — expressions like integer (written in small letters) show that they are replaced by another definition (in this case by the Tag [5] with the IMPLICIT-Unsigned8 definition). Capital letters at the beginning indicate that the definition is terminated here — it is not replaced any more. Here, it is a basic definition.

Figure 58.20 shows an example of an object defined in IEC 61850-7-4 [20]. The circuit breaker class is instantiated as "XCBR1." The hierarchical components of the object are mapped to MMS (according to IEC 61850-8-1 [21]). The circuit breaker is defined as a comprehensive MMS Named Variable.

© 2005 by CRC Press LLC

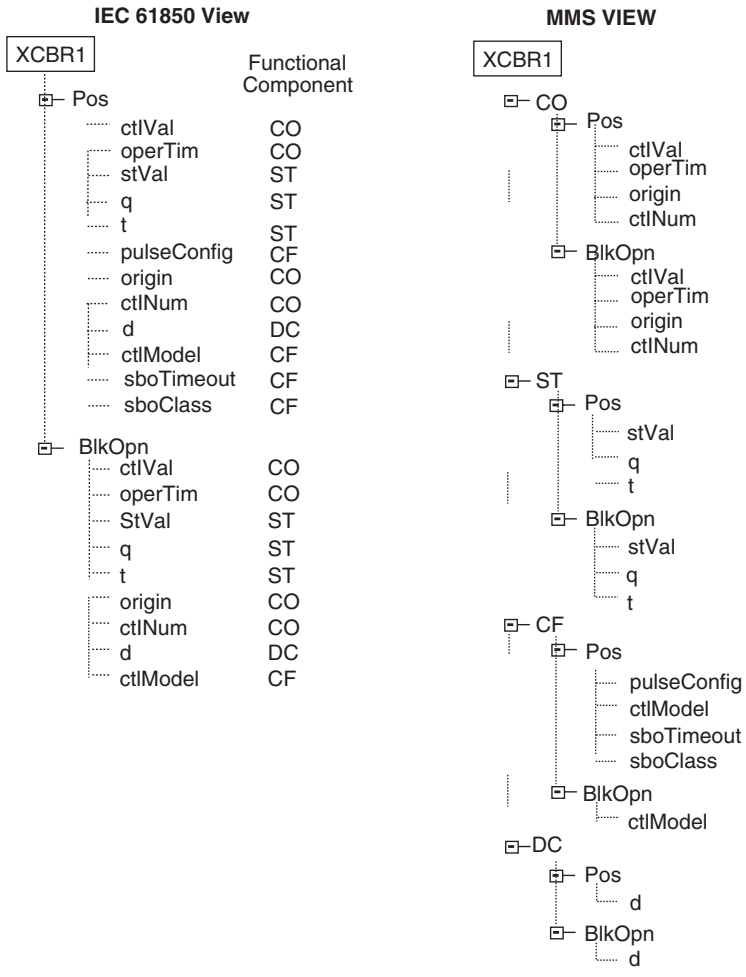

FIGURE 58.20 Example MMS Named Variable.

The components of the hirarchical model can be accessed by the description of the Alternate Access: "XCBR1" → component "ST" → component "Pos" → component "stVal." Another possibility of mapping the hierarchy to a flat name is depicted in Figure 58.21. Each path is defined as a character string.

The Named Variable

The Named Variable Object describes the assignment of a named MMS variable to a real variable. Only one Named Variable Object should be assigned to a real variable. The attributes of the object are as follows:

Object: Named Variable
- Key Attribute: Variable Name
- Attribute: MMS Deletable
- Attribute: Type Description
- Attribute: Access Method (PUBLIC, ...)
  - Constraint: Access Method = PUBLIC
  - Attribute: Address

Variable Name: The Variable Name unambiguously defines the Named Variable Object in a given scope (VMD specific, domain specific, or Application Association specific). The Variable Name can be 32 characters long (plus 32 characters if the object has a domain scope).

© 2005 by CRC Press LLC

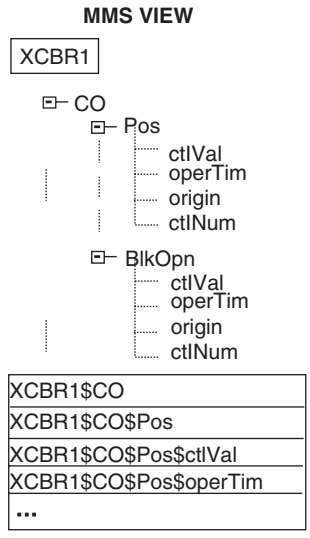

FIGURE 58.21 Example MMS Named Variable.

MMS Deletable: This attribute shows whether or not the object may be deleted using a service.

Type Description: This attribute describes the abstract type of the subordinate real variable as it represents itself to the external user. This attribute is not inherently in the system unlike the Unnamed Variable Object, that is, this Type Description can be defined from the outside.

Access method: This attribute contains the information that a device needs to identify the real variable. It contains values that are necessary and adequate to find the memory location. The contents lie outside MMS. A special method, the method PUBLIC, is standardized. The attribute Address is also available in the case of PUBLIC. This is the address that identifies an Unnamed Variable Object. Named Variables can thus be addressed by the name and the ADDRESS (see Figure 58.22).

Address: See Unnamed Variable Object. Defining a Named Variable Object does not allocate any memory either, because the real variable must already exist; it is assigned to the Named Variable Object with the corresponding name.

Altogether, six operations are defined on the object:

Read: The service uses the V-Get function to retrieve the current value of the real data, which is described by the Object.

Write: The service uses the V-Put function to replace the current value of the real data, which is described by the Object, by the enclosed value.

Define Named Variable: This service creates a new Named Variable Object, which is assigned to real data.

Get Variable Access Attribute: Through this operation, a client can query the attributes of a Named Variable Object.

Delete Variable Access: This service deletes a Named Variable Object if Attribute Deletable is (=TRUE).

Figure 58.23 shows the possibilities to reference a Named Variable Object by names, and if it is required, also by Address (optimal access reference of a given system). For a given name, a client can query the Address by means of the service Get Variable Access Attribute.

This possibility allows the access through technological names (MeasurementTIC13) or with the optimal (index-) address 23 24 hex.

As shown in Figure 58.23, an essential feature of the VMD is the possibility for the client application to define by request Named Variable Objects in the server via the communication. This includes the definition of the name, the type, and the structure. The name by which the client would like to reference the Named Variable later is “TIC42” here. The first component “Value” is of the type Integer32,

© 2005 by CRC Press LLC

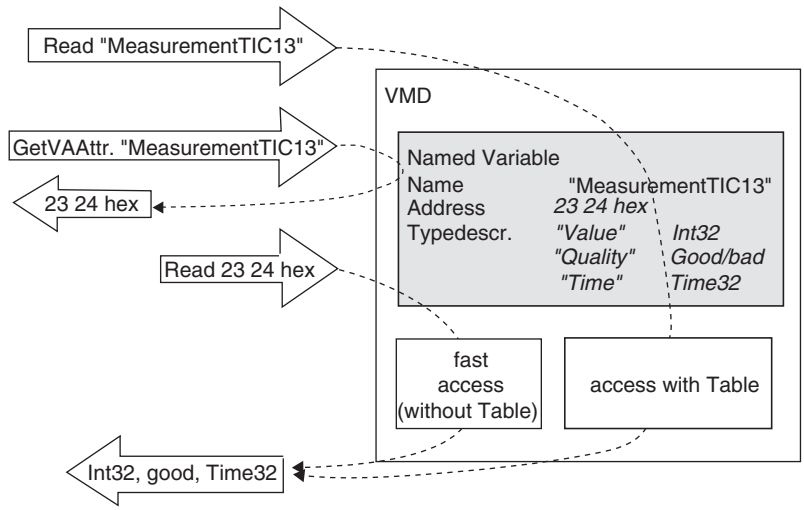

FIGURE 58.22 Address and Variable Name of Named Variable Objects.

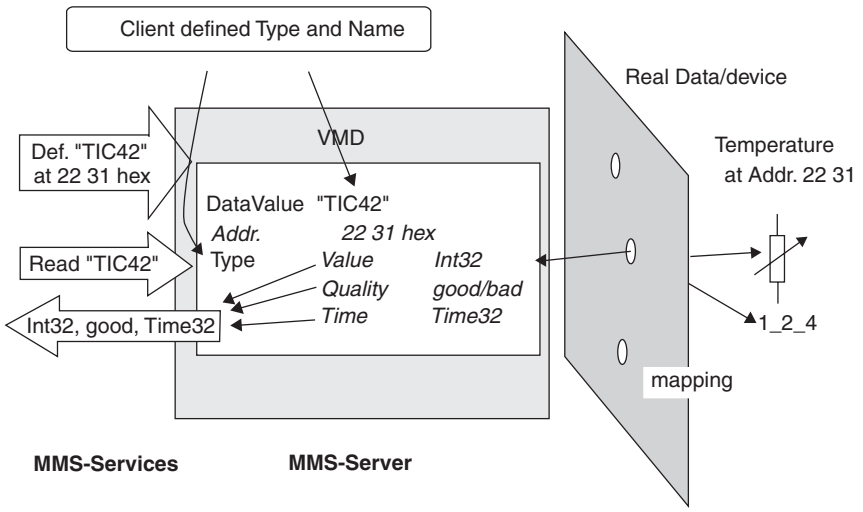

FIGURE 58.23 Client-defined Named Variable Object.

the second is "Quality" with the values "good" or "bad," and the third is "Time" of the type "Time32." The type of the Data Value Object can be arbitrarily simple (flat) or complex (hierarchical). As a rule, the Data Value Objects are implicitly created by the local configuring or programming of the server (they are predefined).

The internal assignment of the variable to the real temperature measurement is made by a system-specific, optimal reference. This reference whose structure and contents are transparent must be known when defining the Named Variable, though. The reference can, for example, be a relative memory address (e.g., DB5 DW15 of a PLC). So a quick access to the data is allowed.

The Named Variable Object describes how data for the communication are modeled, accessed, encoded, and transmitted. What is transmitted is described independent of the function. From the point of view of communication, it is not relevant where the data in the server actually come from or where in the client they actually go to and how they are managed — this is deliberately concealed.

© 2005 by CRC Press LLC

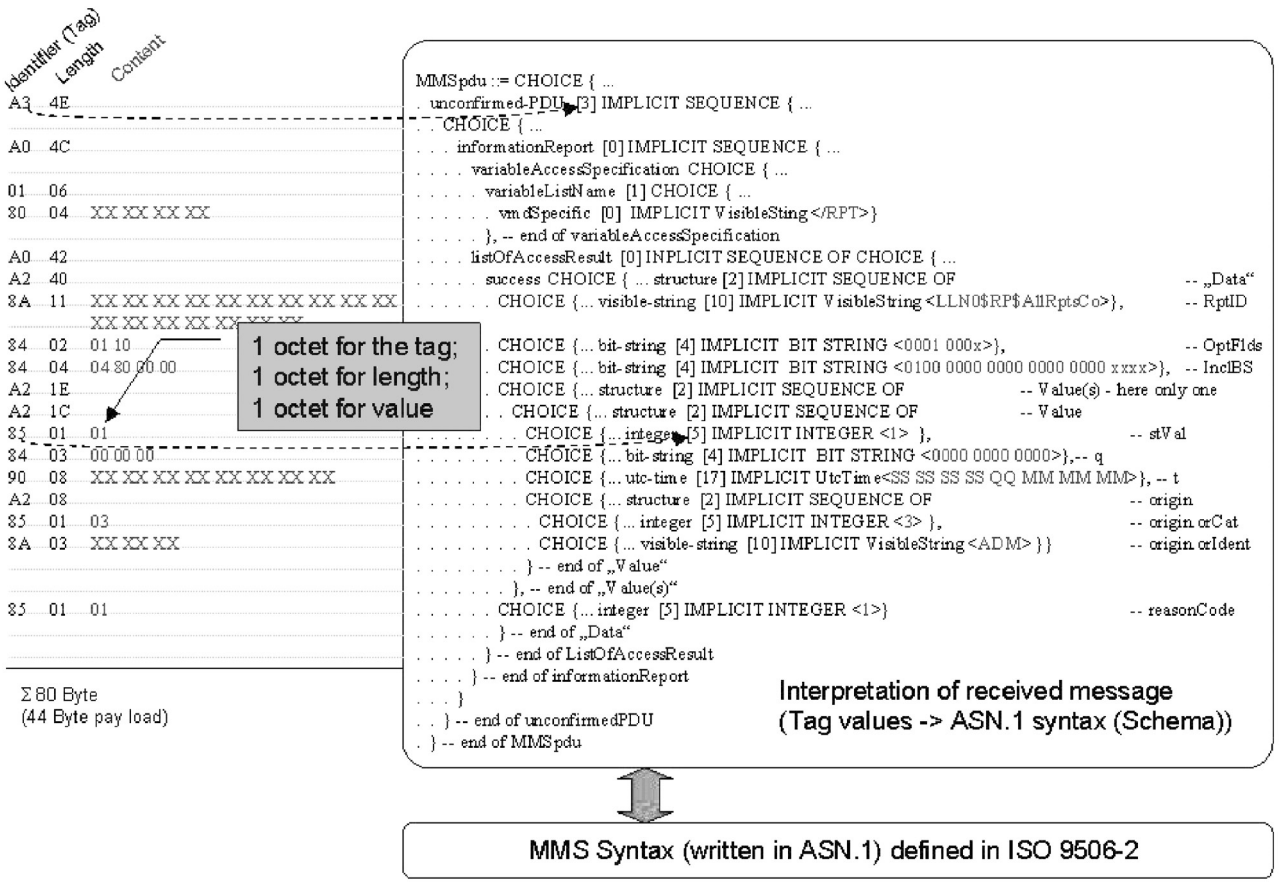

FIGURE 58.24 MMS Information Report (spontaneous message).

© 2005 by CRC Press LLC

Figure 58.24 shows the concrete encoding of the Information Report message. The message is encoded according to ASN.1 BER (the basic encoding rule for abstract syntax notation number one — ISO 8825).

The encoding using XML would be several times longer than when using ASN.1 BER. These Octets are packed into further messages that add lower layer-specific control and address information, for example, the TCP header, IP header, and Ethernet frames.

The receiving IED is able to interpret the Report message according to the identifier, lengths, names, and other values. The interpretation of the message requires the same stack, that is, knowledge of all layers involved — including the definitions of IEC 61850-7-4 [20], IEC 61850-7-3 [19], IEC 61850-7-2 [18], and IEC 61850-7-1 [17].

The Access to Several Variables

Named Variable List

The Named Variable List allows to define a single name for a group of references to arbitrary MMS Unnamed Variables and Named Variables. Thus, the Named Variable List offers a grouping for the frequently repeated access to several variables (see Figure 58.25). Although the simultaneous access to several MMS variables can also be carried out in a single service (Read or Write), the Named Variable List offers a substantial advantage.

When reading several variables in a Read request, the individual names and the internal access parameters (pointers and lengths), corresponding to the names in the request, must be searched for in a server. This search can last for some time in the case of many names or a low processor performance. By using the Named Variable List Object, the search is not required — except for the search of a single name (the name of the Named Variable List Object) — if the references, for example, have been entered into the Named Variables on the list system specifically and thus optimally. Once the name of the list has been found, the appropriate data can be provided quickly.

Thus, the Named Variable List Object provides optimal access features for the applications. This object class is used in the known applications of MMS very intensively.

The structure of the Named Variable List Object is as follows:

Object: Named Variable List
  Key Attribute: Variable List Name
  Attribute: MMS Deletable (TRUE, FALSE)

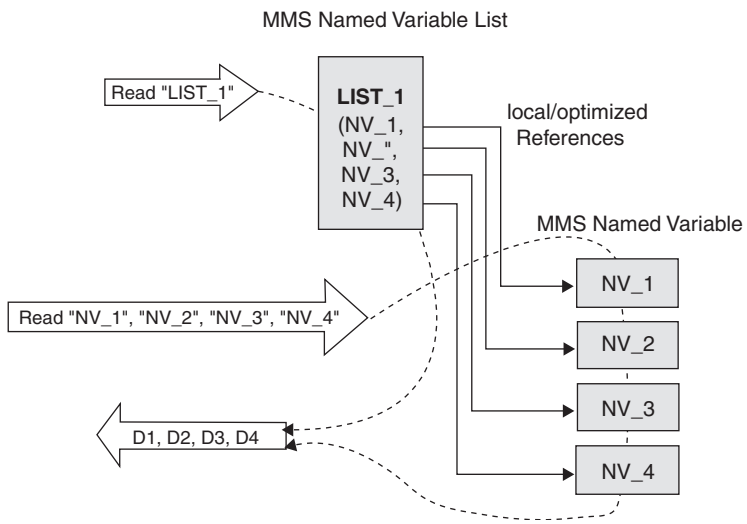

FIGURE 58.25 MMS Named Type and Named Variable.

© 2005 by CRC Press LLC

Attribute: List of Variable
  Attribute: Kind of Reference (NAMED, UNNAMED, SCATTERED)
  Attribute: Reference
  Attribute: Access Description

Variable List Name: The Variable List Name unambiguously identifies the Named Variable List Object in a given scope (VMD specific, domain specific, or Application Association specific). See also MMS Object Names above.

MMS Deletable: This attribute shows whether or not the object may be deleted.

List of Variable: A list can contain an arbitrary number of objects (Unnamed Variable, Named Variable, or Scattered-Access Object).

Kind of Reference: Lists can refer to three object classes: Named Variables, Unnamed Variables, and Scattered Access; no Named Variable Lists can be included.

Reference: An optimal internal reference to the actual data is assigned to every element of the list. If a referenced object is not (any more) available, the entry into the list will indicate it. When accessing the list, for example, by Read, no data other an error indication will be transmitted to the client for this element.

Access Description: In the same way as for the access of a variable — for example in the request during Read — could be defined that only parts (part of a tree) of a variable shall be read, can this also be applied to every element of the Named Variable List.

Services

Read: This service reads the data of all objects being part of the list (Unnamed Variable, Named Variable, and Scattered Access Object). For objects that are not defined an error is reported in the corresponding place of the list of the returned values.

Write: This service writes the data from the write request into the objects being part of the list (Unnamed Variable, Named Variable, and Scattered Access Object). For objects that are not defined an error is reported in the corresponding place of the list of the returned values.

Information Report: As the Read service, as if the read data were sent by the server to the client without prior request (Read Request) by the client, that is, as if only a Read Response would be transmitted.

Define Named Variable List: Using this service, a client can create a Named Variable List Object.

Get Named Variable List Attributes: This service queries the attributes of a Named Variable List Object.

Delete Named Variable List: This service deletes the specified Named Variable List Object.

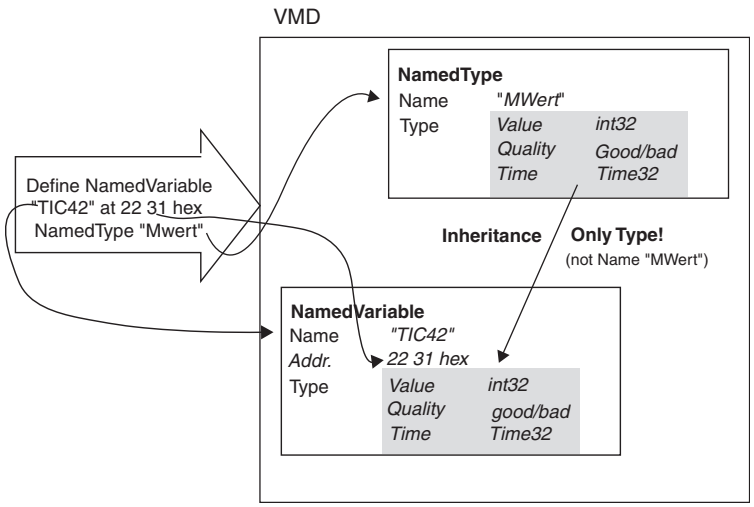

FIGURE 58.26 Inheritance of Type of the MMS NamedType Objects.

© 2005 by CRC Press LLC

The Named Type Object

The Named Type Object merely describes structures. The object model is very simple:

Object: Named Type
Key Attribute: Type Name
Attribute: MMS Deletable (TRUE, FALSE)
Attribute: Type Description

The essential attribute is the Type Description, which was already discussed before for Named and Unnamed Variables. On the one hand, TASE.2 standard data structures can be specified by means of Named Types. This is the most frequent application of the Named Type Objects. On the other hand, Named Types can be used for the access to the server. The read request can refer to a Named Type Object. Or the Named Type Object will be used to define Named Variables.

Figure 58.26 describes the application of the Named Type Objects for the definition of a Named Variable. A variable will be created by the request Define Named Variable.

It shall have the name "TIC42," the address 22 31 hex, and the type that is defined in the Named Type Object "Mwert." The variable inherits the type from the Named Type Object. The inheritance has the consequence that the variable will only have the type but not the name of the Named Type Object. This inheritance was defined so strictly in order to avoid that through deleting the Named Type the type of the variable would get undefined or that by subsequent definition of a differently structured Named Type with the old type name "MWert" the type of the variable would be changed (the Named Type Object and with that the new Type Description would be referenced by the old name).

Perhaps it is objected now that this strict inheritance has the consequence that the type would also have to be saved for each variable (even though many variables have the same Type Description). Since these variables can internally be implemented in a system in whatever way the programmer likes it, they can refer through an internal index to a single (!) type description. He must only make sure that this type description is not deleted. If the accompanying Named Type Object gets deleted, then the referenced type description must remain preserved for these many variables.

The disadvantage that the name of the "structure mother," that is, the Named Type, is not known any more as an attribute of the variables has been eliminated in the MMS Revision.

Services

Define Named Type: This service creates a Named Type Object.

Get Named Type Attribute: This service delivers all attributes of a Named Type Object.

Read, Write, Define Named Variable, Define Scattered Access, Define Named Variable List, and Define Named Type use the Type Description of the Named Type Object when carrying out their tasks.

58.11 Resume

MMS is a standard messaging specification (comparable to web services), widely implemented by industrial device manufacturers like ABB, Alstom, General Electric, and Siemens. It solves problems of heterogeneity so often found in automation applications. MMS is the lingua franca of industrial devices.

MMS provides much more than TCP/IP, which essentially offers a transfer stream of bytes. MMS transfers commands with parameters between machines.

MMS allows a user to concentrate on the applications, application data to be accessible — and not on communication problems, which are already solved. It provides a basis for the definition of common and domain-specific semantic. Examples are the standards IEC 60870-6 TASE.2 [14,15], IEC 61850 [17–21], and IEC 61400-25 [22].

59.1 Introduction

Remote monitoring and control refers to the observation and collection of data in remote locations, the processing of these data, and the emission of control information as a function of the observations to influence the behavior of the distant environment and the monitored entities. Applications range from environmental monitoring (without control) to security and surveillance applications and a high degree of accuracy requiring control tasks (e.g., reactor control, energy control, and industrial process control.)

The remote data are collected through sensors embedded in the environment, which either periodically emit measured values or transmit measurements upon request. Sensors are connected with the monitoring and control system through a communication network. Network connections may be wireless or wired; network protocols may be standard based, such as Internet protocols, or proprietary. The control loop is closed through actuators that influence the controlled process. The monitoring and control system may be distributed to increase the availability of the system and protect against failure of parts of the system. The measured data may be processed at the monitoring and control system or inside the network of sensors. Processing at the monitoring system can be as simple as storing the data in a database or

© 2005 by CRC Press LLC

monitoring the data for unexpected trends or events. Processing of data inside the network can deal with preaggregation of the measured values at the source or at nodes inside the network of sensors.

As can be seen from the above discussion, the design space of remote monitoring and control systems is quite large and will depend highly on the particular application context. In this chapter, we will choose one particular application case study, discuss and motivate the application, and present a detailed account of the design and architecture of the application's remote monitoring and control system. The application case study is a Remote Building Monitoring and Operations (RBMO) system for the management of energy resources in buildings over the Internet. The case study is fully implemented and was experimentally deployed on several large buildings.

The remainder of this chapter is organized as follows. Section 59.2 motivates the application context and reviews the technologies underlying the remote building monitoring and control system described. In Section 59.3, the RBMO system architecture is presented and major design decisions are discussed. The application software is described in Section 59.4. Section 59.5 summarizes our experience in developing, deploying, and operating the system. Sections 59.6 and 59.7 present related work and point out directions that require further exploration.

59.2 Case Study: Building Energy Management

Energy Management

Buildings consume one third of all energy in the United States at a cost of $200 billion per year, with $85 billion per year for commercial buildings. A large amount, perhaps half of this energy, is wasted compared to what is cost-effectively achievable. Much of this waste is related to our inability to optimally control and maintain today's complex building systems. Recent building performance case studies suggest that typical savings of about 15%, and as much as 40% of annual energy use can be gained by compiling, analyzing, and acting upon energy end-use data. The largest source of savings arises from turning off equipment when not needed. Other sources of savings include better equipment scheduling and optimization of temperature set point controls [18, 7]. For an example of the building energy efficiency analysis, which detailed building monitoring enables, see the work by Piette, et al. [26].

The applications under development for the RBMO project are based on utilizing the capabilities of, and expanding upon information available through legacy Energy Management Control Systems (EMCSs), which control the Heating Ventilating and Air Conditioning Equipment (HVAC) in commercial buildings (Figure 59.1).

Several studies have explored EMCS monitoring capabilities [17, 32]. EMCSs for commercial buildings are readily available. There are over 150 EMCS manufacturers [14]. About 50% of all buildings over 45,000 m^2 (500,000 ft^2.) have an EMCS, and they are present in nearly all large office buildings [12]. For buildings built since 1992, almost 50% of the floor area is in buildings with EMCSs.

The RBMO system supports remote monitoring and control of multiple buildings, that is, HVAC, lighting, etc., across the Internet, using CORBA – Common Object Request Broker Architecture protocols. It is designed to work with heterogeneous EMCS and HVAC systems. The RBMO system is also designed for integration with a remote building monitoring and control center, which provides data visualization, database management, building energy simulation, and energy usage analysis tools (cf. Section 59.4 for a more detailed presentation of the application.) The remote monitoring facility is composed of two components:

1. A data acquisition and database management server, which is built on a Unix system.
2. Several analysis (Unix & Windows) workstations, which are used for data visualization, statistical analysis of the data, and simulation.

The ultimate users of the system will be owner/operators of multiple buildings, for example, U.S. GSA (federal buildings), school districts, universities, retail chains, banks, property management firms, and utilities.

© 2005 by CRC Press LLC

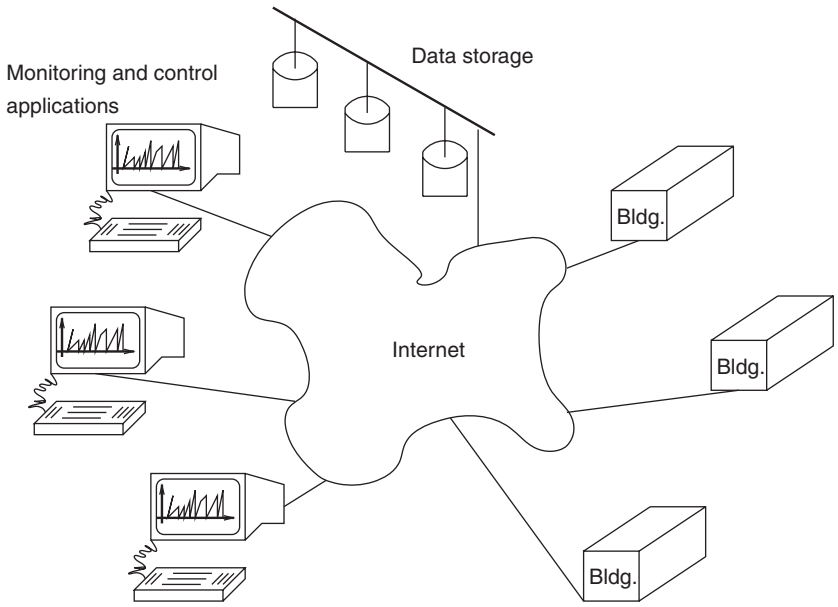

FIGURE 59.1 The RBMO system setup.

The RBMO system pursues three primary design goals: demonstration of technical feasibility of the proposed design, evaluation and experimentation with component software technology and their interoperability across heterogeneous environments, and demonstration of the utility of the system.

Close attention and careful analysis of the data from building EMCSs typically afford many opportunities to improve building operations, resulting in improvements to occupant comfort and reductions in energy use. However, for most buildings, such close attention and analysis are not undertaken due to lack of appropriate software, operator training, staff, and inaccurate or malfunctioning sensors. Remote building monitoring offers the possibility to reduce the labor costs involved in monitoring and analyzing EMCSs by spreading such labor costs over a large number of buildings. This will also make it economically feasible to use expert HVAC engineers.

The use of the Internet as an underlying communication infrastructure has two aspects: use of the Internet communications protocols and use of the actual Internet network.

The use of Internet *networking protocols* permits access to a wide variety of affordable interoperable hardware and software from many different vendors over many different media. Internet markets are huge, in terms of millions of users; hence, vendors can readily amortize development costs. In contrast, proprietary protocols typically entail more expense, because of lack of competition and because development costs are being amortized over smaller markets. Industry-specific protocols, such as BACnet, fall in between these two extremes. Internet protocols are clearly the most popular for wide area networking applications.

Use of the Internet *network* permits users to share the costs of a common communications infrastructure. When building automation applications can share existing Internet infrastructure, substantial savings compared to tele-phone dial-up systems are possible [16]. The Internet also offers the prospect of inexpensive access to high bandwidths when needed, for example, for remote video surveillance for security, fire, or remote diagnostics. Finally, the Internet offers a reliable, redundantly connected, backbone. The downside of using the Internet is the necessity of more stringent security precautions, discussed further below.

A more detailed discussion of the work presented in this chapter has been published in [23, 25, 24]. In [23], we present an overview of the RBMO application and motivate its deployment. In [25], we present a technical account of the system's architecture and design. Based on this investigation, we synthesize in [24] a set of requirements that future middleware platforms for control applications should exhibit.

Energy Management and Control Systems

Today's EMCS have been built primarily for control. EMCSs are special-purpose computerized control systems, programmed to operate building equipment such as chillers, fans, pumps, dampers, valves, motors, and lighting systems. EMCSs are installed for many different purposes such as: controlling equipment, alerting operators to possible equipment malfunction, maintaining comfortable conditions, and permitting modification of control specifications.

EMCSs typically monitor building operational data such as damper positions, set points, state variables of the working fluids, and equipment status. They are not generally used to monitor electrical demand. In some cases, more accurate sensors may be needed for diagnostics than are typically included in an EMCS. For example, to track chiller efficiency, a very accurate measurement of the temperature drop across and water flow rate through the chiller is needed. The sensors in a typical EMCS may not be sufficient for this calculation.

Building Data Model Standards

In 1995, ASHRAE approved a new communications standard, for building automation systems — The Building Automation and Control Network (BAC-net) Standard [1, 3]. This standard views the HVAC system as a collection of objects. However, the standard does not (yet) include standard applications-level objects such as chillers or cooling towers. We expect that BACnet will shortly be used to connect building gateways to EMCSs.

The International Alliance for Interoperability [20, 6] is a consortium of architectural, engineering, and construction software vendors (e.g., Autodesk and Bentley Systems), who are working on developing a standard data model for description of buildings. The data model is intended to be used by architectural and engineering design tools, construction cost estimation software, construction scheduling software, etc. We are tracking these efforts for use in our naming conventions for monitoring points.

59.3 RBMO System Design

In this section, we describe the architecture of the RBMO system in further detail, motivate our primary design decisions, and describe the following components of the system:

- Gateway systems in each building.
- Data acquisition subsystem.
- Application-level object specifications and unit conversion.
- Time series database.

System Architecture

The RBMO system architecture is shown in Figure 59.2. It constitutes a three-tier architecture with the individual components being: the applications, the database management system, and the building gateway. The individual tiers are entire subsystems interconnected through the Internet via CORBA adaptors.

The system has been designed in a modular manner to ease the evaluation of alternative technologies for database, user interfaces, and visualization components (cf. Time Series Database section 3.5). The following subsection will describe the individual components and their design in further detail.

The RBMO system constitutes a highly heterogeneous system incorporating several different hardware platforms and operating systems, ranging from extremely proprietary systems (building EMCSs) to common platforms (Sun workstations/UNIX and PC/NT). This large heterogeneity was one primary motivation for using CORBA instead of alternate protocols, such as OLE, Active X, DCOM, SNMP, MMS, and netDDE protocols. See Table 59.1 for a brief comparision of these along several dimensions.

For additional information on MMS, see [4] (including a bibliography) and [9], or [13] for utility applications. For information on SNMP, see [8, 31, 21, 30, or 34]. For information on netDDE, see [33].

© 2005 by CRC Press LLC

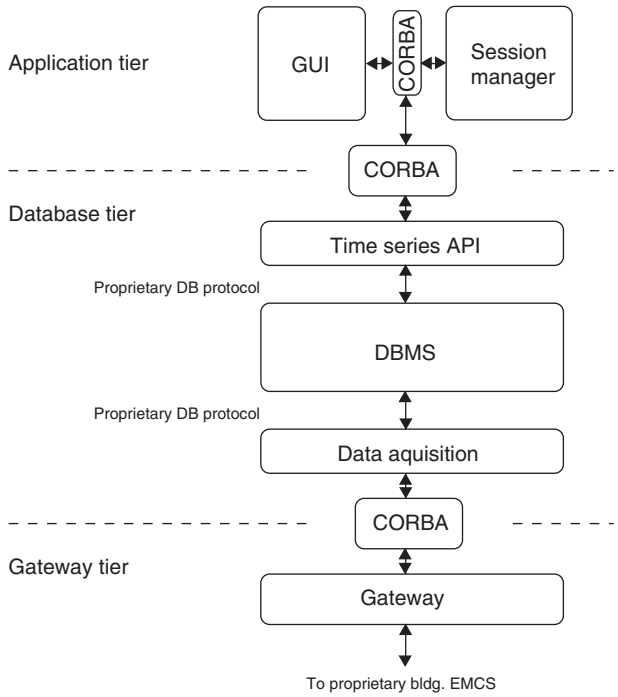

FIGURE 59.2 RBMO system architecture.

TABLE 59.1 Comparison of Interoperability Protocols

Protocol	Application Domain	Characteristics	Platforms	Comments
COBRA	Distributed enterprise applications	OO RPC	All major	Our choice
DCOM	Desktop	OO RPC	PC	Mictosoft only
MMS	Manufacturing, electric utilities,	Messaging	Many	
SNMP	Network management	No methods	Many	
netDDE	Process control	Text messages	PC's	Microsoft only

Building Gateway

The system architecture requires that each participating building have an Internet point-of-presence, also referred to as a building "gateway." These building gateways are addressed in the usual Internet manner (e.g., `north-TowerBuilding.myCompany.com`). Within the gateway itself, further addressing of building-specific objects (more below) is accomplished by a CORBA-compliant Object Request Broker (ORB). The gateway ORB acts as a mediator between incoming CORBA object references and the actual objects resident in the gateway process. Currently, building gateways are Pentium-class PCs running the Windows NT operating system.

One of our goals was to present a network view of a building's monitoring and control data that was consistent across multiple buildings — regardless of EMCS system differences. In order to provide this homogeneous view at the building gateway level, it was necessary to have building-to-building (i.e., EMCS to EMCS) differences resolved within the gateway process itself. This has led to a three-part gateway design consisting of an EMCS adaptation layer, an internal building data point database, and an external CORBA interface layer.

The building data point database portion of the gateway contains entries for all building monitoring and control data points accessible through the building's EMCS. Each entry contains attributes for units,

© 2005 by CRC Press LLC

point name, and description, as well as methods for reading and modifying values. Since this database has to mirror that of the EMCS itself, methods have been developed for deciphering and recreating data point lists for each vendor-specific EMCS encountered. Specific attention has been given to mapping data point units information from vendor or installation-specific descriptions to standard representations. Standard unit representations are required for automatic unit system transformation facilities located further downstream. Since the logical place to resolve any mapping discrepancies is at the building level, these issues are dealt with by the internal gateway database.

The EMCS adaptation layer is responsible for interacting with the building EMCS via the specific communications formats and protocols required by the EMCS vendor. In some cases, for example, the interfacing to the Barring-ton EMCS, involves the use of proprietary message protocols using standard serial communications media. In others, for example, interfacing to the Johnson Controls EMCS, the netDDE protocol over LAN-based media is used. In all cases, specific message formatting and handling algorithms are encapsulated in methods associated with each element of the internal data points database (see above), and vendor-specific differences are not visible above the EMCS adaptation layer.

The external CORBA interface layer provides a common layer of C++ objects that are accessible to the gateway's ORB. These objects have full access to the internal data points database and are able, through appropriate overloaded methods, to query the EMCS system for current monitor and set point values. Since these objects execute as part of the gateway's ORB process and not as a part of the gateway program itself, synchronization mutexes are provided to assure safe and exclusive access to building data object methods and attributes.

Data Acquisition System

Our telemetry data on the building state are initially available as cross-sectional data, that is, we sample the entire building state periodically, typically at 1–2 min intervals. Such high-resolution data permit us to study oscillations in the control system. However, typical analysis uses only a few state variables, but will typically wish to look at long time series of each such state variable. Thus, it is expedient for analysis purposes to have the stored data in a separate time series for each state variable.

The question then arises as to when and where the data are to be transposed from cross-sectional to time series storage formats. This can be done at collection time, analysis time, or some intermediate time.

Transposition at collection time slows the collection process, but speeds the analysis phase. Transposition at analysis time permits very fast data collection, but slows the analysis phase. Transposition at intermediate times permits both very fast data collection and fast analysis. However, the software architecture becomes more complex and costly to implement and maintain. Transposition can also occur either at the gateway machines, the database server, or the analysis workstations.

We chose to transpose the data at the database server as they are collected. This will generate at least one disk I/O operation per data point monitored for each sampling period. This appears to be the simplest architecture to implement, and should have adequate performance for our prototype system.

The Data Acquisition System (DAQ) presently is a polling system residing on the central server together with the time series Database Management System (DBMS). Placing the DAQ on the TS DB server is useful for performance reasons as the DAQ imparts considerable I/O to the DB server.

Polling (pull architecture) was chosen initially over a push architecture from the gateways due to perceived simplicity of implementation. We anticipate moving to a push architecture, which we expect will offer better reliability against single point failures of the central system (assuming it has been replicated), and easier support for replicated or partitioned central DAQ/DBMS systems.

Our data acquisition system is multithreaded, with one DAQ process serving multiple buildings. This offers performance (and software licensing) advantages over a single threaded, one process per building design, at the expense of reliability. Any failure in the DAQ process then causes data acquisition from all buildings to fail. Replication or partitioning of the DAQ would be desirable for large-scale applications.

© 2005 by CRC Press LLC

Measurement Units and Time Zones

In dealing with multiple buildings, we were forced to confront the diversity of the measurement units used for various monitoring points and EMCSs.

There are three approaches to dealing with this issue:

1. record all measurements as pairs (value, units),
2. record the units for each monitoring point as part of the metadata for the monitoring point, and
3. record all measurements in a canonical set of units.

Conventional practice in EMCS systems is method 2. The IAI data model adopts method 1. However, the variation in measurement units across monitoring points and EMCSs renders comparisons and computations in the DBMS extremely awkward. We have adopted the convention of storing all measurements in standard SI (metric) units in the DBMS (the conversion is done by the data acquisition system). This expedites the construction of indices and comparisons or computations in query processing. We plan to permit users to specify a preferred systems of units for display of query results.

Similar difficulties arise with time zones. There are two problems — a collection of monitored buildings may span multiple time zones (e.g., a large retail chain) and the use of daylight savings time introduces anomalies. We address both problems by converting all timestamps to (Universal Coordinated Time (UTC)) (a.k.a. Greenwich Mean Time (GMT)). This is done in the data acquisition system prior to storing data.

Time Series Database

The bulk of the data we are collecting will be time series, for example, of temperatures, power usage, etc. Although the raw data may be irregular time series, we will transform these to regular time series for analysis. Regular time series assumes periodic temporal sampling. Hence, our most important criterion for selection of the DBMS is its suitability for time series data and queries.

It is possible to support time series data on any of several DBMS: relational, object-oriented (OO), or hybrid object–relational. The use of relational DBMS for regular time series data typically offers mediocre performance, and weak support for operations such as smoothing and calendars. Object-oriented DBMSs permit the implementation of time series data collections with better support for calendars, smoothing, etc. To minimize development costs, we initially chose an early object–relational DBMS, Illustra (since merged with Informix) with built-in time series support. When this DBMS proved unreliable we switched to a relational DBMS, Oracle. See discussion below. Recently, relational DBMS vendors (e.g., Oracle) have announced built-in time series support.

Most of the data that are not time series are building description data — that is, Computer Aided Design (CAD) data describing the physical configuration of the building, HVAC system, and the EMCS system. Object-Oriented DBMSs (OODBMSs) are generally much better suited to CAD data than relational DBMSs (RDBMSs).

CORBA interfaces, for at least some of the commercial CORBA implementations, are available for several object-oriented DBMSs, but not yet for most of the relational or object–relational DBMSs. However, Oracle has announced that it intends to support CORBA interfaces. Third-party CORBA interfaces are available for relational DBMSs [19].

Support for client–server DBMS configurations is typically available for all of the DBMSs. This will allow us to move the analysis and visualization codes to the PC-workstations while maintaining the database on a robust database server.

System Partitioning

We have introduced CORBA interfaces at several points in the system. This partitioning serves two key purposes:

- distribution of components and
- decoupling for reengineering.

© 2005 by CRC Press LLC

The CORBA protocols between the time series database, the graphical user interface, and the session management facility (cf. Figure 59.2) permit us to vary the distribution of these components depending on the communications bandwidth and client machine performance. Moreover, they allow us to better decouple the individual components for reengineering purposes, for example, Internet browser integration of GUI.

59.4 The RBMO Applications Software

The RBMO applications are designed around providing the following three capabilities:

- Archiving historical time-series data in a database.
- Providing visualization means for building energy performance analysis.
- Performing a series of regressions and statistical analysis techniques to (1) define "baseline" conditions and (2) evaluate energy performance after a retrofit, operations and maintenance changes, occupancy changes, or for historical tracking.

The archiving and visualization applications presently run on Sun workstations in C++. We envision, however, that a future deployment of the visualization and statistical analysis applications will primarily be PC-based, running Java under Windows NT or a web browser.

The whole building and cooling plant monitoring at one installation of the system consists of a few dozen sensor points (out of 1500 total sensor points in the building) that cover whole-building electricity use, weather variables, plus chiller power and cooling tower status, and several temperatures and water flow rates. We added several power and flow meters, and temperature sensors to the cooling plant to compare them with the original EMCS sensors and augment information that was not available from the EMCS. At another installation, we collected 120 monitoring points concerned with the chiller plant, from a total of 8000 points monitored by the EMCS.

We are developing a standard set of performance tracking plots to allow users to view archived data with a user-friendly menu. This includes daily (24 h) load shapes of 5-min operating data for all values; week-day, weekend, and weekly load shapes (hourly data); and monthly average load shapes. The chiller and cooling plant analysis will consist of plots such as power vs. cooling load (kW vs. tons) and efficiency versus load (kW/ton vs. tons).

The applications are intended for use by a remote expert. Capabilities exist for the user to look at detailed data such as time series of cooling plant water temperatures or cooling tower fan start–stop intervals. The concept is to provide a tool for a remote user who might be responsible for tracking the performance of building systems at multiple locations. The menu of standard graphs are designed to allow the user to easily view the most critical, macrolevel performance data, while providing additional means for more detailed analysis of microlevel data. In other words, the scripted graphs should allow the user to answer the question, "is the building and cooling plant operating well?"

To keep the application extensible, we developed a scripting language that drives the visualization and GUI software. Certain extensions and additions may, however, either be performed on-line, or by preparing a script. The scripting language developed is simple; we therefore omit a detailed discussion. In retrospect, we should have adopted a conventional scripting language.

59.5 Discussion

This section presents a detailed account of our experiences in the design, development, and operation of a prototype of the RBMO system.

Interoperability Platform Concerns

Event Notification Capabilities

Central to any remote monitoring and control system is some mechanism for the remote sites to notify the monitoring sites of "interesting" events. Such event notifications need to be asynchronous, persistent,

© 2005 by CRC Press LLC

and (often) multicast. Ideally, events should be typed (so that certain processes can listen for specific types of events).

Event notification services address the need to propagate notification of significant occurrences to relevant system components. Depending on system functional requirements, this notification may be considered unreliable (e.g., periodic monitoring value updates) or may be required to be reliable (e.g., equipment status changes). In a distributed environment where system components can fail or become unreachable, the technical requirements for implementing these services can be substantial.

Although low-level event delivery protocols are defined in CORBA, the semantics of describing and specifying higher level event service behavior remains (thus far) vendor-specific. Event service reliability and delivery persistence capabilities are not yet consistently defined and implemented. It is therefore important to identify and describe a significant subset of high-level event service functionality. These event service functions should be sufficiently well described to allow multiple implementations that exhibit interoperable behavior. Some of these issues are being addressed in recent OMG proposals on improved Event Notification Services.

Security and Privacy

The principal security requirement for RBMO is to preclude unauthorized persons from altering the programming of the HVAC equipment. Besides disrupting the activities of building occupants, it is possible to damage HVAC equipment with inappropriate (or malicious) commands. Hence, some scheme for secure authentication and access control is required. The absence of such facilities in CORBA implementations at the beginning of the project led us to defer control applications.

In addition, some sites have indicated a desire for privacy of HVAC utilization data (e.g., occupancy data), and hence asked for encryption of all communications.

One of our major concerns has been the interoperability of the security services. We have been unable to identify interoperable CORBA security services software as yet. Furthermore, we would have liked to be able to construct interoperable software composed of different services (e.g., event services, security services, naming services, etc.) from different vendors. We were unable to do so.

Performance

Our experience with CORBA was that the RPC facilities were too slow to permit the modeling of individual measurement points as separate objects. It proved necessary to aggregate many of these measurement points together into named collections (called "scan lists") and to query the groups of points. In database terms, these constituted precompiled queries. This dramatically reduced the number of CORBA invocations (messages) and improved performance. Such aggregation of messages appears to be a commonplace strategy for improving the performance of distributed systems. However, it can be tedious and error prone to implement and maintain. It forces implementors to mix logical and physical design issues. While faster ORBs would certainly help, we believe that network latency in wide area networks will ultimately constrain the performance of fine-grained monitoring systems. Many distributed systems have found it efficient to aggregate messages.

Automatic (or convenient semiautomatic) tools for aggregating individual monitoring points into larger scan objects are very desirable. Such tools are also needed to support multicast publish/subscribe communication protocols. Such tools would permit a clean separation of logical and physical design considerations in the design and implementation of distributed systems.

For latency and throughput measurements of several CORBA ORB implementations (albeit over much higher speed networks), see the work of Schmidt et al. in [15, 28]. Brose [2] also reports recent performance numbers across a high-speed local area network, indicating that commercial ORBs require about 2 msec for a round-trip no-op. Note that many remote building monitoring applications require operation across wide area networks (with latency and lower bandwidth longer than local area networks).

Part of our performance problems arose from a desire to permit run-time binding of the schema of the monitoring points. Such late binding was perceived as necessary to accommodate changes in the HVAC configuration (e.g., due to maintenance, renovation, etc.) without requiring recompilation of the RBMO

© 2005 by CRC Press LLC

code. We could have used CORBA's dynamic invocation capabilities — however, these were perceived as too slow for large-scale RBMO performance requirements.

Finally, in this application and other related applications such as electric power grid monitoring, there is often a need to deal with many objects/points being monitored. It is our understanding that current ORBs maintain in-memory object tables (several tens of bytes per object) for all objects in the system. Such an approach has obvious problems when scaling to very large collections of objects. It is our view that some kind of automatic migration to secondary storage (and related pointer swizzling) similar to that in object-oriented databases will be needed to properly support very large applications.

Legacy System Integration Issues

In the integration of heterogeneous building EMCS into a seamless global distributed system, we have made the following observations.

Wrapping a legacy system with objects can hide essential system features that are critical to both robustness and operation. Even if one is able to hide most of the system's distributed nature using distributed object technologies, the underlying system may still consist of separate components that were designed as stand-alone systems with no expectation of cooperating with, or being controlled from, outside processes.

Centralized input and maintenance of configuration and description data are critical. This feature was mostly discovered by its absence. Although EMCS configuration information may be naturally maintained by that subsystem, these systems are designed as single, stand-alone entities. While it may be possible to create automatic mechanisms for incorporating configuration change information from one component (e.g., EMCS) into other systems (e.g., building simulation), there are typically no mechanisms to effectively signal participating components that such changes have been made. The result is that, although the collection of individual systems into a single larger one has been accomplished via distributed OO techniques (see above), the new, "larger" system depends on a higher, heuristically driven mechanism (e.g., system manager) for both coordination and correctness of operation.

The ability to seamlessly interact with objects within this new "larger" system can lead one to believe that the underlying components are cooperating in a manner that yields synchronized, correct operation. Since each of the respective components (EMCS, automated data loggers, etc.) is typically designed as stand-alone systems, they often lack any mechanism for synchronization or exclusive control path lockout. Therefore, although it may be possible for our system to have a component that tracks chiller performance, factors in near-term weather effects, and changes cooling plant operating setpoints, there is no way to ensure that such a component has exclusive control of all relevant system components. A control layer can be inserted into the architecture; but, its connection to all components may prove problematic.

We believe that part of these issues may be addressed by having stronger support for event specification, event notification, and a system design based on this. We envision a loose coupling of stand-alone components sending and receiving events. For a more complete discussion on event service support, see our discussion above.

Semantic Heterogeneity and Data Management

Naming and Directory Services

Effective configuration description and control is the bane of distributed systems. Distributed systems are constructed, in part, by binding together objects distributed over many platforms. Without a mechanism for describing these bindings, the resulting system lacks flexibility and its complexity remains hidden to all but the original implementors. Naming services provide a way to bind meaningful human names to object instances.

These problems take on greater importance in real-time control environments where systems must accommodate equipment replacement and/or upgrade cycles as well as "live" system reconfiguration. Stable and ubiquitous naming and directory services are a key tool in the design of systems that will accommodate these changes. Examples include the CORBA naming services and LDAP Directory services.

© 2005 by CRC Press LLC

The function of these services goes well beyond the nuts and bolts issues of publishing specific object names and attributes. An effective distributed naming and directory service can expose, through the use of multiple hierarchical views, objects aggregated by function, location, control subsystem, etc. In addition, these services can provide a single, ubiquitous repository for object metainformation. In the case of control systems, this can include information about sensors and instrumentation used in generating object method values, resolution of object name aliases due to differing local and supervisory object namespaces, and provide automated mechanisms for locating physical and/or logical control system components.

Mediation Services

While standard efforts offer some hope in the long run for reconciling semantic heterogeneity among various network devices and controllers (HVAC or electric power grid), the existence of many incompatible legacy systems requires that some facilities for mapping between the global schema and local schemas be provided. At present, for example, in RBMO (and other systems) this is often done in an *ad hoc* manner with handcrafted mapping tables. Such facilities are variously referred to as mediators (partial mappings, late binding) or schema integration tools (nearly complete mappings, early binding). Such tools will require access to metadata (e.g., DB or object schemas). Examples of related work include OMG Object Interface Repository, and Meta Object Facilities.

Static vs. Dynamic Schemas

Traditional database designs specify complete detailed schemas statically. Such static schemas facilitate systematic design, query optimization, etc. However, for many monitoring and control applications (shipped as shrink wrap software), it is desirable to be able to alter the schema (e.g., to accommodate new types of equipment) without rebuilding the DB or recompiling the code. Examples of such approaches include frame-based knowledge representation systems, and the dynamic invocation interface of CORBA, together with interface repositories. Because such dynamic schema capabilities are typically significantly slower than static interfaces, some groups have built hybrid schemas — examples include the International Alliance for Interoperability (building data model), which provide both static schemas (e.g., for geometry) and dynamic schemas (frames) for extensibility. Conceivably, on-the-fly compilation techniques might provide a reasonable performance.

Units Conversion Services

We found it necessary to provide measurement unit conversion capabilities for our RBMO project.

Unit conversions have been a chronic source of errors in data acquisition/management systems. The ubiquity of these issues (in both industrial measurement and commercial trading) suggests their provision as standard services. Ideally, one would like an extensible-type system that incorporated dimensionality and automatic units conversions. However, impure unit conversions (e.g., between mass and volume) are commonplace and difficult to deal with systematically.

Our choice was to store all measurements in canonical units in the DBMS. While this facilitated indexing and querying, it made it very difficult to diagnose errors in the data acquisition system.

Time Zones and Synchronization

For large-scale monitoring applications, we believe that recording all times in Universal Coordinated Time (UTC) is essential. Conversion routines to local time zones, including daylight savings time, are essential.

Some protocol for synchronizing the clocks is needed for monitoring systems. Such protocols, for example, NTP [5], have been developed for other distributed applications. We note that synchronization requirements for monitoring of electric power grids are sufficiently stringent (to measure phase differences among geographically distributed generators) as to lead to the use of GPS timing signals for synchronization.

Time Series DBMS

Our first implementation used the early release of the Illustra DBMS product, chosen because it offered facilities for storing and querying time series data, including calendars. We encountered reliability problems

© 2005 by CRC Press LLC

with the DB server. We therefore switched to storing our time series data in a more mature conventional relational DBMS, that is, Oracle Version 7.3 (at present). This has solved our server reliability problems.

Whereas Illustra provided direct support for storing and querying time-series data, in Oracle we have had to construct these facilities atop a relational system. We have not (yet) replicated the calendar facilities, etc. Note that Oracle has announced time series facilities similar to Illustra/Informix.

Whereas Illustra storage usage was asymptotically 4 bytes/data value (for real numbers), Oracle is presently consuming approximately 25 bytes/data value, because each time series data value has become a full tuple in the DBMS.

For additional research work concerned with time series database management systems and data models, see the works [10, 29, 27, 11].

Data Quality Assurance

We greatly underestimated the difficulty and effort required to assure proper data quality. We have encountered a variety of problems with respect to data quality — some due to errors in units conversion, some due to missing or erroneous documentation of system configuration files, and some due to overflow problems with small (16 bit) counters.

We should have paid much more attention to the development of filtering software in the data acquisition system. The presence of dirty data in the time series database has been a barrier to the use of conventional database query facilities for aggregation. Dirty data are a ubiquitous problem in all kinds of data warehousing applications. Obviously, the preferred approach is to clean up the data at the source. If this is not feasible, concise, powerful methods are needed to specify constraints on data validity.

System Operation

A prototype of the system was operational for over one year. Data were acquired from two remote sites. Approximately 1 year of data (plus one year of historical data) were collected. The data collection involved several dozen monitoring points and sampling rates for both buildings are once per minute. The basic data collection volume is approximately 1 KB per minute.

Soda Hall

Soda Hall, a 109,000 ft^2 Computer Science building, was selected as our case study site for several reasons. The building was equipped with an Energy Management Control System that the research team had worked with before. Second, the building was located near LBNL, permitting easy access. Finally, the building has two, 220 ton screw chillers, for a total of 440 tons of cooling plant capacity (or 248 ft^2/t). Early in the project, we decided to focus on chillers, which are the largest single energy-using component in buildings with central cooling plants. The building has served as the subject of several research tasks that involved commissioning and performance.

Results from this work are reported in [26, 22]. A total of 46 points were monitored for about two years, starting in September, 1995 during the first few months of initial occupancy.

Oakland Federal Building

A total of 107 points were monitored at the Oakland Federal Building. (Note, not all of these points are sampled; many are computationally derived from sampled points.) This building is a 1.1 M ft^2. twin-tower, 18-story office building complex. The building was constructed in 1989 and houses Federal agencies such as the IRS, U.S. District Courts, the U.S. DOE, and Department of Veteran Affairs. The building is served by a central plant with five chillers, three at 1000 t and two at 450 t totaling 3900 t of capacity. This is 280 ft^2/t.

The 107 points cover systems similar to those at Soda Hall, including whole-building power, chiller power and tons, plus cooling tower, and pump data. Additional points include heating loop flow, a series of outside temperatures from five air handlers, and several internal zone temperatures.

One of the interesting questions we are examining at both sites is chiller capacities and oversizing. The operators report that the last 1000 t of cooling are not needed, even in the warmest weather.

59.6 Related Work

Honeywell recently announced a new building monitoring system, Atrium (Honeywell, 1998), quite similar to our project. Atrium uses a different operating system and window system (Windows NT) and a different relational database management system (SQLserver). However, it has a very similar overall architecture. They have also chosen to use a (popular) proprietary distributed object management system, Active X/DCOM, in contrast to our use of the standard CORBA distributed object system. Atrium also uses a standard building automation communications protocol, BACnet, to communicate with the building EMCS systems. BACnet is a recently deployed standard. BACnet equipped EMCSs were not available to us when we developed RBMO.

Other major differences between RBMO and Atrium lie in the time series database. Honeywell has chosen to only store changed data values (discarded repeated measures within dead bands). This results in a smaller, but irregular time series. Honeywell has also implemented a simple time series query language and temporal join operator to query and extract align multiple (irregular) time series.

The Enflex System from CTI Ltd. (CTI, 1998) uses proprietary applications protocols atop TCP/IP.

Finally, readers should be aware that remote building management presents many of the same issues addressed in the management of communications networks. Network management systems have used SNMP and RMON as the principal (standard) communications protocols. See the discussion above under alternative protocols and citations there.

59.7 Future Work

We plan to investigate the use of the CORBA Security Service and Secure HOP for remote control of the HVAC operations, (e.g., authentication).

Remote monitoring of large heterogeneous collections of buildings poses serious problems of software distribution to the buildings. We plan to study static and dynamic software distribution over the Internet onto heterogeneous target platforms.

59.8 Summary

We have described the design and development of the remote building monitoring and operation system, which uses the CORBA protocol across the Internet for communications between remote buildings and a time series database, and to distribute individual *application* components *locally* across different machines. We have discussed design tradeoffs, our development and operational experiences, and related work.

We have argued for the use of CORBA within our project context. We have discussed the design of a distributed system that has to monitor events across large distances, across multiple time zones, heterogeneous sources, and diverse measurement units. The development of the time series database atop different commercial DBMSs has been described.

We found it necessary (for performance reasons) to aggregate individual monitoring points into larger objects for CORBA-based retrieval. Such aggregation is typical of many distributed applications.

None of the commercial DBMS available at the time of the project proved entirely satisfactory for storing and retrieving time series. Recently announced products may remedy this.

The most serious issues included dealing with the heterogeneity of the various building EMCSs, that is, units and naming, and problems with dirty and missing data. Developers of distributed monitoring systems for legacy systems would do well to address such issues thoroughly early in their projects.

This CORBA-based approach is both feasible and competitive with other systems based on proprietary communications protocols. The attraction of our approach lies in the extensive availability of commercial software products, which support distributed computing applications based on the CORBA model and underlying Internet communications protocols.

Acknowledgment

This chapter draws from research carried out in the context of the Remote Building Monitoring and Operations (RBMO) project at Lawrence Berkeley National Laboratories in 1997. The author would like to thank Frank Olken and Chuck McParland. The RBMO system described in this chapter was operational and has been experimentally deployed on two buildings: Soda Hall and the Oakland Federal Building. The central data storage and management site was located at Lawrence Berkeley National Laboratory.

60.1 Introduction

Brief History of Telemanipulation

In about 1945, the first modern master–slave system teleoperator was developed by Goertz at Argonne National Laboratory (ANL) [1]. This system, which was a mechanical pantograph mechanic system, allowed a human operator to manipulate radioactive materials in a "hot cell" from outside. By using a master handle, the human operator could move the slave tong located inside the hot cell and receive force reflection. Soon (in 1954), electrical servomechanisms replaced the direct mechanical master–slave system and able linkages [2]. Closed circuit television was introduced so that the operator could stay at an arbitrary distant place. In addition, the contact force between the slave and its environment was returned to the master arm. In 1964, Mosher developed an impressive work, which was a handy-man containing electrohydraulic arms. Each arm had ten DOF in each arm. The problem of remote control of robotic systems has been the subject of much research in recent years. Remote control of robotic systems has been applied in manufacturing, underwater manipulation, storage tank inspection, nuclear power plant maintenance, space exploration, etc. See an excellent review of relevant historical development in telemanipulation (telerobotics) in [1].

© 2005 by CRC Press LLC

What is Telemanipulation

Telemanipulation is a process where the operator has some task done at the remote hazardous or inaccessible environment as space, underwater, nuclear plants, where he/she cannot physically be. A teleoperator system extends the operator's capability to be able to work at the Remote Workplace. This extension is achieved by a master–slave system. Telemanipulation is divided into two strongly coupled processes. One process is the interaction between the operator and the master device; the other is the interaction between the slave device and the remote environment contact. The master device represents the distant environment at the operator site, and the slave device represents the operator at the remote site. When humans use this device only to move objects and the reaction force from the distant environment has no significant effect on the performance, then measurement of the operator's position and visual feed back may be enough. However, if such tasks are to be performed when the reaction of the environment is important and the salve device can do damage in the remote environment, for example, when screwing a bolt or assembling something, then a force feedback is needed to improve efficiency. Force feedback increases the feeling of being there. The information flow between the operator and remote site can be seen in Figure 60.1 (adapted from [3]), where only three types of information are fed back: visual, audio, and sense of touch. A human being receives five types of sensing from his/her surrounding environment, but only some of these senses are used during telemanipulation.

The structure of this chapter is as follows. The next section overviews the general approach of telemanipulation. It introduces three main layers of a telemanipulation system. Section 60.3 summarizes the basic type of master devices. Section 60.4 provides a short introduction to control modes used for telemanipulation. Section 60.5 presents an application example of a handshaking via Internet.

60.2 General Approach of Telemanipulation

Basic Definitions

Figure 60.2 shows the general concept of telemanipulation. The "world" is divided into two sets: the Master Site and the Slave Site. The master–slave system is realized as two information channels: Action and Reaction channel. The Action channel transfers the information from the operator to the Remote Workplace. The Reaction channel transfers the information to the opposite direction: from the Remote Workplace to the Operator. In the early days of telemanipulation, the human operator's hands and the remote environment were mechanically coupled. The information was transferred mechanically, which limited the type of the tasks that they could perform. Nowadays, the information is transferred electrically, which opened a new dimension at the slave side. A Human–Robot System may be considered as a type of telemanipulation,

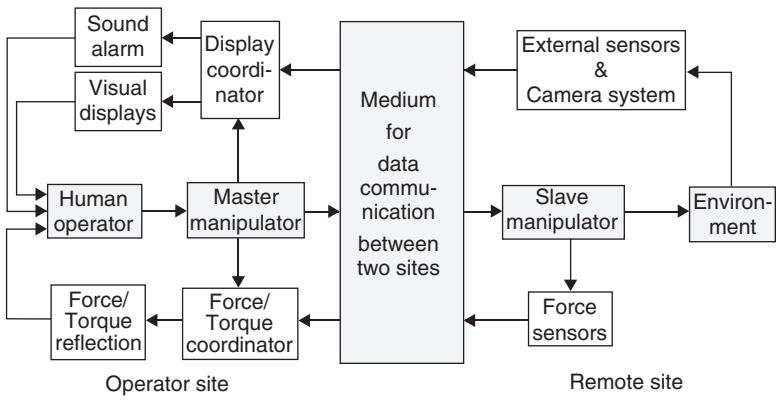

FIGURE 60.1 Information streams of the Telemanipulation (adapted from [3]).

© 2005 by CRC Press LLC

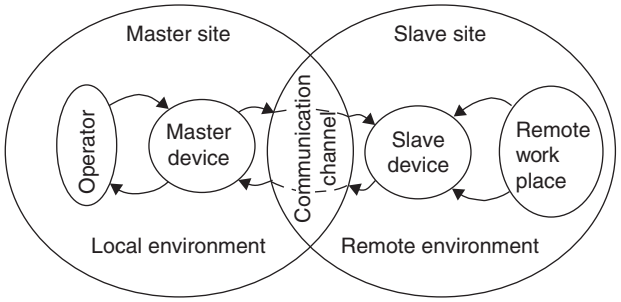

FIGURE 60.2 General concept of the telemanipulation.

where a human and a robot work simultaneously together to achieve a task. For example, in the case of remotely deactivating of a bomb, the robot must reach the bomb and then the timer must be disassembled with the help of a pair of slave manipulators. In this example, the navigation and manipulation tasks may be separated. When a group of mobile robots move a large object cooperatively, the operator must control the overall action. In general, the Slave Device can be a Multi Robot System as well, where more than one robots are working together to achieve a task. Computer Networked Control enables systems to be distributed. The concept of an operator and robot can be replaced with some combination of multiple operators, multiple robots, and maybe even multiple assistant agents that work together in a cooperative environment [4]. The Human–Robot type of telemanipulation can be classified into the following:

- Singlemaster–single slave.
- Multimaster–single slave.
- Singlemaster–multislave.
- Multimaster–multislave.

We can conclude that the meaning of telemanipulation has extended, and new terminologies have appeared. Some of them are presented here.

Teleoperator is the machine itself, which can perform the task in a distant place. Using a general sense of teleoperator, *Telerobot* is a subclass of it. Originally, telemanipulation means the action in which a slave manipulator tracks the motion of the master manipulator. In this case, the salve and master manipulator have the same structure. The extension of this concept means a manipulation in the remote environment with a slave device controlled by a master device moved by a human operator. Using this extended meaning, the structure of master and slave device can be different, but the whole manipulation process is controlled by the human operator, that is, the slave side has no intelligence of its own. The next step is the distribution of intelligence. The slave device may learn the behavior of a human operator and may follow the learned behavior during the period when the command is delayed because of the latency caused by Internet communication [5]. Some authors use the word of teleoperation for the extended meaning of telemanipulaton, and some authors use "telemanipulation" and "teleoperation" in the same sense.

A human operator needs the illusion of direct contact with the remote environment to perform fine tasks such as telesurgery or remote assembling (disassembling) fine mechanism (timer bomb). A human operator receives five types of sensing (sight, hearing, touch, smell, taste) but the combinations of the first three are used during a manipulation. The psychological feeling of "being there" in an environment based on a technologically founded immersion environment is called as *Telepresence* [6,7], which should provide the ideal sensation, that is, we obtain the necessary information fed back from the slave to the master side in a natural way to have the feeling of being physically at the distant location. *Telepresence systems* are a subclass of teleoperators. The technology of audio–visual feedback is well developed and available nowadays. The main challenge is the *haptic feedback*, which is necessary to feel the physical contact with the environment. It is an extension of force feedback. A human operator has different types of receptors

© 2005 by CRC Press LLC

for sensing different types of contact forces. *Tactile (cutaneous) feedback* is sensed by mechanoreceptive nerve endings in the glabrous skin (especially in the finger tips). Its bandwidth is about 50–350 Hz [8]. It provides information on small-scale details, for examples of the type of surface. *The force (kinesthetic) feedback* has a lower bandwidth (up to 10 Hz) sensed by receptors on the muscle tendon and in the skeletal system. It provides information related to body posture. Force feedback not only increases efficiency, but it helps to filter the smaller imprecision of the operator.

Ideal Telepresence

In a typical telepresence, information about task at the remote site is required to help a human operator to feel as if he/she physically is present at the remote place. Accordingly, a teleoperator must provide complete *transparency,* which means the positions, velocities, and forces of the master and slave device are equal. An example of simple remote device is remote pliers used to handle objects in a nuclear plant [5]. If this plier is stiff and easy to move, the operator simply performs the task. Images of the ideal connection between the master and slave for revolute motion and linear motion are shown in Figure 60.3(a) and (b). If the operator rotates (move) the master stick by q_m (x_m), the motion of the slave stick must be the same ($q_m = q_s$ or $x_m = x_s$) and the operator must sense the reaction force of the environment ($F_o = -F_e$), in an ideal case. From this example, the aimed dynamic behavior of the teleoperator is therefore close to a rigid rod, whose mechanical properties are minimal inertia and maximal stiffness. The connection of the master and slave arms should have 0 mass with ∞ stiffness.

However, our work deals with a teleoperator with a time delay, whose master and slave are assumed to be physically equivalent. The ideal responses for the Telemanipulation with time delay are definite and as follows:

- The teleoperator must remain stable.
- The force that the human operator applies to the master arm is equal to the force reflected from the environment in the steady state. This can help operators to realize force sensation.
- The master position is equal to the slave position in the steady state.

Layer Definitions

The Master Site and the Slave Site are partitioned into three main layers (see Figure 60.4). The layers can communicate vertically with the local layers as well as horizontally with the remote layers via the Internet. The Sensor Layer contains the necessary sensors to observe the Remote Environment, and the Remote Workplace. In general, these sensors are noncontact sensors. The Manipulator Layer makes the effective work in the Remote Workplace. This layer involves the Slave Device typically. This layer may contain contact sensors. The Transporter Layer includes a Transporter (mobile unit), which can carry the slave device. The Monitor Layer at the Master Site shows the processed data of the Sensor Layer. These monitors are usually noncontact displays or indicators. The Manipulator Layer has real contact with the Operator. This layer involves the Master Device typically. This layer, included with the Master Device, may contain contact sensors and contact actuators. The contact actuators relay the sensed data of the contact sensors of the Manipulator Layer. The Transporter Control Layer controls the Transporter at the Slave Site. This layer may contain services that can help in the navigation of the Transporter Layer at the Slave Site.

Sensor Layer

The configuration of the Sensor Layer can be seen in Figure 60.5. The noncontact sensors on the Slave Site are observing the Far Environment. The Intelligent Sensed Data Computing System at the Slave Site is a preprocessor for the sensed data. The purpose of this device is filtering, correction, and compression. The audio and video compression formats are widely used in the Internet to decrease the necessary bandwidth. The Computing System may contain a pattern recognition module to improve the efficiency and intelligence of the Slave Site. The purpose of the Intelligent Sensed Data Computing System at the Master Side is data decompression and recovery of lost data.

Manipulator Layer

There is another approach for the telemanipulation. The process of the telemanipulation can be partitioned into two coupled subprocesses. One subprocess is running in the Local Environment: Local

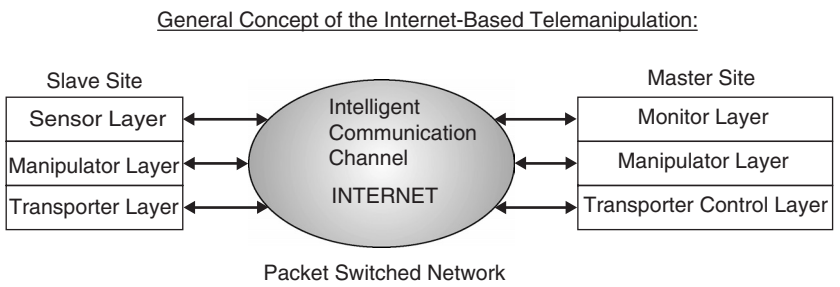

FIGURE 60.4 Layer definition for the general concept of the Internet-based Telemanipulation.

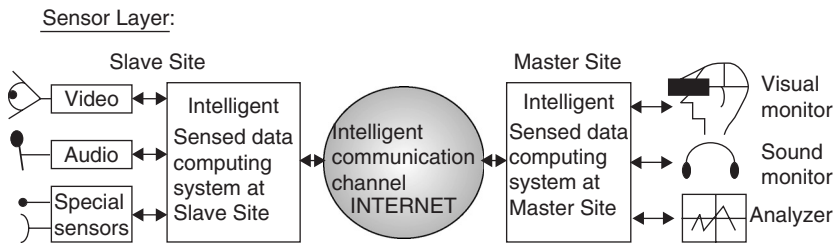

FIGURE 60.5 Sensor Layer definition for the general concept of the Internet-based Telemanipulation.

© 2005 by CRC Press LLC

Process. The other subprocess is running in the Remote Environment: Remote Process. The Local Process is the information circulation between the Operator and the Master Device. The Distant Process is the information circulation between the Slave Device and the Remote Environment. If telemanipulation is ideal, the two processes are the same. In case of ideal telemanipulation, the Master Device represents the Remote Workplace in the Local Environment and the Slave Device represents the Operator in the Far Environment. The Communication Channel is the coupler between the two subprocesses. The main task of the Communication Channel is to ensure total transparency in case of ideal telemanipulation.

The configuration of the Manipulator Layer can be seen in Figure 60.6. Typically, this layer includes the Slave and the Master device, as mentioned above. The main purpose of this layer is the position control and the force-feedback. The force-feedback is an information flow between the layers and between the Master and Slave Site. The force- feedback is a typical action–reaction process. The exact realization of the force-feedback depends on the specific approach. The configuration of the Master Device is not equal to the configuration of the Slave Device in a general case. The main purpose of the Intelligent Path Planning is to couple the master and the slave in position and force.

Transporter Layer

The configuration of the Transporter Layer can be seen in Figure 60.7. The configuration of the Slave Site of Transporter Layer is very similar to one side of the Manipulator layer. The Transporter Layer has a connection with the Far Environment. The Transporter Layer carries the Slave Device and the necessary sensors.

The Task-Oriented Path Planning System controls the transporter on the Slave Side. This device may use advanced services for navigation such as Global Positioning System (GPS), Geographic Information System (GIS), and Intelligent Transport System (ITS).

Special Types of Telemanipulation

Telemanipulation in virtual reality is beneficial when an operator is learning to perform dangerous or difficult tasks such as working with radioactive materials or disassembling explosives, or driving an airplane, helicopter, or submarine in a real-time simulator. In addition, "Flight and other vehicles simulators" are very popular in the field of entertainment. It can be a very attractive target in both main fields: professional and commercial. Telemanipulation in a virtual reality application is shown in Figure 60.8. The operator wears a *head-mounted device* that provides visual feedback and *an arm and glove type master device* giving tactical sensation. The operator can see the visual objects and can touch and move them [10].

Micro- and nanotechnology opened a relatively new, emerging dimension in the field of telemanipulation. Going from macro to micro/nanoworld, the main phenomenon is the reduction of the size of objects where the effect of length change is defined as scaling. It is obvious that *Force and position must be scaled* (see Figure 60.9). There is another problem called as *bandwidth effect*, which means that bandwidths of the master device including human operator's reaction and slave device including nano/micro environment are different. The micro/nano actuator has a smaller time constant than the macro force feedback device. Thus, an impedance scaling is necessary to avoid instabilities and unreliable force feeling. It can be considered as a kind of time scaling. In other words, the micro/nanophenomena might be too fast for a human sensation and it must be slowed down by virtual coupling impedance [11].

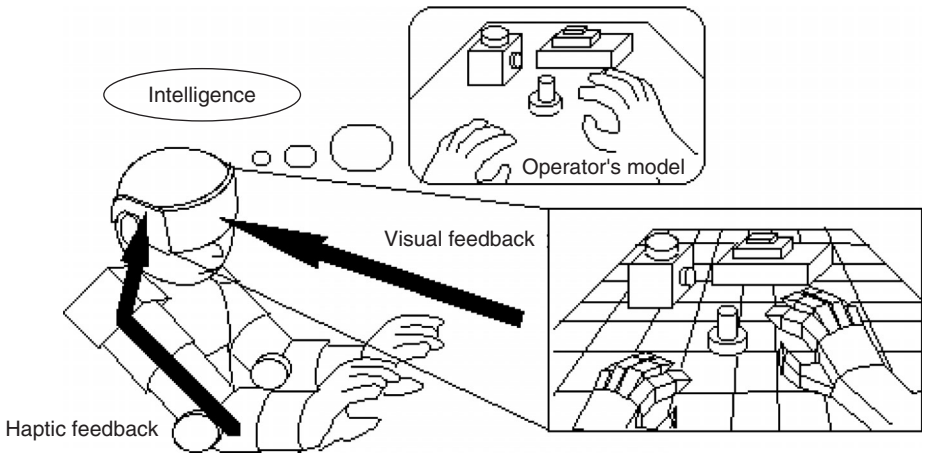

FIGURE 60.8 Telemanipulation in the virtual reality.

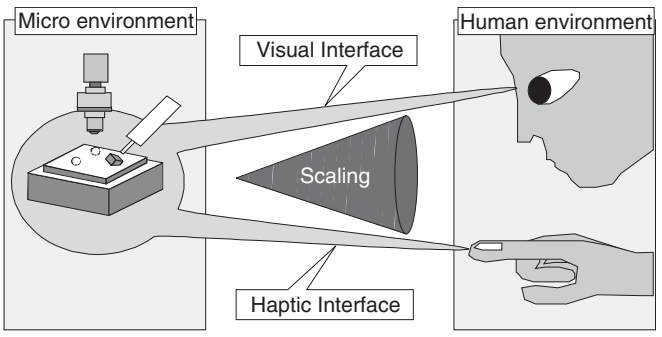

FIGURE 60.9 Micro/nano teleoperation system.

60.3 Master Devices as Haptic Interfaces

Human operators perform their tasks mostly by hand, and the master device must fit the operator's hand. In the field of telemanipulation, many haptic devices have been developed. The applications of the haptic devices cover various fields, such as medical application, working in nuclear power plants, and entertainment. In this section, four important master device concepts are presented.

- *Joystick with force feedback* was developed in the early stage of telemanipulation. Nowadays, several commercial joysticks with force feedback are available. This device is optimal for low-quality telemanipulation application. This device is optimal for "pick and place" operation. Joysticks with force feedback are very popular in recent video game systems. Another important application area is the real-time simulators of vehicles, such as airplanes, helicopters, and submarines. The main problem with these devices is the dynamics change "on the fly." An additional device is needed for balancing the dynamics of the joystick. This feature is necessary in applications where different precision operations are required. Another disadvantage of the device is the two controlled degrees of freedom.
- *The point type master device* is similar to a six DOF manipulator. The operator can point at the remote site. The Phantom [12] is a point-type device (see Figure 60.10) using direct drive and is noted for its high resolution. However, it can cover only fingertips. The operator can control a tip-type slave device with this device. Tip-type slave systems are widely used in surface manipulation applications, such as telemanipulation in the nanospace [11].
- *The arm type master devices* in Figure 60.11 cover the human arm from the shoulder to wrist. It has 6 degrees of freedom. The arm-type haptic device is useful in applications where the operator uses his arm to do some task in the remote environment, for example, some mining workplace. In several applications, the arm-type master device is a subsystem of a complex master device.
- *The glove type master device* allows the most complex and dexterous manipulation [13]. The human hand is the most widely used tool. The final goal is to make such a device that the operator can feel as if the function of whole of his hand were expanded. Several types of manipulation cannot be performed without force feedback. A 20 DOF sensor glove-type device with force feedback (see in Figure 60.12) is discussed in the next section.

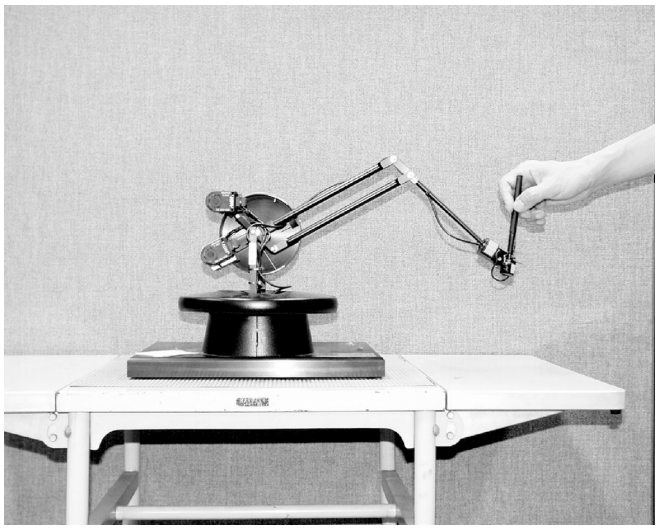

FIGURE 60.10 A point-type master device.

A Glove-type Haptic Interface

Mechanical Structure

The wrist location is measured by an inductive sensor. The sensor glove is equipped with force feedback capability to each joint of the operator fingers; hence, the operator can feel the remote environment as he/she is there. The mechanical structure of a finger is shown in Figure 60.13. The device is designed with consideration of space for sensors and actuators. The device is attached to a human hand by bands. A fixed base for all movements of the glove is constructed on a metallic plate fixed on the back of a human palm. Five yawing drive units are fixed in the plate. Three pitching drive components are placed on the yawing drive units.

Figure 60.14 shows the structure of one DOF of the device. The torques of the finger joints are measured by strain gauges. Rotary encoders in the motors are used to measure the angles of the joints. Ideally, the motors move the joints directly; however, there was no motor available that was small and light enough to be attached on the hand. The pulleys and wires in tubes are used to transmit forces to the motors. Single motors can control all the 20 joints of a human hand independently. One joint of the finger corresponds to two links of the device. The main problem is the friction. Because of this additional force, the operator may not distinguish which force has emerged in a remote environment. The friction compensation is discussed in Section 60.4.

Animation of the Operator's Hand Wearing the Sensor Glove

Visual feedback is aimed at giving a quite real representation of the operator's hand, and the program enables the user to wander it in full three-dimensional space (Figure 60.15).

© 2005 by CRC Press LLC

The program was designed to run either locally in full simulation mode or over TCP/IP connection, such as Internet or Local Area Network. In simulation mode, the program can be used to represent all the motions of the human hand. To accomplish this, both anatomical and mathematical models were built, and these models were implemented in OpenGL. The mathematical deduction uses the *Denavit–Hartenberg notation*, because it can be quite well applied both for hands and in OpenGL. The model uses several basic assumptions as follows:

- The base coordinate frame is the same for all fingers. This is used for having a completely general case, where the fingertip coordinates are calculated with respect to a common frame of the wrist.
- This common frame is considered to be at joint 0. This joint is used in order to have the possibility to extend the model at a later time if needed.
- One finger contains three joints: the first has two degrees of freedom, the other two have only one, which means planar rotation. The position of the first joint is determined by a variable l_0 ,which is the distance between the first, common coordinate frame and the first joint.
- Along one finger, the value of d_i is 0, which means that the common normal line on the same line.
- Along one finger, the value of a_i is the length of the link.
- The twist angle is taken into account only at the base coordinate frame and at the first joint, since lateral movement of the finger is also considered.

It is important that coordinate frame 0 be the same for all fingers, and is a common reference to the whole hand. The individual θ_i angles and l_0 variables determine the exact position and orientation of the next frame of the next joint in each finger. Between the two frames d_i is just equal to the length of the link, l_0. Since joint 0 is of the revolute type, q_0 is θ_1, the relationship between the two joints is as follows:

$$X = A_1^0 X^1 \tag{60.1}$$

In Equation (60.1) $A^0{}_1$ is the 4×4 *homogeneous transformation matrix* between the two adjacent joints and X^s are position vectors in the respective coordinate frames.

$$A_1^0 = \begin{bmatrix} \cos\theta_1 & -\sin\theta_1 \cos\alpha_1 & \sin\theta_1 \sin\alpha_1 & a_0 \cos\theta_1 \\ \sin\theta_1 & \cos\theta_1 \cos\alpha_1 & -\cos\theta_1 \sin\alpha_1 & a_0 \sin\theta_1 \\ 0 & \sin\alpha_1 & \cos\alpha_0 & d_0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{60.2}$$

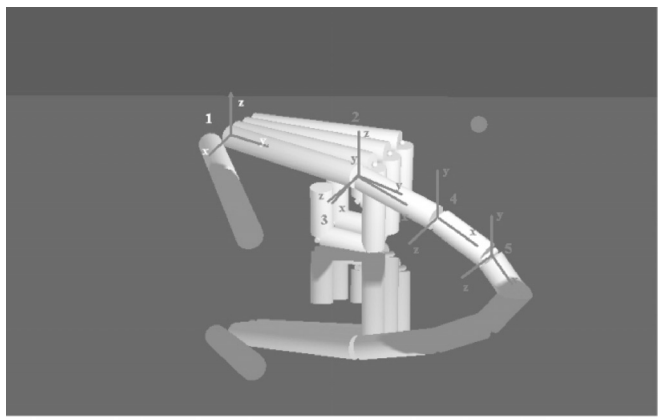

FIGURE 60.15 Computer animation of the robot hand with the coordinate systems.

© 2005 by CRC Press LLC

$$\begin{bmatrix} x_0 \\ y_0 \\ z_0 \\ 1 \end{bmatrix} = \begin{bmatrix} \cos\theta_1 & -\sin\theta_1\cos\alpha_1 & \sin\theta_1\sin\alpha_1 & a_0\cos\theta_1 \\ \sin\theta_1 & \cos\theta_1\cos\alpha_1 & -\cos\theta_1\sin\alpha_1 & a_0\sin\theta_1 \\ 0 & \sin\alpha_1 & \cos\alpha_0 & d_0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ 1 \end{bmatrix} \tag{60.3}$$

As stated, in this case α is 0°, which means that its cosine is 1 and its sine is 0. For the two joints, d is considered to be 0 and a is the length of the link. Substituting these values simplifies the previous equation and yields.

$$\begin{bmatrix} x_0 \\ y_0 \\ z_0 \\ 1 \end{bmatrix} = \begin{bmatrix} \cos\theta_1 & \sin\theta_1 & 0 & l_0\cos\theta_1 \\ \sin\theta_1 & \cos\theta_1 & 0 & l_0\sin\theta_1 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ y_1 \\ z_1 \\ 1 \end{bmatrix} \tag{60.4}$$

Now, the position and the orientation of the coordinate frame at joint 1 are received; further transformations can be carried out.

Now there is a general formula for calculating the position of the finger tip with reference to the common base coordinate frame. Equation (60.3) shows this, and it is very similar to (60.1). Matrix T contains the position and orientation of the tip in the base coordinate system.

$$T = A_1^0(\theta_1)A_2^1(\theta_2)A_3^2(\theta_3)A_4^3(\theta_4)A_5^4(\theta_5) \tag{60.5}$$

It is useful to state that joint 2 has two transformation matrices and frames because of the two possible axies of rotation.

$$P_1 = T_1 X^{15} \tag{60.6}$$

where X^{15} is the position vector of the fingertip in its local coordinate frame.

The position and orientation of all five fingertips with respect to the common base frame (the wrist), are given by (60.7) as a function of joint angles.

$$P = [f(\theta_{11},\theta_{12},\theta_{13},\theta_{14})\, f(\theta_{21},\theta_{22},\theta_{23},\theta_{24})\, f(\theta_{31},\theta_{32},\theta_{33},\theta_{34})\, f(\theta_{41},\theta_{42},\theta_{43},\theta_{44})\, f(\theta_{51},\theta_{52},\theta_{53},\theta_{54})] \tag{60.7}$$

Grasping

Figure 60.16 illustrates the transformations between finger-tip, contact, and object coordinate frames [10]. Let us define homogeneous transformation matrices $U_i \in R^{4\times4}$ and $V_i \in R^{4\times4}$, where U_i transforms

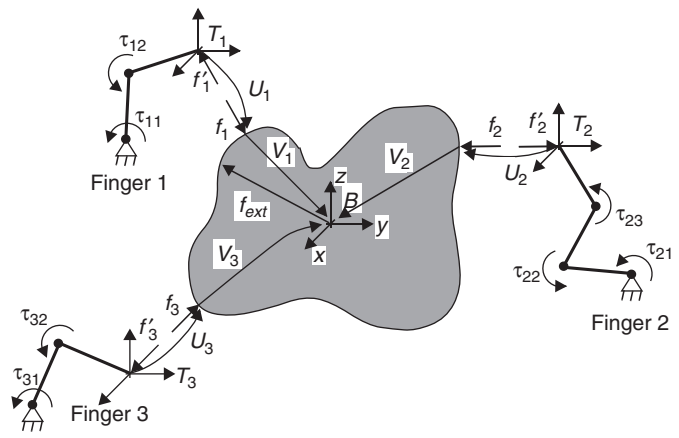

FIGURE 60.16 Object grasped by three Fingers.

© 2005 by CRC Press LLC

from the finger-tip coordinate frame $T_i \in R^{4\times4}$ to the contact frame $C_i \in R^{4\times4}$ and $V_i \in R^{4\times4}$ from the contact frame to the object frame $B_i \in R^{4\times4}$. The x- and y-axis of the contact coordinate frame C_i are tangents and the z-axis is perpendicular to the object surface curvature. (Figure 60.17). The transformation matrices $\boldsymbol{\Gamma}_i \in R^{6\times6}$ and $\boldsymbol{\Lambda}_i \in R^{6\times6}$ are defined in such a way that $\boldsymbol{\Gamma}_i$ transforms finger-tip forces ${}^{Ti}f_i$ into forces ${}^{Ci}f_i$ in the contact coordinate frame and $\boldsymbol{\Lambda}_i$ transforms these to forces ${}^{B}f_i$ in the object reference frame B.

The relationship of coordinate transformations can be written as

$$\begin{aligned} C_i &= T_i U_i \\ B &= C_i V_i = T_i U_i V_i \\ {}^{Ci}f_i &= \boldsymbol{\Gamma}_i {}^{Ti}f_i \\ {}^{B}f_i &= \boldsymbol{\Lambda}_i {}^{Ci}f_i = \boldsymbol{\Lambda}_i \boldsymbol{\Gamma}_i {}^{Ti}f_i \end{aligned} \tag{60.8}$$

where U_i, V_i are homogeneous transformations and $\boldsymbol{\Gamma}_i$, $\boldsymbol{\Lambda}_i$ are force transformations [10]. The sensor glove has two types of sensor outputs, the torques actuated by the human operator $\tau \in R^{5\times4}$ and the finger joint angle values $\theta \in R^{5\times4}$. T_i are calculated from the forward kinematical equations using θ.

60.4 Overview of Control Modes

Basic Architectures

As can be seen in Figure 60.2, the communication takes place in two directions in a telemanipulation system. The controller with two directions for the control commands collectively referred as *bilateral controller* [9]. Before the electrical master–slave system was developed, in order to realize force reflection, the traditional bilateral controlled master–slave system had been proposed since in 1952 (see Figure 60.18) [1]. Figure 60.19 shows another traditional control approach for the master–slave system, which was introduced in 1954 [2]. The two position controllers control both the master and slave positions.

These basic architectures are often used as a starting point to design new controllers. Three main problems and some possible solutions are discussed here.

- Nonlinear scaling (Virtual coupling impedance).
- Time delay compensation of internet-based telemanipulation.
- Friction compensation of master device.

Nonlinear Scaling (Virtual Coupling Impedance)

There are basically two approaches: linear and nonlinear scaling. In the case of linear scaling, a single corresponding constant is used between the slave force/position and master force/position:

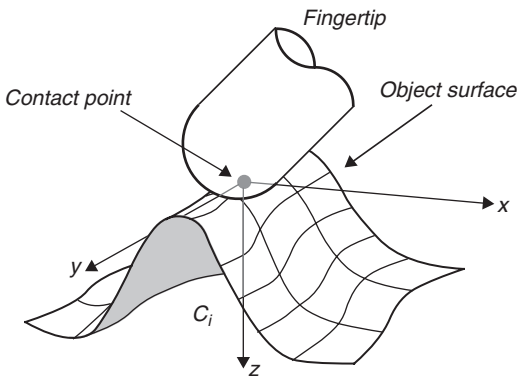

FIGURE 60.17 Contact point and contact frame.

© 2005 by CRC Press LLC

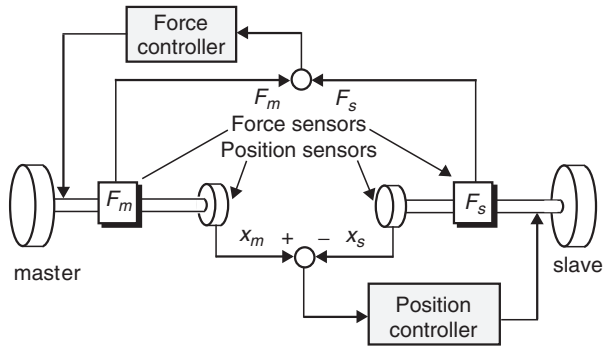

FIGURE 60.18 Conventional bilateral control schema with force and position feedback.

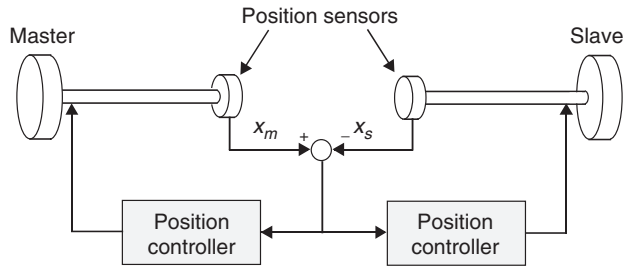

FIGURE 60.19 Conventional bilateral control schema with two position control loops.

$$\begin{aligned} x_s^*(t) &= \alpha_p x_s(t) \\ F_s^*(t) &= \alpha_f F_s(t) \end{aligned} \tag{60.9}$$

where x_s^* and F_s^* are the scaled values, α_p and α_p are the constants of position and force scale, respectively. In case of nonlinear scaling, which is also called impedance scaling [14], forces are scaled independently with respect to their length scaling power relation as follows:

$$\begin{aligned} x_s^* &= \alpha_p x_s(t) \\ F_s^* &= \alpha_p^3 M_v \ddot{x}_s + \alpha_p^2 D_v \dot{x}_s + \alpha_p K_v x_s \end{aligned} \tag{60.10}$$

where M_V is the virtual mass, D_V is the virtual viscosity constant, and K_V is the virtual stiffness. Note that this scaling method is similar to the concept of virtual impedance, which is widely used in the field of robot manipulators. Impedance scaling improves the performance, especially when the sizes or structures of the master and slave devices are different. The mechanical size has some correlation to its bandwidth. There are certain frequency and amplitude ranges, that are necessary for comfortable manipulation. The reaction force must be transformed into these ranges by the virtual coupling impedance. For example, in case of micro/nanomanipulation, the reaction times of the micro/nanoactuator and the micro/nanoenvironment may be too fast for human tactile receptors. The reaction force must be slowed down, that is, the high-frequency components must be shifted to the lower frequency range with the help of virtual coupling impedance. In addition, the virtual coupling impedance behaves as a low-pass filter in the communication channel. It can suppress the high-frequency components, which can destabilize the system with time delay. On the other hand, it contradicts the requirements of ideal telepresence and transparency. In general, an impedance scaling may help prevent instabilities and unreliable force feeling but the price that must be paid for this is the loss of the degree of telepresence and transparency.

© 2005 by CRC Press LLC

Time Delay Compensation of Internet-Based Telemanipulation

The efficiency of telemanipulation has grown in the last few years. The application of the Internet gives new possibilities to the researcher [15]. The medium for data communication is the Internet in Figure 60.1. It allows connecting places electronically that are thousands of miles apart. By combining network technologies with the capabilities of mobile robots, Internet users can discover and physically interact with places far away from them, creating opportunities in resources sharing, remote experimentation, and long-distance learning. Burgard et al. [16] proposed an interactive museum tour guide robot for guiding the user to visit a museum. Simmons [17] presented an autonomous tour guide robot at Carnegie Mellon University. These tour guide robots have the capabilities of obstacle avoidance, self-referring, and path planning. Web users can control the autonomous robot through a web browser such as Netscape and Microsoft Internet Explorer, and click mouse on a map to assign the desired visiting position. Farzin and Goldberg [18] developed an interactive on-line lightbox system to provide users with the function of controlling the camera view for captured images. Stein [19] provided web users with a robot arm to paint a picture through a Java™-based user interface. Kosuge et al. [20] proposed the VISIT system using predictive strategy. Hirukawa and Hara [21] constructed a visual model robot arm to assist the teleoperation.

The main problem of Internet-based Telemanipulation is the variable time delay. Transport Control Protocol/Internet Protocol (TCP/IP) is mainly used to stream data via Internet. It is a packet-switched protocol. This means that the driver divides the data into packets, and sends the packets individually. The receiver tries to collect all the packets and rebuild the original data from the packets. A time delay always occurs when the signal extend from point A to point B. In addition, variable time delay is an immanent characteristic of a packet switched network. Variable time delay has two main reasons. One, the routes of the packets might be different on the network. Second, some packets might be lost. In this case, the receiver asks the driver to send the lost packet again and again. This time delay can destabilize a bilateral teleoperator system. The instability caused by time delay has been revealed by Ferrell [22] as early as in 1965. Since then, various approaches for handling the problem of time delay [23] have appeared in the literature, like delay modeling and control system design [24], predictive displays and advanced operator interfaces [25], shared compliance control [26], impedance control [27], or supervisory control [28]. One possible solution for elimination of the effect of time delay, namely virtual coupling impedance with position error correction method [29], is discussed in detail. This control approach is an extension of the control approach by Otsuka et al. [30]. Virtual coupling impedance is applied both at the operator and the remote site. An additional position correction loop is used to synchronize the two distant sites. This control approach is useful to compensate the effect of variable time delay, also appearing on the pocket-switched computer network, like TCP/IP.

The Smith Predictor

The Smith Predictor is a classical configuration for time delay compensation [31]. Let the $P(s)$ be a first-order filter with transportation leg T_d. The $P_0(s)$ is the model of the plant $P(s)$ in which the time delay is eliminated

$$P(s) = \frac{e^{-T_d s}}{T_f s+1}, \quad -P_0(s) = \frac{1}{T_f s+1} \tag{60.11}$$

There are two loops in Figure 60.20. In the inner loop, a compensation signal $v(t)$ contains a prediction of $y(t)$. $C_0(s)$ is a PID controller.

The closed-loop transfer function is

$$W(s) = \frac{y(s)}{r(s)} = \frac{C(s)\,P(s)}{1+C(s)\,P(s)} = \frac{C_0(s)P(s)}{1+C_0(s)P_0(s)} \tag{60.12}$$

Note that the transcendental term is eliminated in the characteristic equation of the closed-loop transfer function. In practice, the perfect model $P(s)$ is not known, that is, perfect elimination is impossible, but the Smith predictor reduces the effect of time delay.

© 2005 by CRC Press LLC

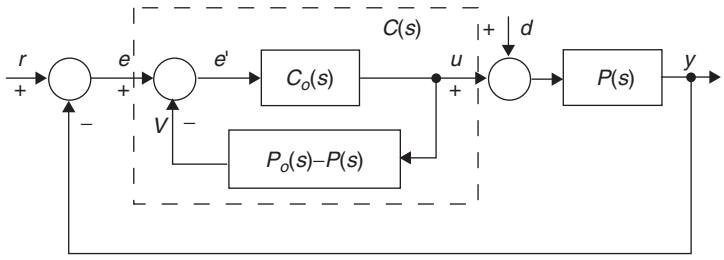

FIGURE 60.20 The configuration of the Smith Predictor.

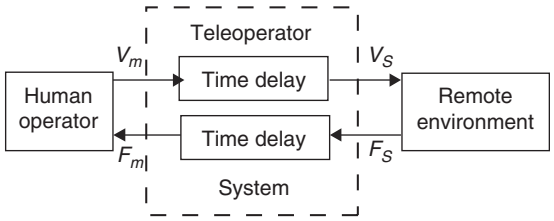

FIGURE 60.21 A simple teleoperator with time delay T_d.

Wave Variable Approach

This approach is based on the *passivity theory* [32], which has a close relationship with the Lyapunov stability. The passivity formalism represents a mathematical description of the intuitive physical concepts of power and energy. The basic idea behind passivity is to limit the input power flow such that it does not exceed the output power flow. If the power dissipation is zero, the system is called lossless. In case of a simplified telemanipulation, the operator moves a master device and its velocity v_m is transmitted to the slave device, which is forced to follow the master movement; ideally, $v_s = v_m$. The slave device contacts the remote environment and the reaction force F_s is transmitted back to the operator, who senses $F_m = F_s$. Figure 60.21 shows a simple telemanipulation with a constant time delay T_d in the communication channel, where

$$\begin{aligned} v_s(t) &= v_m(t-T_d) \\ F_m(t) &= F_s(t-T_d) \end{aligned} \tag{60.13}$$

To handle the stability problem caused by the time delay, the bidirectional communication channel is considered as a transmission line with a pressure-type wave $w_V(t)$, a flow rate-type wave $w_I(t)$, and a power $P(x,t) = w_V(x,t)w_I(x,t)$, where x indicates that the wave variables must be measured at the same position. For stable operation, the transmission line must be passive, and the dissipated energy must be nonnegative.

$$\int_0^t P_{diss}(\tau)\, d\tau \geq 0 \tag{60.14}$$

where P_{diss} is the power dissipation.

The trivial selection of wave variables ($w_I = v_m$ and $w_V = F_s$) does not lead to a passive transmission line. It highlights the source of the original problem. If the master velocity signal is sent and the slave force signal is received via the Internet, the time delay may destabilize the operation of the telemanipulation system. To achieve a passive, that is, stable system, the "damping" or "leakage" of the transmission line must be increased. Introducing the following normalized wave transformation proposed in [33]:

$$w_I = \frac{bv_m + F_m}{\sqrt{2b}},\ w_V = \frac{bv_s - F_s}{\sqrt{2b}} \tag{60.15}$$

© 2005 by CRC Press LLC

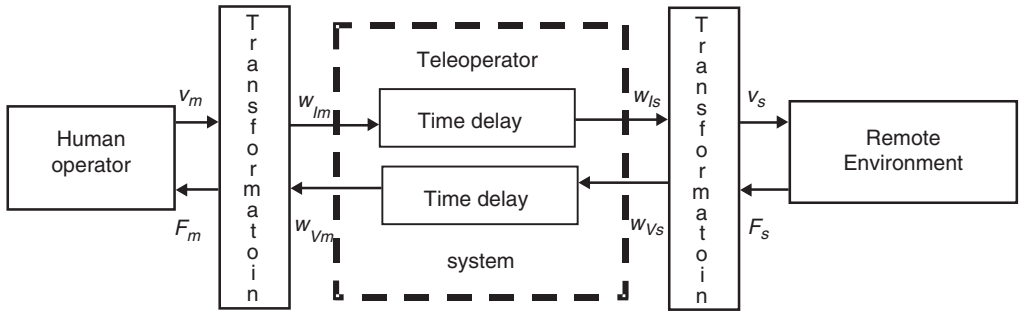

FIGURE 60.22 Telemanipulation with wave variables.

the transmission line becomes passive and lossless, which means the dissipated energy is zero. The velocity and force signal is transferred into wave variables before sending and they are re-transferred after arriving (see Figure 60.22). A possible interpretation of (60.15) is that there are direct feedbacks from the velocity to the force at the master side and from the force to the velocity at the slave side.

Mechanical impedance can be defined in the frequency domain:

$$Z(s) = \frac{w_V(s)}{w_I(s)} \tag{60.16}$$

According to [36], perfect transparency can be ensured by perfect impedance matching. It can be interpreted as the reflected wave deteriorates the transparency. The terminating impedance of this transmission line includes the characteristics of the remote environment. For ideal transparency, the frequency response of the remote environment must be known, and the transmission line have to be modified to match it in the whole frequency domain. There is no such ideal solution but several papers are published to propose an optimal solution.

Friction Compensation for Master Devices

The main problem is that the mechanism applied as a human interface device usually has a reasonable immanent friction. When the operator moves the master device, the friction might be too large to move it smoothly. Because of this additional force, the operator cannot feel which force is exerted in remote environment and which force moves the master mechanism. The whole effect of the friction and the whole dynamics of the mechanic construction cannot be eliminated (since it would need infinite input power) but it can be significantly reduced. The aim of the compensation is to make the system follow an ideal model with small friction. In other words, because of the compensation, the operator feels that it is very easy to move the master device. Usually, the following simplified, linearized reference model is selected for each degree of freedom of the master device:

$$G_m(s) = \frac{1/J_m}{\mathrm{s} + D_m/J_m} \tag{60.17}$$

where torque is the input and velocity is the output signal, J_m is the artificial inertia, and D_m is the artificial viscous friction constant. The subscription m refers to the model. Parameters J_m and D_m must be small enough for comfortable manipulation but they must be large enough to avoid the undesirable motion (jitter).

© 2005 by CRC Press LLC

To compensate nonlinear friction force, sliding mode-based friction observer will be introduced in this section. Consider the following model with external disturbances and uncertain parameters satisfying the so-called Drazenovic condition, written in the regular state equation form,

$$\begin{bmatrix}\dot{x}_1\\ \dot{x}_2\end{bmatrix}=\begin{bmatrix}\bar{A}_{11} & \bar{A}_{12}\\ \bar{A}_{21}+\Delta A_{21} & \bar{A}_{22}+\Delta A_{22}\end{bmatrix}\begin{bmatrix}x_1\\ x_2\end{bmatrix}+\begin{bmatrix}0\\ \bar{B}_2+\Delta B_2\end{bmatrix}u^0+\begin{bmatrix}0\\ E_2\end{bmatrix}f(t) \tag{60.18}$$

where $x_1 \in R^{n-m}$, $x_2 \in R^m$, $u \in R^m$, $\bar{A}_{ij}\,(i,j=1,2)$ and The bar ¯ refers to the nominal or desired (ideal) system matrices. $\Delta A_{2j}(j=1,2)$ and ΔB_2 are the respective uncertain perturbations and $f(t)$ is an unknown, but bounded disturbance with bounded first time derivative with respect to time.

Now, η is defined as the uncertainties and the disturbance of the system.

$$\eta = \Delta\bar{A}_{21}x_1 + \Delta\bar{A}_{22}x_2 + \Delta\bar{B}_2u^0 + E_2f(t) \tag{60.19}$$

The second line of (60.18) can be rewritten by η.

$$\dot{x}_2 = \bar{A}_{21}x_1 + \bar{A}_{22}x_2 + \bar{B}_2u^0 + \eta \tag{60.20}$$

According to [34], $\hat{x}_2$ is estimated by a discontinuous observer:

$$\dot{\hat{x}}_2 = \bar{A}_{21}x_1 + \bar{A}_{22}\hat{x}_2 + \bar{B}_2\,(u^0+\nu) \tag{60.21}$$

where ν is the discontinuous feedback. The goal of the design to find a feedback signal, denoted ν, such that the motion of the system (60.18) is restricted to belong to the manifold S.

$$S = \{x_2 | \sigma = x_2 - \hat{x}_2 = 0\} \quad \text{where } \sigma \in R^m. \tag{60.22}$$

In sliding mode ($\sigma = x_2 - \hat{x}_2 = 0$), ν contains information on the system's parametric uncertainties and the external disturbance, which can be used for feedback compensation (compare (60.20) and (60.21).

The simplest control law, which can lead to sliding mode, is the relay:

$$\nu_i = M_i\, sign(\sigma_i). \tag{60.23}$$

If η is in the range of B_2 ($\eta \subset$ range (B_2)), the ideal sliding mode occurs [35].

In the practice, there is no way to calculate the equivalent control ν_{eq} precisely, but it can be estimated by a low-pass filter for ν as shown in Figure 60.23. There are two loops in Figure 60.23. The observer-sliding mode controller loop should be as fast as possible to achieve an ideal sliding mode. This is granted because

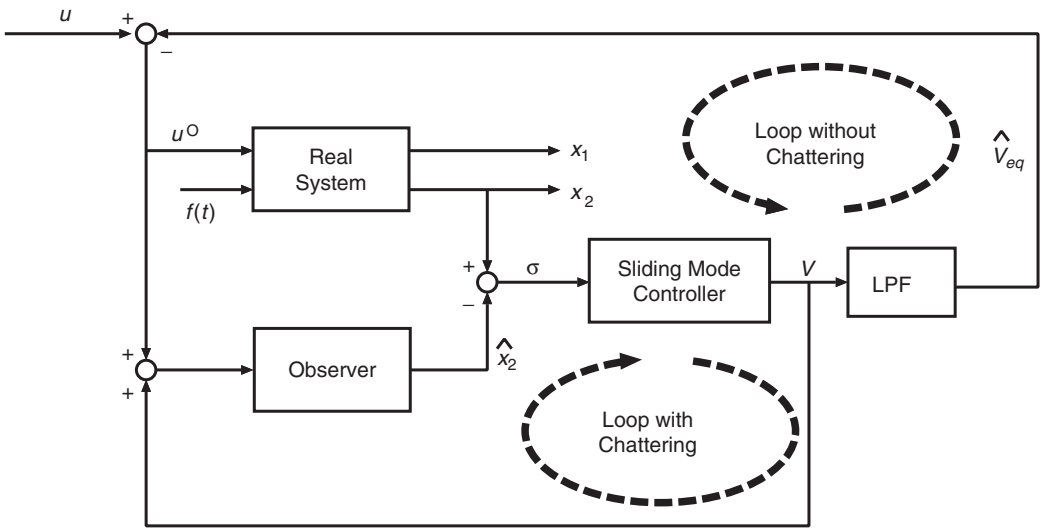

FIGURE 60.23 Sliding mode-based feedback compensation.

© 2005 by CRC Press LLC

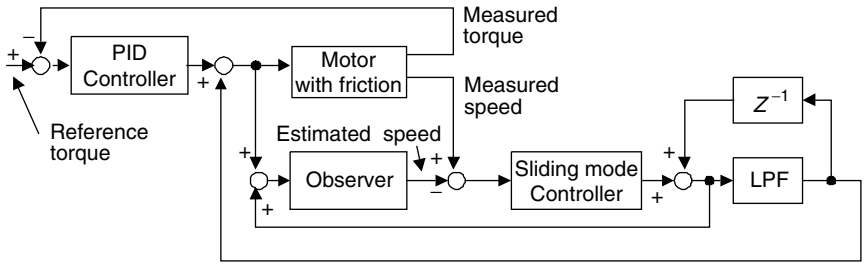

FIGURE 60.24 Overall control scheme for force control.

this loop is realized in a computation engine in the recent application. The real system-compensator (consisting of Sliding Mode Controller and LPF) loop should be faster than the change of the disturbance. On the other hand, the smallest un-modeled resonant frequency of real system should be out of the bandwidth of that loop to avoid chattering.

Applying the above method for friction compensation of a single joint, the parameters are

$$\bar{A}_{21} = 0,\ \bar{A}_{22} = \frac{D_m}{J_m},\ \bar{B}_2 = \frac{1}{J_m} \tag{60.24}$$

The friction compensator provides an additional compensation signal to any conventional closed-loop controller and it improves its performance. A possible overall control scheme for force control of a single joint is shown in Figure 60.24. There is a simple torque control loop, with a PID controller. Because of the nonlinear characteristics of the friction, it cannot be tuned well. The additional sliding mode-based friction compensation may improve the performance significantly [13].

60.5 A Complete Application Example: A Handshake Via Internet

A handshake via Internet is an interesting type of telemanipulation [29]. The task is to realize a handshake between two people at two different corners of the world. Let one be the operator and the other be the far environment reacting to the operator (hand) movement. The master device will be a hand-shaped device in the operator's hand. The slave device is identical. When the operator grasps the master device (see in Figure 60.25 a and b), the master device transforms the movement and force to the slave device. The slave device gives this movement to the far environment (the other person's hand). This person gives a reaction force and a movement to the slave device. This information is transmitted to the operator via a master device. The handshake will be realized between two people far from each other. The main challenge is compensation of the time delay.

Virtual Impedance with Position Error Correction

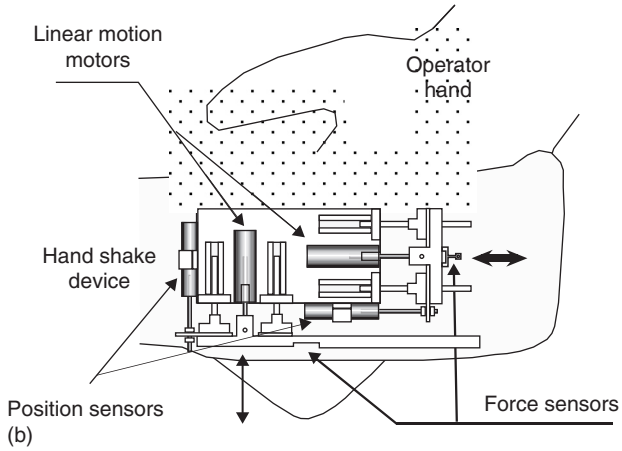
Virtual Impedance with Position Error Correction (VIPEC) is based on the concept of the impedance control. VIPEC is composed of two major parts: a virtual impedance model (VI) and a position error correction part. The virtual impedance model generates a motion trajectory for a manipulator based on input forces and its dynamics. The position error correction part is added to decrease the position difference of the master and slave.

Virtual Impedance

In the case of a 1 DOF linear motion manipulator, it is assumed that a virtual mass, M_v, is attached to a manipulator arm. This virtual mass is supported by a virtual damper, D_v, and a virtual spring, K_v. The structure of the VI is shown in Figure 60.26.

© 2005 by CRC Press LLC

(a)



(b)

FIGURE 60.25 Tele Handshaking Device. (a) photo, (b) structure.

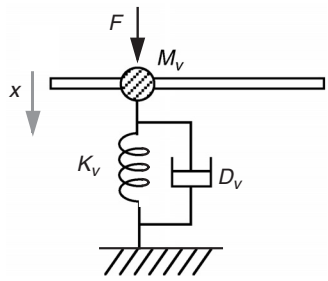


FIGURE 60.26 One DOF linear motion manipulator with virtual impedance.

When a force is applied to the virtual mass, the position of the virtual mass is modified according to the dynamics of VI. The dynamic equation of VI is as follows:

$$F(t) = M_v \ddot{x}(t)\, D_v \dot{x}(t) + K_v x(t) \tag{60.25}$$

© 2005 by CRC Press LLC

where $F(t)$ is the force detected at the virtual mass and $x(t)$ is the displacement of the virtual mass. The transfer function of the VI acts as a second-order low-pass filter to convert force into displacement. Thus, the displacement is always smooth even if the force contains high-frequency components.

Position Error Correction

The structure of a teleoperator with time delay utilizing the VIPEC is illustrated in Figure 60.27. The PEC part (the shaded part) is added to the original approach [30] in order to improve the response of the teleoperator by reducing the position error between the master and slave positions.

In Figure 60.27, F_o denotes the force that an operator applies to the master arm, and F_e denotes the reflected force when the slave arm contacts the environment. x_m and x_{mr} denote the position and the reference position of the master arm. x_s and x_{sr} denote the position and the reference position of the slave arm. T_d represents a delay time in data transmission between the two sites. A_f is a scalar unit, which can be varied depending on the size ratio of the slave and the master.

Each VI generates the reference motion trajectory for each manipulator arm based on the sum of two forces: the force from its own site and the force received from the other site. The data transmission from one site to the other site is delayed by T_d. The reference motion trajectory from VI is sent to a servo controller to control the position of the manipulator arm.

The control approach can be used for the master and the slave arms, which are different in size by appropriately adjusting A_f and the parameters of each VI, for example, when the slave is a micro robot, which is smaller than the master.

The dynamic equation of VI at the operator site is

$$F_o(t) - \frac{1}{A_f} F_e(t-T_d) = M_v \ddot{x}_{mr}(t) + D_v \dot{x}_{mr}(t) + K_v x_{mr}(t) \tag{60.26}$$

The dynamic equation of VI at the remote site is

$$F_e(t) - A_f F_o(t-T_d) = M_v \ddot{x}_{ms}(t) + D_v \dot{x}_{ms}(t) + K_v x_{ms}(t) \tag{60.27}$$

Without loss of generality, $A_f = 1$ and both VIs have the same parameters. When the parameters of VI are appropriately determined, the system should remain stable. In the steady state, F_o is approximately equal to F_e when K_v is set to a low value, and the master and the slave positions should be identical. However, when a time delay is present in the teleoperator, the control approach VI without PEC part causes the position error between the master and slave positions, since there is no comparison between these two positions. To reduce this position difference, the PEC part is added in order to make a closed-loop system. Therefore, the position error can be reduced. The slave position, delayed by T_d, is transmitted to the master site and compared to the master position. The difference between the two positions is sent through the PEC gain, and then modifies the reference motion trajectory of the master arm.

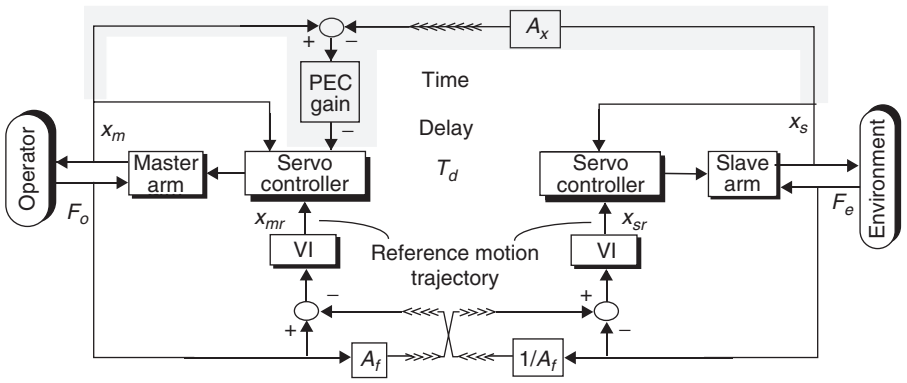

FIGURE 60.27 Virtual Impedance with Position Error Correction for a teleoperator system with time delay.

© 2005 by CRC Press LLC

Control Model of The Handshaking Device

Figure 60.28 shows the control system diagram of the master–slave system inside the telehandshaking system with VIPEC approach. The armature inductance, L_a of each motor is neglected. The two linear motion motors represented by the master block and the slave block can be modeled as simple DC-motors with the transfer function.

$$C(s) = \frac{X(s)}{E_a(s)} = \frac{K_m}{s(T_m s+1)} \; K_p \tag{60.28}$$

where X and E_a are the Laplace transformed of motor shaft displacement and the applied armature voltage, K_m is the motor gain constant, T_m is the motor time constant, and K_p is a constant to convert the angular displacement into displacement.

The servo controller is a proportional controller whose gain is G. The closed-loop transfer function of the manipulator arm and the controller is

$$M(s) = \frac{C(s)G}{1+C(s)G} = \frac{\dfrac{GK_pK_p}{T_m}}{s^2 + \dfrac{1}{T_m}\,s + \dfrac{GK_pK_p}{T_m}} \tag{60.29}$$

Gain P represents PEC gain. For simplicity, the environment is modeled by a spring with stiffness constant K_e. Therefore, the dynamics of the spring interacting with the slave arm is modeled as follows:

$$F_e(t) = K_e x_s(t) \tag{60.30}$$

where x_s is the displacement of the spring. The dynamics of the operator including the dynamic interaction between the operator and the master arm is approximated by

$$F_{op}(t) - F_o(t) = M_{op}\ddot{x}_m(t) + D_{op}\dot{x}_m(t) + K_{op}x_m(t) \tag{60.31}$$

where F_{op} is the force generated by the operator's muscles. M_{op}, $B_{op,}$ and K_{op} denote mass, damper, and stiffness of the operator and the master arm, respectively. Similar to Equation (60.30), the displacement of the operator in Equation (60.31) is represented by x_m since it is also assumed that the operator is firmly grasping the master arm and never releases the master arm during the operation.

Experiment

Using the telehandshake system, two human operators, operator A and operator B, shake hands with each other. When operator A tries to shake the hand of operator B by moving the master arm A, the slave arm

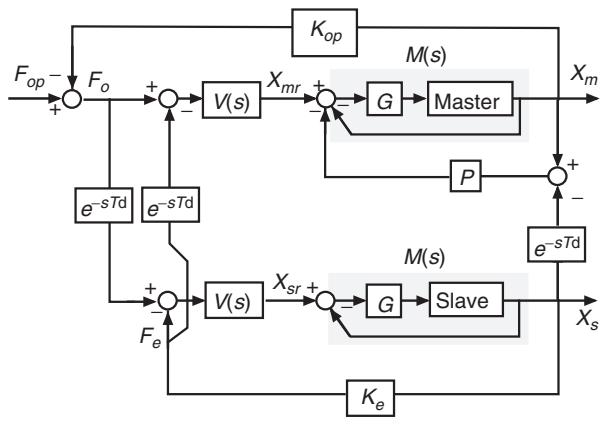

FIGURE 60.28 Control diagram of the handshaking device.

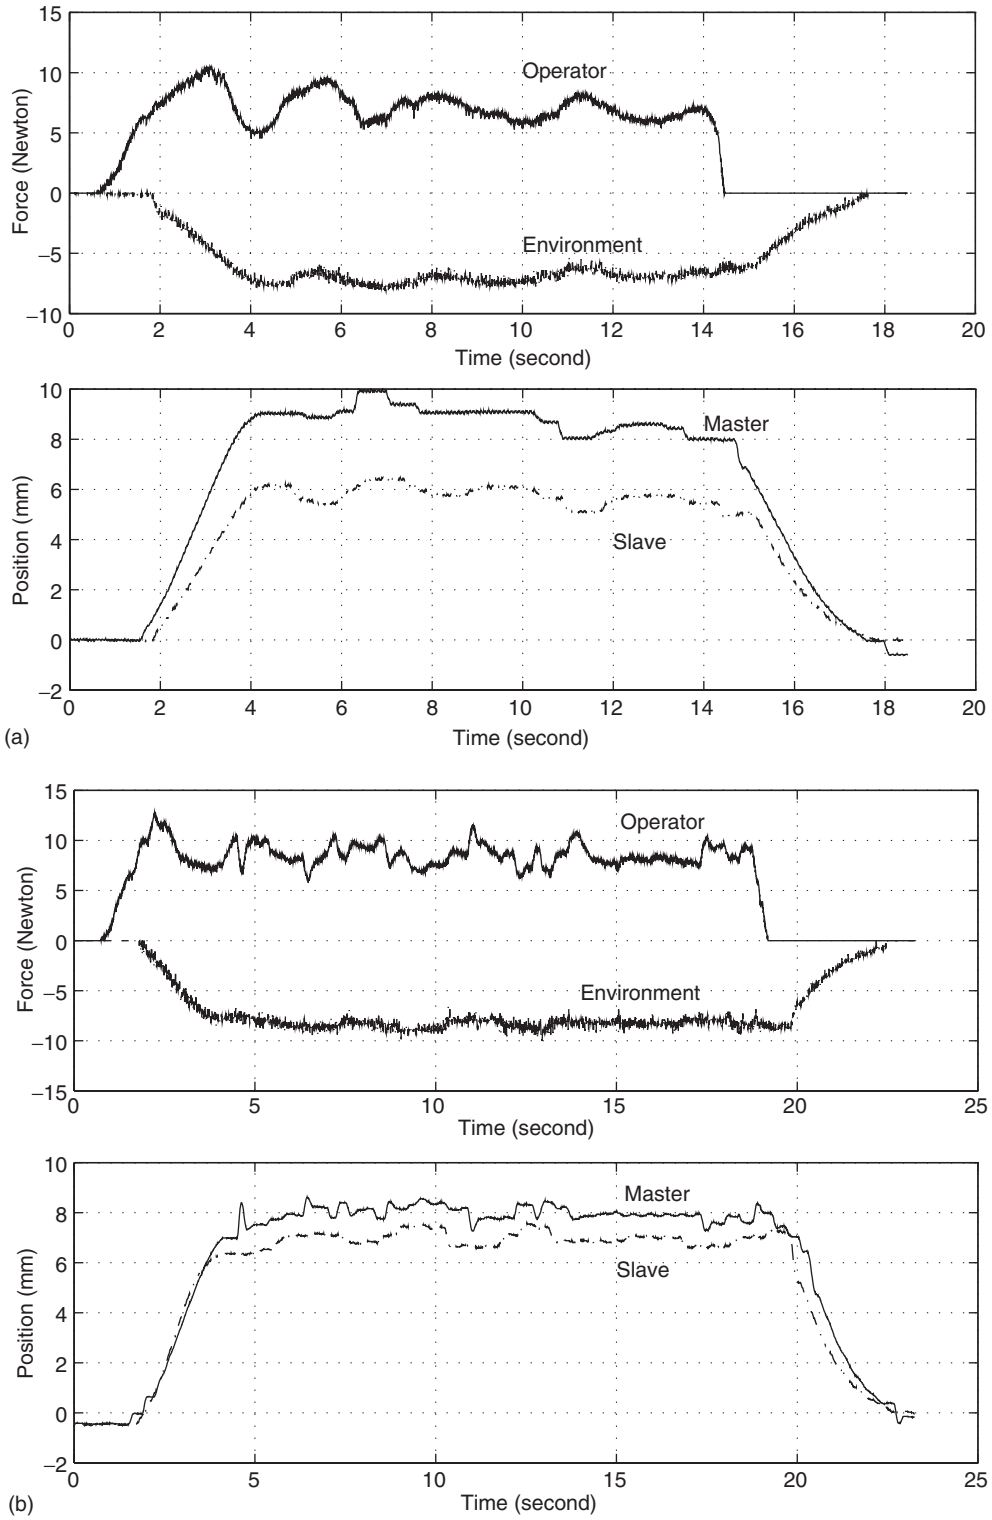

FIGURE 60.30 Experimental results of a telehandshaking device with 400 ms time delay: results with VPEC. (a) results with VI and without PEC, and (b) results with VIPEC.

© 2005 by CRC Press LLC

A should move the same as the master arm A does. When the slave arm A contacts the palm of operator B, operator B can feel the grasping force of operator A. Operator B can also grasp the virtual hand of operator A in the same way. Two operators succeeded in shaking hands with each other and achieved force sensation through the tele-handshaking Device. Experimental results of simple VI and VIPEC methods are compared in Figures 60.29 and 60.30. In Figure 60.29, the time delay is negligible. The difference between the two methods is not significant. In both cases, the positions of the master and slave device are approximately the same. Figure 60.30 illustrates the experimental results with 400 ms time delay. In both cases, the system is stable and the operators can feel the grasping force. However, the position difference between the master and slave device is smaller in case of the VIPEC method.

60.6 Conclusions

The Internet-based telemanipulation is a relatively new and attractive research field. It is a fruitful ground for applying new and sophisticated control methods to eliminate the time delay and nonlinear friction force, which are the main challenges in this field. Of course, total elimination is impossible, but a stable operation may be achieved. This chapter presented a promising method, namely Virtual Impedance method with Position Error Correction. The effectiveness of this method has been proved by measurement results of a telehandshaking device.

61.1 Introduction
61.2 Architecture
61.3 Experience with a Pilot Installation
61.4 Discussion and Conclusion

61.1 Introduction

A service engineer's task of maintaining a huge installation is an immense task. He relies on information that is available about his plant. Previously, information about installed components or the process itself was provided by paper documents delivered by the system manufacturer at the time the system was installed. This documentation was then updated and maintained by its users, normally service engineers, machine operators, or service personal. After a period of time and numerous minor changes, this documentation became outdated and incomplete because it had not been updated adequately. Another problem with paper documentation is that it is hard to search for specific information on equipment in a timely manner.

The shift from paper to electronic documentation was an easy decision — it made it possible to search an entire library for information at one workplace. Secondly, it occupies much less space than the paper documents. The drawback, however, is to know what you were looking for, for example, which component does the process include, how is it connected, and what are the parameters and its current status. In large installations, this can typically be found only by walking to the physical component, writing down the information off of the label, and comparing the data to some connected information system to gain information about the current status. With this information, the electronic documentation can be searched or a help desk can be called. In cases where the information is showing white spaces, it becomes more difficult to find a solution for a specific problem. Modern search engines, like the ABB SolutionsBank [1], use wizards to lead the user to the requested information. Even in this case, the user needs to know specifically what he is searching for.

This fits very well with recent studies, which clearly show that critical problems in the service business arise due to lack of information. This begins with faulty failure diagnosis followed by calling the wrong expert and asking irrelevant questions often not related to the hardware but to the process, and ending with difficulty finding spare part information [2].

© 2005 by CRC Press LLC

ABB offers several different web applications for helping with this problem including SolutionsBank, the e-mmediate Agent, and the ABB University. For most service engineers, these tools are helpful but it is difficult to find the right information in a very limited time frame. The KnowledgeConnect project was initiated to overcome this problem by automatic filling in the white spaces of a request through the use of plant information.

The remainder of this chapter will describe the scope of the project. Section 2 will provide an overview of the architecture based on the aspect object model [6]. Section 3 will summarize the experience of using KnowledgeConnect on a real paper mill control system. Finally, in Section 4, some constraints, advantages, and prerequisites will be discussed together with an outlook.

61.2 Architecture

The basic concept of KnowledgeConnect is based on ABB Industrial^{IT} [1] and consists of the connection from the control system and its engineering with several external databases such as SolutionsBank[3] and the e-mmediate agent. This concept will be made available to different user groups, although the service engineers will mainly use it. The initial project used process graphics available on any Process Portal application for accessing the implemented services. Figure 61.1 shows an overview of the project and the connected external services.

The procedure used for all three Aspect Systems is similar:

- Collect information about the object that the user wishes to search information for
- Request the information from an external application
- Display the results to the user.

While this sounds fairly simple, it is a tricky task, which requires considerable engineering effort to create such a system and keep it up to date while it is used. The main task of using this architecture is to find a solution that needs very little engineering and that is usable straight out of the box.

KnowledgeConnect makes use of the Aspect Directory [5] of the ABB's 800xA System. Any real object is represented in the process portal by an aspect object. Each aspect object has properties, which describe

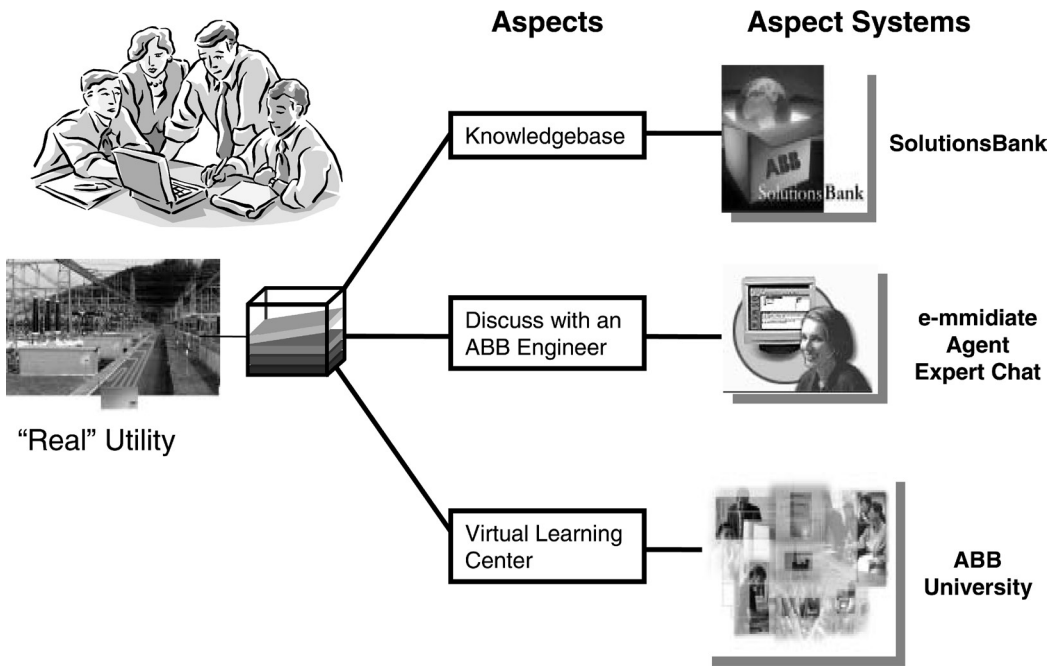

FIGURE 61.1 Architectural overview of KnowledgeConnect.

© 2005 by CRC Press LLC

the object such as the name, the type of component, for example a thermo sensor, the configuration in the engineering tool, or the actual status of it. All this information is available as OPC DA data items for any application. Special information, for example, related to dependencies with other objects might need special applications to calculate those and can be accessed by standardized interfaces through the aspect directory. This information source is used in KnowledgeConnect to describe a very specific search string, which can be sent to the external application, that is capable of returning precise information to the user. This information does not need to be engineered for KnowledgeConnect. This information can be in any form including MS Word, MS Excel, or Adobe PDF. All KnowledgeConnect has to do is to make intelligent links to this data source.

In the aspect directory, the aspect objects are hierarchically sorted [7] and each instance refers to a specific object type, which again belongs to an object category. Each object type owns a special set of aspects, for example configuration data, faceplates, symbol information, and control configuration [8]. These aspects are inherited when a new object is instantiated in a hierarchical structure, for example, Functional Structure (see Figure 61.2).

KnowledgeConnect is formulated as a set of aspect systems, which are added to the desired object types, and categories, which will later refer to service information. When an object is instantiated, all KnowledgeConnect aspects automatically come ready to be used.

When a user selects a KnowledgeConnect aspect, the aspect starts building up a query from the information specified in the object's relevant aspects. Additionally, a Global Configuration aspect is used to provide general information about the customer's site, the database to refer to, and the required log-on information for this database (see Figure 61.3).

The advantage of this procedure is that the system only needs a minimal amount of preconfiguration effort. The object-type definition only has to be defined once, which is typically done by the solutions provider of the SolutionsBank. They are knowledgeable of the object types used in their specific industry systems. Their task is to add the KnowledgeConnect aspects to the appropriate object categories and types and fill them with minimum information, typically the object name. They can also point to other aspect system information, which does not come with the standard package or add specific keywords to these aspects. These preconfiguration data are stored in an extra aspect also available to any other application, which might want to make use of the KnowledgeConnect features (see Figure 61.4). The object types can then be released and distributed to customer sites.

Currently, the following KnowledgeConnect aspects have been developed and tested:

- Technical Information such as release notes, feature changes, etc. (TechInfo).
- Equipment manuals and user documentation (ManualsOnline).
- "Fix a problem" with a component (KnowledgeBank).
- Enter an on-line Chat-Session with an Service Engineer (e-mmediate Agent).
- e-Learning courses available over the web (ABB University).
- On-line Part ordering (Parts Online).

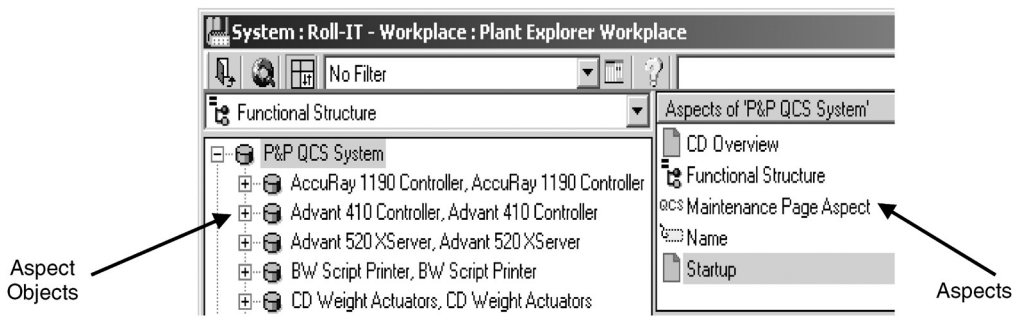

FIGURE 61.2 An object instantiated in the Functional Structure.

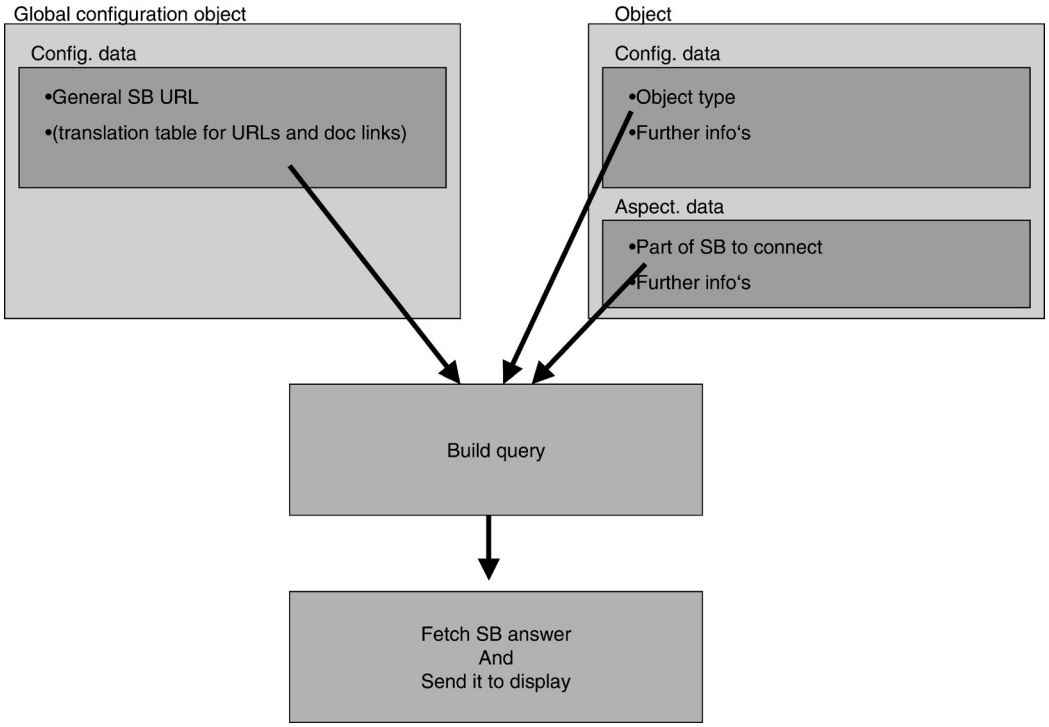

FIGURE 61.3 How a query is built up.

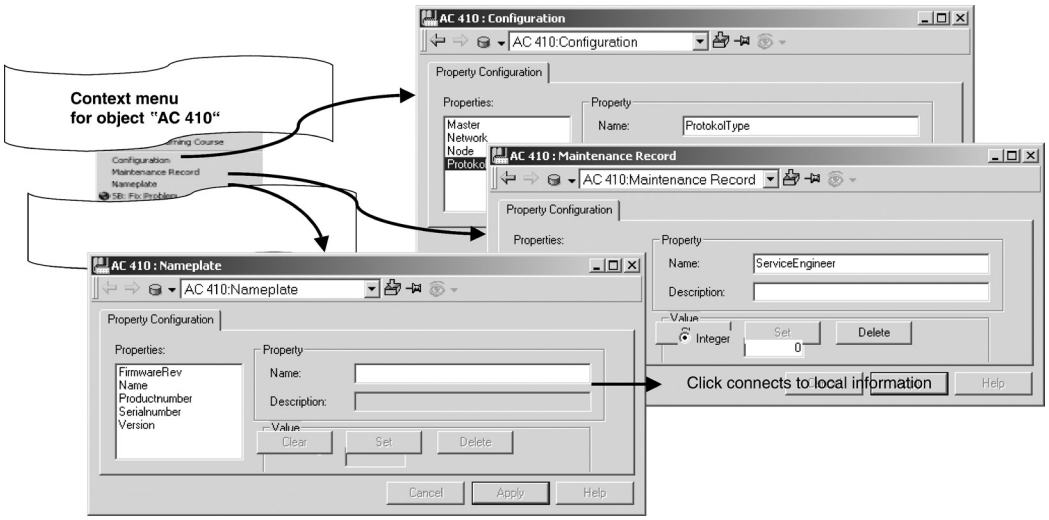

FIGURE 61.4 Standard aspect configuration.

The KnowledgeConnect aspects are an integral part of the process portal application and can be accessed from any user's workplace that owns the specified rights in the system. Typically, the user accesses the KnowledgeConnect aspects from the KnowledgeConnect Maintenance Display as mentioned previously (see Figure 61.5).

When the local user needs help with a question or with a problem, a right click on the asset opens the aspect context menu, which leads to all functionality available to this specific object. The process

© 2005 by CRC Press LLC

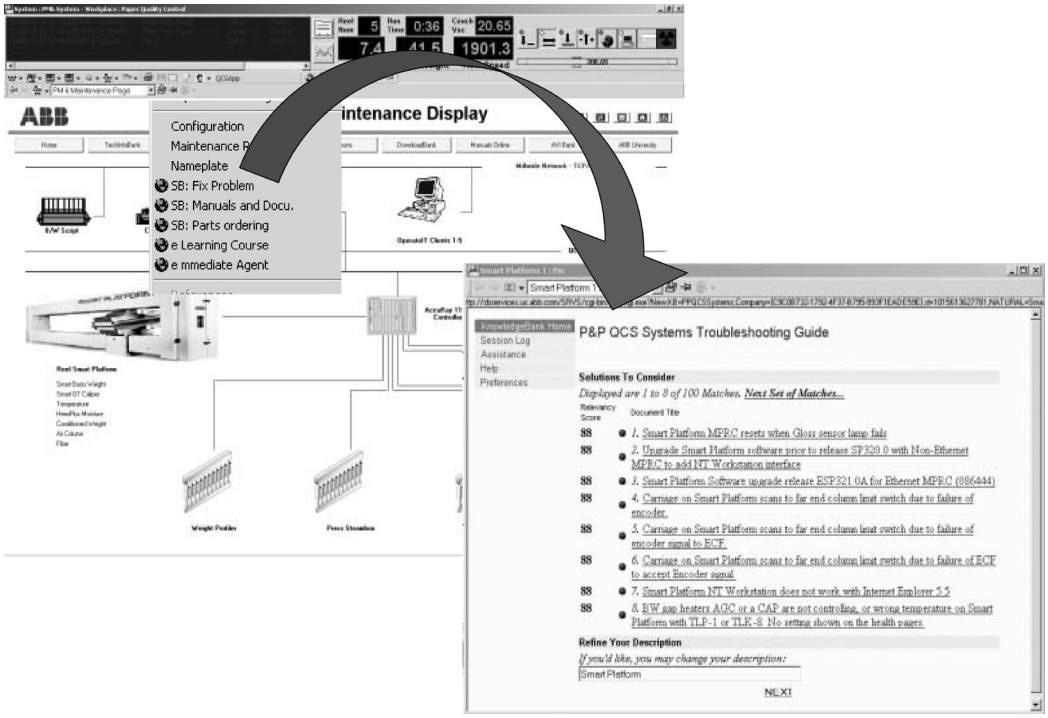

FIGURE 61.5 Maintenance Display with troubleshooting example.

portal application opens the aspect view showing the solutions available for the selected asset, and is ready for further analysis to pinpoint the desired solution using the mechanism described above.

61.3 Experience with a Pilot Installation

KnowledgeConnect was successfully installed on one of ABB's customer sites, a paper mill near Jackson, MS. This site had a new Pulp and Paper quality control system based on Industrial^{IT} installed.

The installation was simple, and the adoptions to the process could be managed within half a day. After the KnowledgeConnect installation and introduction, the service technicians were left alone with testing out the system. Two months later, a follow-up interview was conducted with the service responsible person as well as the service technicians.

The first finding was that all users stated that the system was of great value for them. The system considerably helps to find the appropriate information with a single mouse click for components, that are actually installed. The value is that it normally takes the service engineer an enormous amount of time to figure out which component, version, etc., is actually installed in his system and how it is configured and related to other system components. This information is made accessible on the Maintenance Display and the relationship between the components is visualized as a process display. As a graphical representation, the Maintenance Display acts like a plant explorer for the service engineer. From this one location, information regarding all components can be retrieved. The process portal locates the necessary search criteria and displays the results to the user. Due to this visualization, the Maintenance Display can also be used to look up information, which might be required at a later date.

Two Examples of the Maintenance Display Usage include the following.

© 2005 by CRC Press LLC

Example one

A failure in the control network was discovered and even after calling the Help Line, this failure could not be resolved. The system gave periodic error messages about the system status and only a bypass with some network cable could keep the paper machine running, although with less control and quality. KnowledgeConnect helped the service people to resolve the problem. Searching through the control net-object entries of the KnowledgeBank aspect of the Maintenance Display, a small component was discovered, which was suspected for the failure. It was only found because the component was indicated on the Maintenance Display and information about it was available in SolutionsBank.

Example two

A second example concerned a specific sensor at the frame. The service engineers had very little information about this component and they did not find it in SolutionsBank because the naming and versioning were different from what was used in the plant. Through the use of the Maintenance Display, it became very easy to connect to all the information relevant to this component and the service engineers quickly learned from the on-line manuals to correctly use this new sensor more efficiently than before.

These two examples illustrate that it is important to have an on-line help system like the KnowledgeConnect maintenance display available to retrieve information. Since these capabilities are embedded into ABB's process portal framework, access is not limited to the service staff. Even more, the KnowledgeConnect aspects are naturally coupled with all other functionalities in the system, for example alarm and event lists, process graphics, etc.

More comments were made on the following issues: while the operators, the controllers, and the optimization people have their own views of the control system and the production process, the maintenance people still do not have their own user interface to the process. Service engineers are using the views of the other user groups but they wish to have their own displays to collect important information for their work. The Maintenance Display is exactly what they are looking for. Additionally, they wish to be able to extend and use it as part of their daily work. To do so, it must be easy to add new functionality and details of their system to this display. New links to information sources should be easily added to the display along with objects containing even more details.

Another important task is the illustration of the components. Having only the descriptive name of an object does not help in a complex system to identify it in the process. This means that it is important that a good illustration is available for each component of the system stored as an image icon with the object type. It should then be possible to extend the Maintenance Display with the new information and illustration.

61.4 Discussion and Conclusion

This chapter presented a new aspect system out of the world of Industrial^{IT}. KnowledgeConnect reuses information, which it collects from other sources, for example applications running on the same software platform, the ABB Process portal [4]. From this information, the user can easily find relevant information to solve typical service engineer problems. The key mechanisms used are aspect objects, which lead to an efficient and low-effort engineering of such a support system.

There are some constraints that have to be mentioned here. To use such a support system, it is necessary that the service engineer's workplace be connected to both the Internet and the control system at the same time. Only in this configuration can the optimum performance of the system be gained. Unfortunately, connecting a control system directly to the Internet is normally not accepted by most customers due to network security problems. On the other hand, very often, access to control data is already available by links to the company's office network. This makes it essential that network administrators

© 2005 by CRC Press LLC

install the required network protection so that it remains possible to use such services that will have a very important role in the future of automation.

KnowledgeConnect demonstrates a very small fraction of the possibilities of communicating applications in the Industrial^{IT} world, but the results of this project are very promising for future services to our customers.

62.1 Introduction

This chapter provides an introduction in the Openness, Productivity, and Connectivity (OPC) technology. After explaining the history of OPC, the structure of the OPC Foundation, use, cases, and advantages of OPC, the introduction of the specifications follows. The chapter closes with an outlook into the future.

© 2005 by CRC Press LLC

62.2 Open Standards — Automation Technology in Flux

The pace of change in industrial control and automation technology is accelerating. Demands on machines and systems concerning flexible retrofit, production speed, and fail safety are increasing, as are cost pressures. Software is becoming more and more the essential factor with products, systems, and complete plants.

At the same time, changes in the field of automation brought about by the use of the PC as an automation component, by the Internet, and by the tendency to more open standards, can be clearly seen — to the benefit of the user and the manufacturer.

The PC is more and more used for visualization, data acquisition, process control, and the solution of further tasks in automation. It complements or replaces the traditional PLC and the operator terminal. The reasons for this are the continual decrease in the price of the mass-produced PC, the permanent multiplication of the computing capacity of the CPU, the availability of even more efficient and comfortable software components, and the ease of integration with Office products.

Efficiency and cost savings are achieved through the reuse of software components and the flexible compilation of such components into distributed automation solutions.

Horizontal integration of the automation solutions through communication between the distributed components also plays an important role. Immense additional savings are achieved by means of vertical integration by optimizing the process of product planning, development, manufacturing, and sales. This optimization is realized through a consistent data flow, permanent data consistency, and the availability of data on the field level, control level, and office level.

The use of standardized interfaces by several manufacturers is a prerequisite for the flexible compilation and integration of software components.

OPC is now generally accepted as one of the most popular industrial standards among users and also among developers. Most of the Human Machine Interface (HMI), Supervisory Control and Data Acquisition (SCADA), and Distributed Control System (DCS) manufacturers in the field of PC-based automation technology, as well as the manufacturers of Soft PLCs, are offering OPC client and/or OPC server interfaces with their products. The same is true for suppliers of devices and interface cards. In the last few years, OPC servers widely replaced Dynamic Data Exchange (DDE) servers and product-specific drivers in this field.

Today, OPC is the standard interface for access to Windows-based applications in automation technology. Most of the OPC Specifications are based on the Distributed Component Object Model (DCOM), Microsoft's technology for the implementation of distributed systems. Besides the DCOM-based communication in future, in the context of new OPC concepts, more and more data will be exchanged via Web Services.

OPC specifications define an interface between clients and servers as well as servers and servers for different fields of application — access to real time data, monitoring of events, access to historical data, and others. Just as any modern PC can send a print task to any printer, thanks to the integration of printer drivers, software applications can have access to devices of different manufacturers without having to deal with the distinct device specifications. OPC clients and servers can be combined and linked like building blocks using OPC technology.

At present, OPC clients and servers are mainly available on PC systems with Windows 9X/Me/NT/2000/XP and x86 processors. Due to the availability of Web Services for multiple operating systems, the use of OPC components in different environments and in embedded systems will become more important in future.

Why is OPC so successful? The approach of the OPC Foundation has always been to avoid unnecessarily detailed discussions and political disputes and to create practical facts within a very short time.

The development of the Data eXchange specification can serve as an example. More than 30 companies joined the effort and delivered the specification 18 months after starting.

OPC has succeeded in defining a uniform standard worldwide, which has been adopted by manufacturers, system integrators, and users.

© 2005 by CRC Press LLC

62.3 History of OPC

Since reusable software components made their entry into automation technology and replaced monolithic, customized software applications, the question of standardized interfaces between components has increased in significance. If such interfaces are missing, every integration is connected with cost-intensive and time-consuming programming supporting the respective interface. If a system consists of several software components, these adaptations have to be carried out several times.

Following the immense distribution of Windows operating systems and their coherent Win32-API in the PC area, different technologies were created to enable communication between software modules by means of standardized interfaces. A first milestone was DDE, which was complemented later on by the more efficient technology Object Linking and Embedding (OLE). With the introduction of the first HMI and SCADA programs based on PC technology between 1989 and 1991, DDE was used for the first time as an interface for software drivers to access the process periphery.

During the development of Windows NT, the DCOM was developed as a continuation of the OLE technology. Windows NT was rapidly accepted by industry. In particular, the highly expanding HMI, SCADA, and DCS systems were made available for NT.

With the increased distribution of their products and the growing number of communication protocols and bus systems, software manufacturers faced more and more pressure to develop and maintain hundreds of drivers. A large part of the resources of these enterprises had to be set aside for the development and maintenance of communication drivers.

In 1995, the companies Fisher-Rosemount, Intellution, Intuitive Technology, Opto22, Rockwell, and Siemens AG decided to work out a solution for this growing problem, and they formed the OPC Task Force. Members of Microsoft staff were also involved, and supplied technical assistance.

The OPC Task Force assigned itself the task to work out a standard for accessing real-time data under Windows operating systems, based on Microsoft's (OLE/)DCOM technology OLE for Process Control, or OPC. The members of the OPC Task Force worked intensively, so that already in August 1996 the OPC Specification Version 1.0 [3] was available. In September 1996, during the ISA Show in Chicago, the OPC Foundation was established; it has been coordinating all specification and marketing work since then.

An important task of the OPC Foundation is to respond to the requirements of the industry and to consider adding them as functional extensions of existing or newly created OPC specifications. The strategy is to extend existing specifications, to define basic additions in new specifications, and to carry out modifications with the aim of maximum possible compatibility with existing versions. In September 1997, a first update of the OPC Specification was published in the form of version 1.0A [4]. This specification was no longer named "OPC Specification" but, more precisely, Data Access Specification. It defined the fundamental mechanisms and functionality of reading and writing process data. This version also served as the basis for the first OPC products, which were displayed at the ISA Show 1997. Consideration of further developments in Microsoft DCOM and industry requirements led to the creation of the Data Access Specification version 2.0 [5] in October 1998.

Already, rather early, after the release of version 1.0A, it could be seen that there was a need for the specification of an interface for monitoring and processing events and alarms. A working group formed to solve this problem worked out the Alarms and Events Specification, which was published in January 1999 as version 1.01. Version 1.10 of the Alarms and Events Specification is available since October 2002 [9].

In addition to the acquisition of real-time data and the monitoring of events, the use of historical data offers another large field of application in automation. The work on the Historical Data Access Specification already began in 1997 and was completed in September 2000 [11].

Defining and implementing security policies for use with OPC components is also of great importance. A corresponding specification has been available since September 2000 and is titled OPC Security Specification [15].

In particular, from the field of industrial batch processing, additional requirements have been forwarded to the OPC Foundation, which have led to the OPC Batch Specification [13].

© 2005 by CRC Press LLC

During work on version 2.0 of the Data Access Specification and the other specifications, it emerged that there are elements common to all specifications. These elements have been combined in two specifications. The document OPC Overview [1] contains explanatory aspects only, while the OPC Common Definitions and Interfaces Specification [2] contain normative definitions.

With the increasing implementation of the OPC specifications in products, and their application in multiple environments, further requirements arose. New working groups have been created by the OPC Foundation. The Data Access 3.0 working group extended the existing Data Access Specification with further functionality. The specification [7] has been available since March 2003. The OPC and XML group defined a way to read and write data by using Web Services, and enables the use of OPC components via the Internet and on operating system platforms without DCOM. The specification Version 1.0 [16] is available since July 2003. The OPC DX working group defined a specification for server-to-server communication without using a client. It is available since March 2003 [8].

The rapid growth in the number of OPC products, from only a few in 1997 to some thousands in 2003, shows the enormous acceptance of this technology. OPC has succeeded in developing from a concept to an industrial standard within only three years.

62.4 OPC — An Overview

OPC is the technological basis for the convenient and efficient link of automation components with control hardware and field devices. Furthermore, it provides the condition for integration of Office products and information systems on the company level such as Enterprise Resource Planning (ERP) and Manufacturing Execution Systems (MES).

Today, OPC, on the one hand, is based on Microsoft's DCOM; on the other OPC XML-DA uses the concept of Web Services. The DCOM describes an object model for the implementation of distributed applications as per the Client–Server Paradigm. A client can use several servers at the same time and a server can provide its functionality to several clients at the same time.

At the core of DCOM is the term interface. DCOM objects provide their services through interfaces. An interface describes a group of related methods (functions).

The most diverse OPC components of different manufacturers can work together. No additional programming for adaptation of the interfaces between the components is necessary. Complex correlation, for example, dependencies of the software component on hardware components, remain concealed behind this abstract interface. Complete components (hardware and software) can be exchanged, provided the interface described in the specifications is supported.

The OPC standards are freely accessible technical specifications that define sets of standard interfaces for different fields of application in automation technology. These interfaces allow a highly efficient data exchange between software components of different manufacturers.

Figure 62.1 shows the currently available specifications or those under work and their relations to each other. These specifications concern different fields of application and are thus largely independent of one another. However, it is possible to combine them in one application.

Areas of OPC Use

What is the industrial environment for using OPC products?

Today, and especially in the future, information drives more and more production. This information exists in different forms in various devices at different levels of production. And this information must be available in different forms at different places. OPC provides a way to access and deliver data at the different levels. Figure 62.2 shows an example for the use of OPC in real applications.

OPC technology is well established in a number of industries (energy, building automation, chemical engineering, ...).

OPC technology can be used to immediately monitor and influence the production process. Process information is visualized, and control information is sent to the devices.

© 2005 by CRC Press LLC

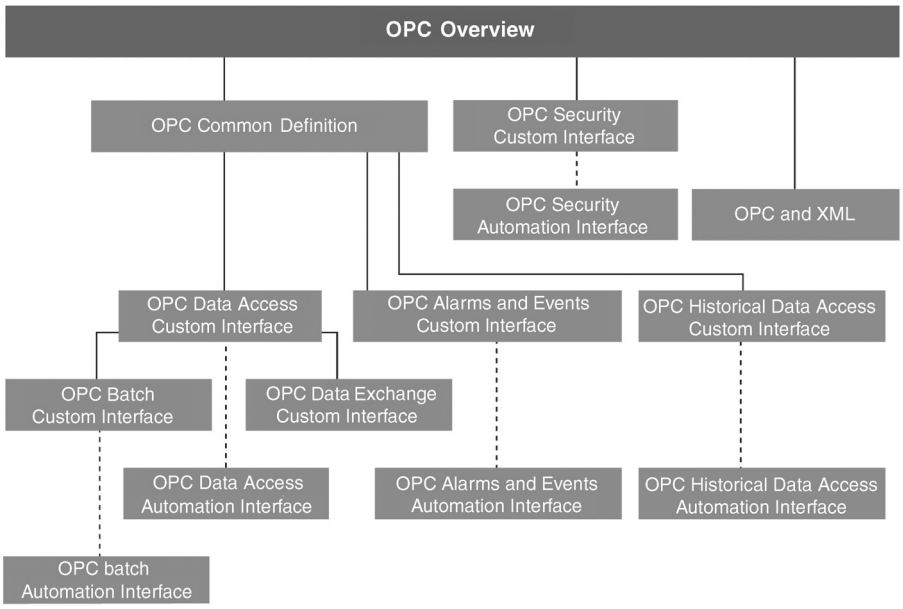

FIGURE 62.1 Available and in-progress specifications.

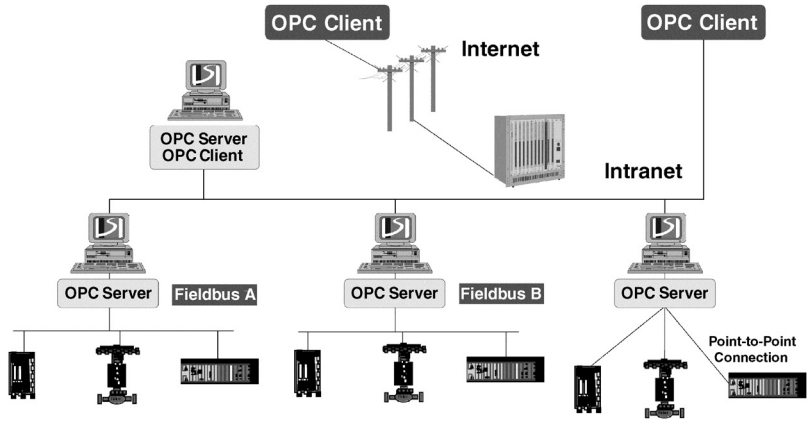

FIGURE 62.2 Examples for the use of OPC in real applications.

In other areas (administration, planning), there is more interest in aggregated information (machine use per hour, ...).

There are a number of OPC specifications and products that can be used in various areas (production, administration, planning).

62.5 OPC — Advantages for Manufacturers and Users

For hardware manufacturers, for example, manufacturers of devices (PLC, barcode reader, measurement devices, embedded devices …) or PC interface boards (fieldbus interfaces, data acquisition systems, etc.), usage of OPC technology provides a number of advantages:

The product can be used by all OPC-compatible systems in the market and is not limited to an individual system for which a corresponding solution (i.e., specific drivers) must be developed. Due to the

© 2005 by CRC Press LLC

existence of standardized interfaces and the interoperability related to them, there is no need to become familiar with the specific requirements of other systems.

The Time-to-Market for new device generations is significantly reduced as only one OPC server has to be updated, not a large number of drivers.

The effort needed for support is also reduced as less products have to be supported.

Manufacturers of software applications for data acquisition, visualization, or control benefit like hardware manufacturers by a clear encapsulation of the software interface from the specific features of the accessed hardware. The product can be used with all devices and communication protocols on the market that make an OPC interface available. The manufacturer no longer has to develop corresponding solutions (specific drivers). Due to the existence of standardized interfaces and the interoperability related to them, there is no need to become familiar with the specifications of other devices and communication protocols.

The time needed for support is considerably reduced as many products to be supported (product-specific drivers up to now) no longer exist.

Using the OPC technology brings much benefit to system integrators. Their flexibility in the choice of products for their project is considerably increased. Consequently, the number of projects that can be processed increases considerably.

The time needed for integration and training is considerably reduced, as OPC provides a standardized interface that remains the same for all products.

Last but not the least, many advantages are the result for the end user by the usage and the huge distribution of OPC: OPC provides additional flexibility (distribution of components, use of new technologies, choice between products, etc.) during the design of the overall system as products of various manufacturers can be combined.

62.6 Structure and Tasks of the OPC Foundation

An important prerequisite for the success of a standardization initiative is an authority coordinating the interests of the members involved. The task of this authority is to protect the common objective from the political interests of individuals. Specification work has to be initiated and marked with clear mission statements in order to avoid a proliferation of variants and derivatives. Furthermore, public relations have to supply the market with information and support the common standard.

The OPC Foundation was founded in 1996 as an independent nonprofit organization with the aim of further developing and supporting the new OPC standard.

Besides specification development, other tasks are distributed to different offices and persons within the OPC Foundation.

The Board of Directors is the Foundation's decision-making body. It is elected once a year at the General Assembly by the members entitled to vote.

Once a year, the Board of Directors appoints the persons who safeguard the interests of the Foundation between the general meetings.

The Technical Steering Committee (TSC) establishes working groups for several target projects. It consists of representatives of the same companies as the Board of Directors plus the chairmen of the working groups of the OPC Foundation.

There are two kinds of OPC Foundation members: the OPC technology users and the OPC technology providers. The technology provider companies are further categorized as profit and nonprofit organizations. The latter do not have voting rights.

The annual membership fees for technology users and nonprofit organizations are independent of their size. The annual membership fees for the technology providers depend on their annual turnover.

In March 2003, the OPC Foundation had over 300 members worldwide, from North America, Europe, and the Far East.

The OPC Foundation has an Internet Web site. At www.opcfoundation.org, visitors can find information regarding the organization, its members, the working groups, and current events. Furthermore, visitors can download released specifications and technical reports in the form of "white papers." An electronic product catalog allows visitors to search for OPC subjects under several headings, such as

© 2005 by CRC Press LLC

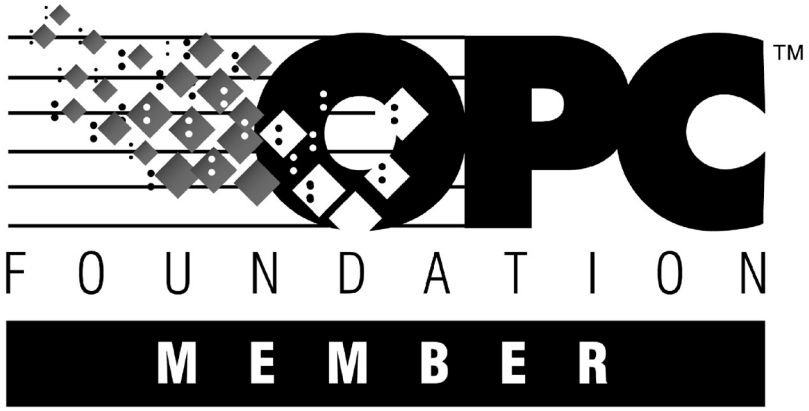

FIGURE 62.3 Logo to be used by OPC Foundation Members.

manufacturer, client, server, development tool, and training. In addition, it is possible to exchange questions and opinions in discussion forums.

From the central Web site of the OPC Foundation, the links www.opceurope.org, www.opcjapan.org, and www.opcchina.org lead to the sites of the European, Japanese, and Chinese subcommittees.

The OPC Foundation provides a membership application form on its Web site. Members of the OPC Foundation may use the logo shown in Figure 62.3 for public relation activities.

Specification work counts among the tasks of the OPC Foundation with the greatest importance. The specification process has to be clearly defined, progress has to be monitored, and the results have to be released.

First of all, the Board of Directors defines the specification issue in the form of a mission statement and appoints the chairman of the working group. The chairman addresses the member companies of the OPC Foundation and asks them to cooperate. Interested companies then appoint members. The working group meets several times and prepares the specification. Creation of a sample code, which proves the principal implementation possibility and use of the new specification, is effected in parallel. The specification and the sample code are then passed to the Technical Steering Committee for approval. If approved, the specification and code are submitted to the Board of Directors for release. Otherwise, they are returned to the working group for further processing.

62.7 Technological Basis of OPC

As it has already been mentioned, today's (and future) OPC specifications are based on two technologies — DCOM and Web Services. That is why, a short introduction into these technologies is provided, before explaining the specifications.

DCOM

The DCOM describes Microsoft's solution for the implementation of distributed, object-oriented applications in heterogeneous environments. A component object is the basic component of such applications. It has one or more interfaces providing methods that permit access to data and functionality of the object (Reading and writing of data, accessing properties, adding and deleting of objects).

One or more component objects belong to one server component providing a large number of services. To make use of these services, a client accesses methods at interfaces of the server's component objects. The individual services to be provided are described in specifications (e.g., OPC specifications). The structure of the component objects, of their interfaces, methods, and parameters is defined in an IDL file, which describes the contract between a client and server. DCOM ensures binary interoperability at runtime. A client can query at runtime whether the server supports a certain interface.

© 2005 by CRC Press LLC

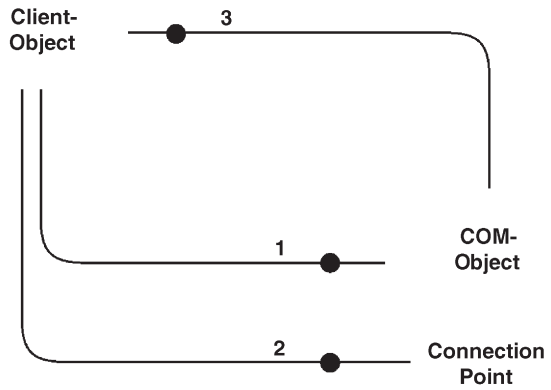

FIGURE 62.4 Creation and use of a callback connection between server and client.

A number of identifiers are used to designate server and interfaces uniquely, for example, CLSID (ClassID) and IID (InterfaceId). The life cycle of an individual component object and of the server is managed via reference counters.

DCOM permits the implementation of interactions between client and server as well as between server and client (callback). This possibility is provided by using connection points. Figure 62.4 shows the relations. The client queries the server whether it supports a specific connection point (1). In this case, the client transmits a reference to an interface on its side to the server (2). The server can later call methods at this interface (3).

62.8 XML, SOAP, and Web Services

There are a large number of products that implement DCOM-based OPC Specifications. But there are also some restrictions that have to be considered during the development and use of this kind of products.

- DCOM does not pass firewalls, that is, direct addressing of computers through the firewall is not possible. However, this is precisely what DCOM needs to perform an internal check.
- There are some devices and applications that provide or require data and that do not run on Microsoft systems. They include, for example, applications in the ERP or MDS areas as data consumers or Embedded Devices as data sources.

These restrictions have been the reason why OPC foundation has started the OPC XML-DA specification effort. This specification is no longer based on DCOM, but on a technology independent of a specific operating system. Since this specification is explained later, the relevant components of this technology will be introduced below.

The eXtensible Markup Language (XML) is a flexible data description language, which is easy to comprehend and learn. Information is exchanged by means of readable XML documents. An XML document is called well-formed if it corresponds to the XML syntax; it is called valid if, in addition, it corresponds to a default schema. The creation of XML documents and schemas as well as validation and processing of the files are supported by a variety of tools.

Today, the support of XML is guaranteed by practically all systems. Thus, even heterogeneous systems can easily interact by exchanging XML documents.

The Simple Object Access Protocol (SOAP) is an interaction protocol that links two technologies: XML and HTTP. HTTP is used as the transport protocol. The parameters of the interactions are described with XML. SOAP is thus predestined specifically for the Internet. SOAP is a protocol independent of object architectures (DCOM, CORBA). A SOAP telegram consists of a part describing the structure of the HTTP call (request/response, host, content type, and content length). This part is included in all the HTTP telegrams. A UniversalResourceIdentifier (URI) was added, which defines the end point and

© 2005 by CRC Press LLC

the method to be called. The method parameters are transferred as XML. The programmer is responsible for mapping the SOAP protocol to a concrete implementation. In the meantime, SOAP has been submitted to the World Wide Web Consortium (W3C) for standardization. In this context, the name has changed to XML protocol. Version 1.2 has been available since December 2001.

Based on the technologies introduced above, it is already possible to implement distributed applications that interact via SOAP and are independent of the operating system and the hardware. However, something is still missing: a way of describing an application's interface and of generating program components from this description that are, on the one hand, compliant with the existing infrastructure (HTTP etc.) and that, on the other, can be integrated in existing programs. This is where Web Services come into play.

The World Wide Web is used increasingly for application-to-application communication. The programmatic interfaces made available are referred to as Web Services. SOAP is used as the interaction protocol between components.

Web Services are described using XML. The language used is Web Services Description Language (WSDL), which is standardized in the W3C. An application interacting with the Web Service will deliver a valid XML message that is compliant with the schema. The function call is sent as an XML message. This also happens with the response and a possible error information. Components that support or use Web Services can be implemented on any platform supporting XML and HTTP.

The introduced technologies were not defined by individual companies or company groups, but by the W3C.

This fact is also of importance for future OPC specifications. In the past, the fact that OPC is only based on DCOM has been criticized. This point should disappear if specifications are based on XML and Web Services.

Table 62.2 shows the current status of the different specifications. Recommendation stands for agreed standard and draft stands for a standard that is still not agreed. Note stands for a rather detailed working paper.

TABLE 62.1 OPC Specifications — Contents and Release Status (Status July, 2003)

Specification	Contents	Release Status
OPC Overview [1]	General description of the application fields of OPC specifications	Release 1.00
OPC Common Definitions and Interfaces [2]	Definition of issues concerning a number of specifications	Release 1.00
OPC Data Access Specification [7]	Definition of an interface for reading and writing real-time data	Release 3.0
OPC Alarms and Events Specification[9]	Definition of an interface for monitoring events	Release 1.1
OPC Historical Data Access Specification [11]	Definition of an interface for access to historical data	Release 1.1
OPC Batch Specification [13]	Definition of an interface for access to data required for batch processing. This specification is based on the OPC Data Access Specification and extends it	Release 2.0
OPC Security Specification [15]	Definition of an interface for setting and utilization of security policies	Release 1.0
OPC XML-DA Specification [16]	Integration of OPC and XML for the building of Web applications	Release 1.0
OPC Data eXchange (DX) Specification [8]	Communication between server and server in process	Release 1.0
OPC Complex Data [17]	Definition of possibilities to describe the structure of Complex Data and of ways to access this type of data.	Release 1.0

62.9 OPC Specifications

OPC Overview [1]

As it has already been mentioned, there are several OPC specifications for different applications in automation technology. All specifications describe software interfaces. The existing specifications and their relationships are shown in Figure 62.1.

The "OPC Overview" contains general, nonnormative guidelines for OPC. It contains, for example, facts about OPC applications and OPC basic technology.

OPC Common Definitions and Interfaces Specification [2]

Before the specifications for data accessing are explained, some remarks related to the content of the OPC Common Definitions and Interfaces Specification will be made.

In the preceding part of the chapter, some information about the history of OPC was provided. The specification discussed here came into being when the Data Access Specification was being prepared together with other specifications. During this process, the OPC Foundation members realized that there are some definitions relevant to all specifications. They are summarized in this specification and comprise:

- Functionality to be provided by all servers. This includes the possibility of adapting the server to the geographical area of application (setting the language for the textual messages from the server to the client).
- The procedure of server recognition. Entries in the registry database contain information necessary for starting the server. The entries are shown in Figure 62.5 and explained below. A client will search the database to obtain this information, which is simple in the local registry, but difficult on remote computers. A component offering this functionality was specified and made available.
- The procedure of installation. There are several components (proxy/stub) used together by all servers and clients of one specification. These components must be available on the computer as long as OPC products are used.

An OPC Server is characterized by the following registry entries:

- *ProgId*: Every DCOM Server is characterized by a Program Identifier (ProgId). Rules exist regarding how to generate this Identifier. But these rules do not guarantee that this identifier is unique. Below the ProgId key, a specific key OPC exists. This entry is used to differentiate between OPC Servers and other DCOM servers.
- *CLSID*: This 128-bit-long numerical identifier uniquely describes a DCOM Server, that is, also an OPC Server. There is a way of generating this number that makes it unique. The implementers will use the generated number for exactly one server. The LocalServer32 key contains a reference to the location where the server executable can be found. The Implemented Categories keys contain information regarding which specification is implemented by a server. This is used by a client or the Server Enumerator.
- *AppId*: The Application Identifier contains more information about the server. This includes security settings. The AppId can, but must not be the same as the ClassId.

Data Access Specification [4, 5]

Data Access Servers permit transparent read and write access to any kind of values. These values can be made available by field devices and fetched via different communication systems. Also, servers permitting access to hardware and software (plug-in cards, other programs) in the PC are possible.

OPC specifications are supposed to support interoperability and plug'n'play. One prerequisite is that a client can obtain information on the available values in the server very conveniently. For this purpose, a namespace and functionality for browsing the namespace were defined. This functionality is implemented in the server and used by the client.

© 2005 by CRC Press LLC

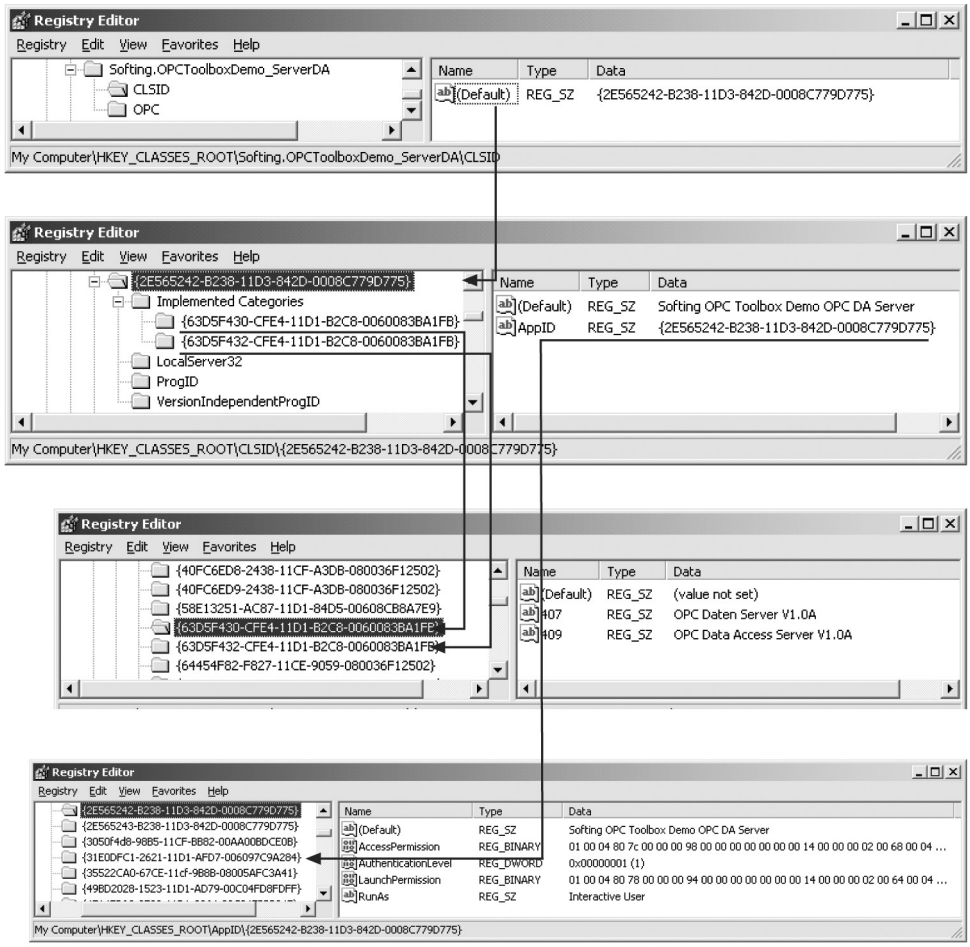

FIGURE 62.5 Registry keys for OPC Servers.

A client is not necessarily interested in all values. Different clients may want to register values under different aspects, for example, all temperature values. Therefore, the specification defines different COM objects organized in a hierarchy. By creating the specific objects, the client can adapt the server to its requirements.

Figure 62.6 shows the components that form part of a Data Access application — OPC Data Access Client and Data Access Server with namespace and object hierarchy.

A namespace can be hierarchical or flat. It can be a result of the commissioning process for the server. The specification does not define how the namespace has to be created, how many hierarchical levels the namespace may have, or how the nodes and leaves are to be designated. Only methods at an interface are defined, which enable the client to read out the information.

The namespace is identical for all clients having access to the same server. The object hierarchy, in contrast, is specific to the client. After the server is started, the client has access to an interface of the OPCServer object. It can create OPCGroup objects and, in this way, determine how access to values is structured. The value that a specific client is interested in is represented by an OPCItem object. For the OPCGroup objects, the client can have OPCItem objects created by the server, which permit access to data. OPCItem objects have no interfaces. This is due to the requirement that several values have to be efficiently read and written at the same time. The necessary functionality is available at interfaces of the OPCGroup object.

A server can also call methods at interfaces of the client. It can, for instance, inform the client of process value changes.

© 2005 by CRC Press LLC

Furthermore, methods with parameters have been specified for the various objects. Methods are grouped at interfaces.

At the OPCServer object methods for adding and removing of OPCGroup objects do exist. Other methods can be invoked by the client to store and load configuration information related to process communication (communication parameter). It is not intended to use this functionality to store the recent object hierarchy of the server. Methods for browsing the namespace are grouped at another interface of this object. The client can furthermore access state information of the server (vendor, version, and others).

The OPCGroup object provides access to methods that can be used to add and remove OPCItem objects. Different methods to read and write data are grouped at different interfaces. This also includes methods supporting the creation of callback connections. The state of the OPCGroup object can be obtained and influenced by various methods. Parameter values can be changed, which influence the data are acquired from the process.

One standardized format for exchanging data between server and client is necessary for interoperability. In automation technology, many different data types are used (IEC 61131, fieldbuses, visualization, ...). The OPC specification creates a standardized representation by defining that DCOM data types are used when values are exchanged between server and client. The data type conversion between application data types and DCOM data types by the server and the client is application-specific. The data format

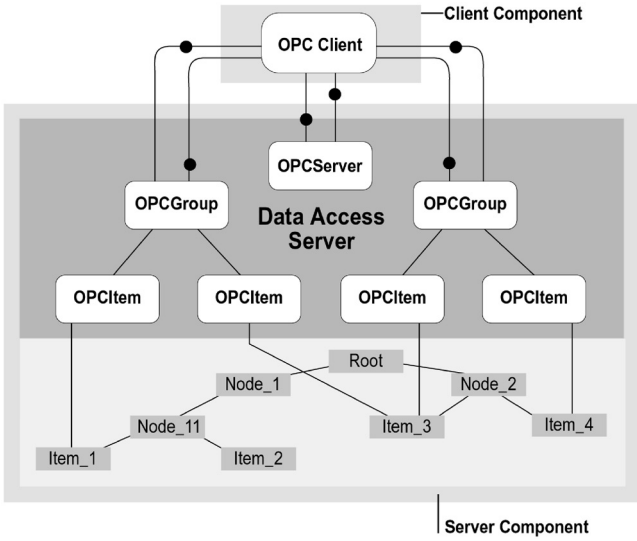

FIGURE 62.6 Components of a Data Access application.

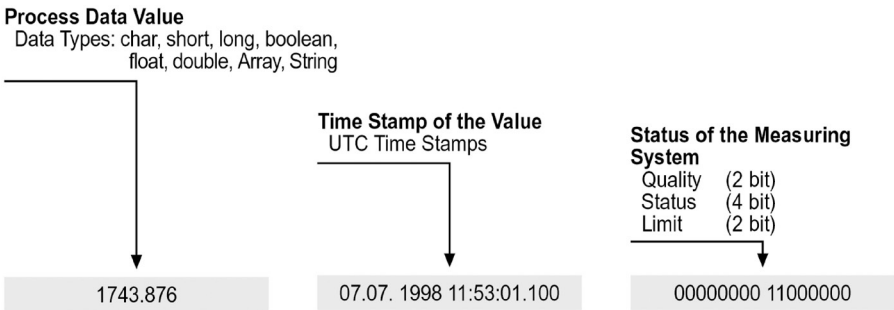

FIGURE 62.7 Data format.

© 2005 by CRC Press LLC

shown in Figure 62.7 contains in addition to the process value also a time stamp and quality information. The time stamp can be either generated in the server or, if it already exists, it can be transferred from the device. The quality information contains a description of the value validity (good/bad/uncertain). The quality is described in more detail by the status value (e.g., bad — not connected).

For the data exchange between client and server, there are a number of requirements that the specification takes into account in defining different types of data exchange.

A client is supposed to read or write values. For this purpose, it can use synchronous and asynchronous read and write requests. Reading can take place for the server cache or for the device (place where the process value is created, e.g., the device connected by a communications link). With synchronous calls, the request is processed completely before information is sent to the client. Under certain circumstances, this may not be efficient. Therefore, there is also a possibility of asynchronous reading and writing. Here, the client calls the specific method at the corresponding interface of the OPCGroup object and passes some information. The server then processes the request and provides the client with the remaining information at a later point in time.

Both types of request processing are also available for writing. However, a client can only write to the device and not to the cache.

For synchronous and asynchronous read requests, the client always has to address the corresponding OPCItem objects in the OPCGroup object. With a refresh, values of all OPCItem objects of an OPCGroup object can be requested either from the cache or from the device. Here, addressing is implicit.

In the procedures mentioned above, the client is always active — it polls for data. However, a type of data exchange where the server automatically transmits values to the client is required as well. The transmission is based on the evaluation of relevant default values. This procedure is also supported in the specification.

After this short overview about the Data Access Specification some functionality will be explained in more detail in the next paragraphs.

As already mentioned, the namespace contains all data points provided by the server. From these points, the client selects those in which it is interested and requests the server to create OPCItem objects for them. As a criterion for the assignment of points in the namespace to OPCItem objects in the server, fully qualified ItemIds are used. They normally consist of sections of the namespace that uniquely identify a data point. In a hierarchical namespace, a fully qualified ItemId will therefore contain the identifier of the leaf representing the data point as well as one or more identifiers of nodes in the namespace. The different identifiers are separated by server-specific delimiters.

The client will first query the structure of the namespace and, in the next step, identifiers for leaves and nodes. By setting method parameters, the client can influence the return values. Different values for one parameter determine whether only node identifiers or leaf identifiers as well are to be passed by the server. Another parameter contains filters. They are used as a criterion, which leaf identifiers must be passed. A limitation in terms of data type, access rights and character string is possible. The client can navigate in the namespace by indicating node identifiers and thus informing the server that this is the current view of the namespace. From a specific node, the client will finally query all identifiers for the items. In a real application, many different types of information may be relevant for clients. This concerns all values that change or are to be changed by a client. However, some rather static values are also of interest to clients (manufacturer, revision number of devices, description of measurement methods, telephone number of maintenance staff, etc.). If all this information were mapped to leaves in the namespace, the latter might become very large. Also, this information on devices and values (manufacturer, version...) might occur repeatedly. For efficient access to this information, properties were introduced with version 2.0 of the Data Access Specification.

As already mentioned, the client has access to an interface of the OPCServer object right after the server component was started. After browsing the namespace, the client will start creating a corresponding object hierarchy in the server. To do this, it can generate one or more OPCGroup objects for structuring data access. Later, the client can assign all values to be read or written with a request to OPCGroup objects (i.e., create OPCItem objects). By defining three parameter values, the client determines how values are to be acquired automatically by the server. With an update rate (in msec), the client defines at which rate values are to be read and written into the cache. The value of PercentDeadband determines the conditions under

© 2005 by CRC Press LLC

which values are automatically sent to the client. An OPCGroup object can have the state "active" or "inactive." If the latter is the case, the values of the OPCItem objects are not obtained automatically.

In the last step, the client creates the OPCItem objects for the different OPCGroup objects, which can also be "active" or "inactive." This determines whether or not they are included in automatic data acquisition.

The object hierarchy and object properties can be changed at any time.

The client is able to read data from the server by invoking synchronous or asynchronous calls. A more efficient way to obtain data from the server will be explained in the remaining part of this section.

First, the client has to create the desired object hierarchy and to build the callback connection. This is used to pass values from the server to the client. Besides the hierarchy of the object their behavior also influences the method of data exchange explained below. It works only if both OPCGroup and OPCItem objects have "Active" state.

Timeliness and sensitivity of the data access are influenced by the parameter values "UpdateRate" and "PercentDeadband" of the appropriate OPCGroup object. The "UpdateRate" (msec) value defines how often values of (active) OPCItem objects are automatically read. The "PercentDeadband" value (in%/100, e.g., 0.01) influences the sensitivity of the data exchange.

Besides changes of the value, state changes for the values are also reasons for passing data automatically from the server to the client.

A number of OPCGroup objects can be created of course at the same time, which support this way of data exchange.

The diagram in Figure 62.8 explains the automatic data exchange in detail.

The namespace was configured for the server. For different variables, the EngineeringUnit Type and EngineeringUnit information were defined. The following explanations will only be valid if "analog" is indicated as EU type and the value is of a simple data type.

The client has created an active OPCGroup object and assigned values for UpdateRate (1000 ms in the example) and PercentDeadband (0.1 in the example). Furthermore, the client has created an active OPCItem object for a temperature value. After all objects were generated and the callback connection exists, a value is immediately returned to the client via the callback connection. This value (44) is used as a reference value for the following calculations in the server. According to the given update rate, the temperature value is read from the process every 1000 ms. For each value that is read, a calculation takes place according to the following algorithm: first, the absolute difference between the values of the EU information is calculated (30 in the example). After creation of the OPCGroup object, this value is multiplied by the percent deadband (in the example, $0.1 \times 30 = 3$). For every scanning process, the absolute difference between the value last transmitted to the client and the current value is calculated and compared

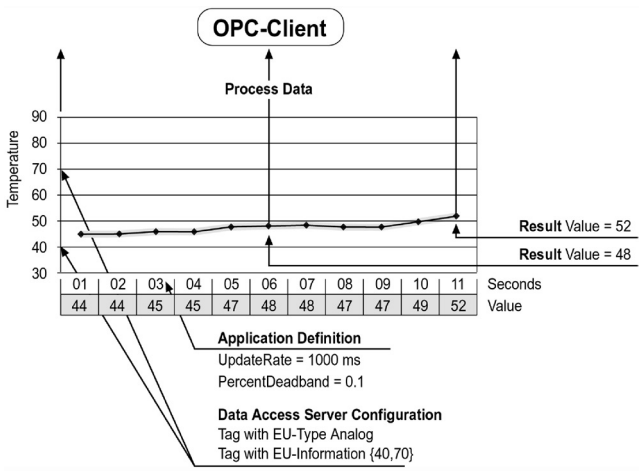

FIGURE 62.8 Automatic data exchange between server and client.

© 2005 by CRC Press LLC

with the other calculated value. If the former is larger than the latter (after 6 sec, the result for the example is 4>3), the scanned value is sent to the client and used as a new reference value.

As has already been mentioned, the procedure in this form works only for values with simple data types and EU type "analog." For other EU types (e.g., "discrete") and structured variables, the value is transferred with each change that takes place. The sensitivity of the data transmission can be influenced by the EU information for every value or by the percent deadband for all OPCItem objects of an OPCGroup object. If the criterion applies to several OPCItem objects, all values are transferred with one call.

OPC Data Access 3.0 [7]

In Version 3.0 of the Data Access Specification, some new functionality and enhancements are defined. Products implementing Data Access 3.0 have to be able to interact with products implementing Data Access 2.0 or Data Access 1.0A, of course. The server is characterized by a CategoryId (refer to chapter Common Definitions and Interfaces). That is why the client already has a hint, as to which functionality can be used.

The following specification issues are new for Data Access 3.0:

- Data can be read and written without the need to create OPCGroup and OPCItem objects. This concerns applications, where Data Access Server are used as an IO layer together with PC-based Control Systems.
- Deadband and SamplingRate can be set at OPCItem object level in addition to the settings for the OPCGroup object. This provides for a more precise setting as the way to set the value only at the OPCGroup level.
- Browser interface, with a functionality comparable to OPC XML-DA. It makes it easier to implement browsing at the client side.
- Connection monitoring functionality has been added to the specification.

OPC XML-DA [16]

The use in the Internet is a case of application for OPC XML-DA products. Therefore, the following conditions had to be taken into account when the specification was written:

- The interaction parameters are coded using XML, which leads to an overhead.
- Interactions take place by HTTP, which is a stateless protocol. Due to the desired scalability of the servers and the line costs, interactions in the Web mainly take place on a short-term basis. A client fetches information from the server; after this, the server "forgets" about the client. Some solutions implement state but this is a specific approach.

Therefore, the Data Access Specification model with an object hierarchy for each client and with callbacks cannot be applied to a Web Service.

An OPC XML-DA Service is stateless. There is no functionality for the creation of objects as defined in the Data Access Specification.

During browsing as well, no information about the position of the client in the namespace is stored in the OPC XML-DA Service, but all information about the namespace (or a defined part of it) is transferred to the client at the same time. The client can poll for values at the server, but it should also be possible, to receive changed values automatically.

Nevertheless, the definition of subscriptions does provide the service with state information. The service must know which data the client is interested in, at what rate they have to be recorded (UpdateRate) and when they have to be transferred (deadband). Since, however, a server cannot call the client on its own initiative with HTTP (it does not know about the client), the specification defines a query of the subscription values, which is initiated by the client. If nothing has changed, the client will not receive any values.

Another important point is monitoring of the connection between client and server and, in case of a subscription, monitoring of the client's availability. Therefore, most function calls contain time values

© 2005 by CRC Press LLC

indicating the maximum time that the client will wait for a response from the server or the minimum number of times it will call the server (subscription).

Table 62.3 contains the defined methods.

How does the subscription work in OPC XML-DA?

The sequence of function calls is shown in Figure 62.9 and explained below.

To set up a subscription, the client sends a request indicating the variables it is interested in as well as the values for RequestedSamplingRate and Deadband. These two values can be defined both for a number of variables or single variables in one call. The SubscriptionPingRate defines with what frequency the service is supposed to check whether the client still exists.

The service responds with a subscribe response that contains the handle for the callback and the supported SubscriptionPingRate. Based on RequestedSamplingRate, the server acquires the values and decides based on Deadband regarding whether to send it to the client or not.

By sending a SubscriptionPolledRefreshRequest message to the server, the client requests for the data for a subscription. It receives the data with SubscriptionPolledRefreshResponse. In the request, the client can tell the service how long it will wait for the response and, in this way, determine how long the connection will remain open. The server will delay the sending of the response accordingly. The service will at least wait the Holdtime to send the SubscriptionPolledRefreshResponse to the client. It will continue to acquire data if no data have changed for another period — the WaitTime. If a value has changed, the service will immediately send the SubscriptionPolledRefreshResponse. If WaitTime also expires and

TABLE 62.3 Methods of the OPC XML-DA Specification

GetStatus/GetStatusResponse	Client obtains server status
Browse/ BrowseResponse	Client obtains name space information
GetProperties/GetPropertiesResponse	Client obtains property information
ReadRequest/ ReadResponse	Client reads data
WriteRequest/ WriteResponse	Client writes data
Subscribe (Client)/ SubscribeResponse (Server)	Client establishes subscription
SubscriptionCancel/Response	Client cancels subscription
SubscriptionPolledRefresh(Client)/ SubscriptionPolledRefreshResponse(Server)	Client initiates requests for the values that are provided in the subscription

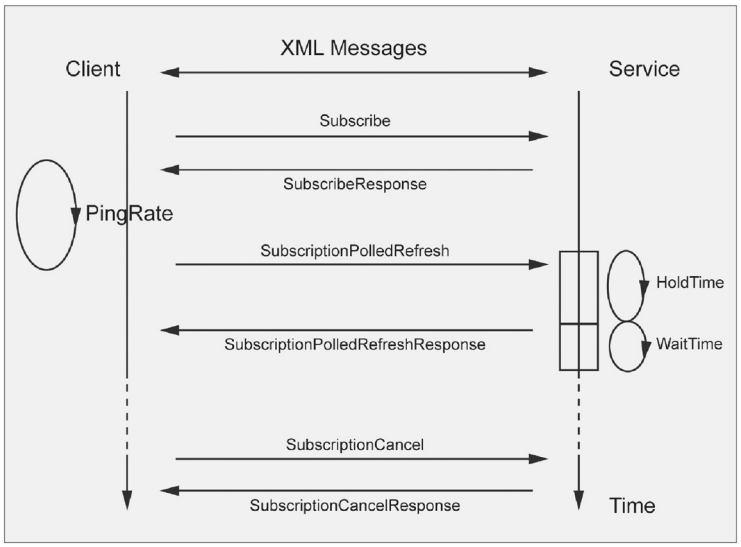

FIGURE 62.9 Subscription based on OPC XML-DA specification issues.

© 2005 by CRC Press LLC

nothing has changed, the service will send an "empty" SubscriptionPolledRefreshResponse, that is, a message without data.

The client will cancel a subscription by passing a SubscriptionCancelRequest message. The service responds with SubscriptionCancelResponse message.

OPC Data eXchange Specification [8]

Why do we need the OPC DX Specification?

As already mentioned, OPC has a huge installed base. There are cases when OPC Servers have to directly interchange data, for example, if information must be transferred from one area of production to another area. Currently, transferring data between servers is only possible using clients or proprietary bridges, which slows down the exchange and excludes overall solutions.

There are a number of fieldbus systems that use TCP/IP on Ethernet as their transport and network protocol. All of them use the same medium, but cannot directly intercommunicate. Here also, OPC DX is supposed to offer a solution.

Figure 62.10 shows the structure of an OPC DX application. A DX Server can receive data from one (or more) DA Server(s) or from one (or more) DX Server(s). For this purpose, a DX Server has implemented DA Client functionality. By means of this client, the DX Server creates OPCGroup and OPCItem objects. The data point from which the data are recorded is called Sourceitem; the data point where they are written is called Targetitem. This linkage and their property are called "connection." All connections taken together are called "configuration." Connections are defined by a configuration client and mapped in the namespace of the DX Server. A monitoring client monitors the connections. Data Access functionality is used for this purpose. Other clients (visualization) can access the existing items in a "normal" way.

The specification distinguishes between the configuration model and the run-time model.

The configuration model defines the semantics of the connections as well as possibilities of creating, deleting, and changing connections and transferring events.

The run-time model defines the data transfer between DX and DA/DX Servers. Here, the manner in which the data are recorded as well as error and status monitoring are important.

The information on connections is stored in a defined branch of the namespace The attributes of a connection and, consequently, the structure of this branch are specified. A Data Access Client is able to browse the name space and create OPCItem objects for values of interest. A DX server therefore also implements Data Access Server functionality besides Data Access client functionality.

Connections are created, modified, and deleted by different commands issued by a configuration client.

The specification not only defines the configuration but also the behavior of a DX Server at runtime, that is, during horizontal data exchange.

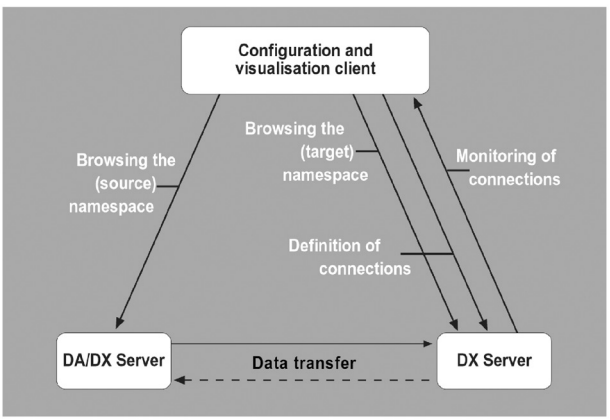

FIGURE 62.10 Structure of an OPC DX application.

© 2005 by CRC Press LLC

The DX Server can subscribe to values from a Data Access Server that supports the specification versions 2.04, 2.05, and 3.0. Another possibility is for the DX Server to support the OPC XML-DA Specification and to receive data from OPC XML-DA Servers.

The target item and the source item can have different data types. During creation of the OPCItem object, the DX Server can request the DA/DX Server to perform the conversion. If this is not supported, the DX Server must perform the conversion itself.

The specification also defines the run-time behavior of a DX Server if the connection to the source server is interrupted. In this case, the DX Server tries to reestablish the connection with the frequency of a ping rate, which can be set as desired. If this is not possible, this information is mapped to the corresponding attributes of the target item. Depending on the properties of the connection, the DX Server can set a substitute value instead of the actual value.

A monitoring client can sign up for the corresponding items in the configuration branch of the namespace and thus obtain information on the state of the connections.

The DX Server stores the entire current configuration at runtime. This means that all results of the calls for adding, modifying, and deleting connections are stored. The specification does not define how and where this is done. During starting of the DX Server, the current configuration is reloaded and available again.

Complex Data Specification [17]

The Data Access Server supports access to simple and complex data. A temperature value is an example of simple data, whereas records of diagnostic information serve as examples of complex data. Both data types (simple and complex) can be read or written in OPC Data Access applications. Yet, the existing OPC specifications do not define the means for a client and a server to exchange structural information about complex data. Therefore, the client can only pass complex data as octet strings to other applications (e.g., database and visualization applications).

The following behavior is requested:

- The client understands the structure of the data. In this case, the client may forward individual elements of the complex data item to other applications.
- The client understands the structure of the data and knows its semantics. In this case, the client is not only able to distinguish between elements but also knows about their type and relations with each other.

The description of complex data type is a prerequisite for this behavior.

The new specification proposes two approaches for the description of complex data:

- type descriptions defined within OPC specifications and
- type descriptions defined outside OPC specifications (e.g., Fieldbus organizations)

OPC-type descriptions are concerned with the definition of the structure of complex data. This allows the client to know the elements of complex data items. The type description is effected using XML. This description system is not very flexible, but it provides for easy implementation.

The type description systems of other organizations can also contain semantic definitions and allow a client to know the semantics. These descriptions can be more flexible but they increase the requirements for implementation, as client and server should be able to understand a number of type description systems.

The new specification defines that information on and about complex data items must be provided using defined properties. Table 62.4 shows the defined properties and their meanings.

Only items with complex data types must support these properties.

Besides the possibility of describing complex data types, the new specification also defines the behavior during writing of complex data.

© 2005 by CRC Press LLC

TABLE 62.4 Properties Used to Describe Complex Data

PropertyId	Name	Meaning
109	Complex Data Type Description System	Identifies the type description system used (e.g., OPC, Fieldbus Consortium)
110	Complex Data Type Description ID	Identifies the type description of a complex data item (e.g., reference to an XML file, reference number related to a type description system of consortia)
111	Complex Data Type Description Version	Identifies the version of the type description
112	Complex Data Type Description	A BLOB that contains the information necessary for clients to interpret the value of the complex data item

Not all elements of the complex data item, once written, may be writable. In this case, the client supplies the entire buffer in a write request and the server ignores the values of nonwritable elements.

In a case where the value for one or more writable elements is invalid, or cannot be applied, the server rejects the entire write request.

OPC Alarms and Events [9]

By implementing Data Access Specification definitions, values can be automatically transmitted from the server to the client if these values have changed within a certain time period or if the values' states have changed. This is not sufficient or not efficient regarding the following requirements:

- It is not only important to be informed about changes of the value, it is also important to be informed that a parameter has exceeded a certain limit.
- The value changes sometimes during the UpdateRate.
- Alarms have to be acknowledged.

The Alarms and Events specification has been written to fulfill these (and other) requirements. The next chapter explains the model specification issues and their practical use.

The specification model differentiates between things that happen (simple events and tracking-related events) and things that exist (condition-related events, i.e., alarms).

The occurrence of an alarm can be acknowledged. An object hierarchy has been defined, where a client can adapt the server to its requirements.

The client normally will not be interested in all events that can be monitored by a server. It can select the interesting events by applying filter. The filter consists of parts from the event area and the filter space. The event area provides a topological structuring of events. The filter space provides event structuring based on event attributes (event type, event category, event severity, ...). Both can be configured during adapting the server to the real environment.

Figure 62.11 shows the components that are part of an Alarms and Events application — OPC Alarms and Events Client and Server. Events can be structured in an event area that is always hierarchical. In the server itself, different DCOM objects with interfaces and methods must be implemented. After launching the server, the client has access to an interface of the OPCEventServer object. Then, the client can either create the OPCEventAreaBrowser object to obtain information on the content of the event area, or it can create OPCEventSubscription objects. These objects are used to monitor event sources and, in case of events, transmit relevant messages to the client. Events are assigned to the OPCEventSubscription objects via filters.

This specification also permits both directions of interaction (client → server and server → client).

Filters are used for assigning events to OPCEventSubscription objects. In this way, a client determines which events are to be monitored by the server. Values of filter parameters are derived from information that concerns the event area (fully qualified AreaId, fully qualified SourceId) or properties of events (type, category...).

© 2005 by CRC Press LLC

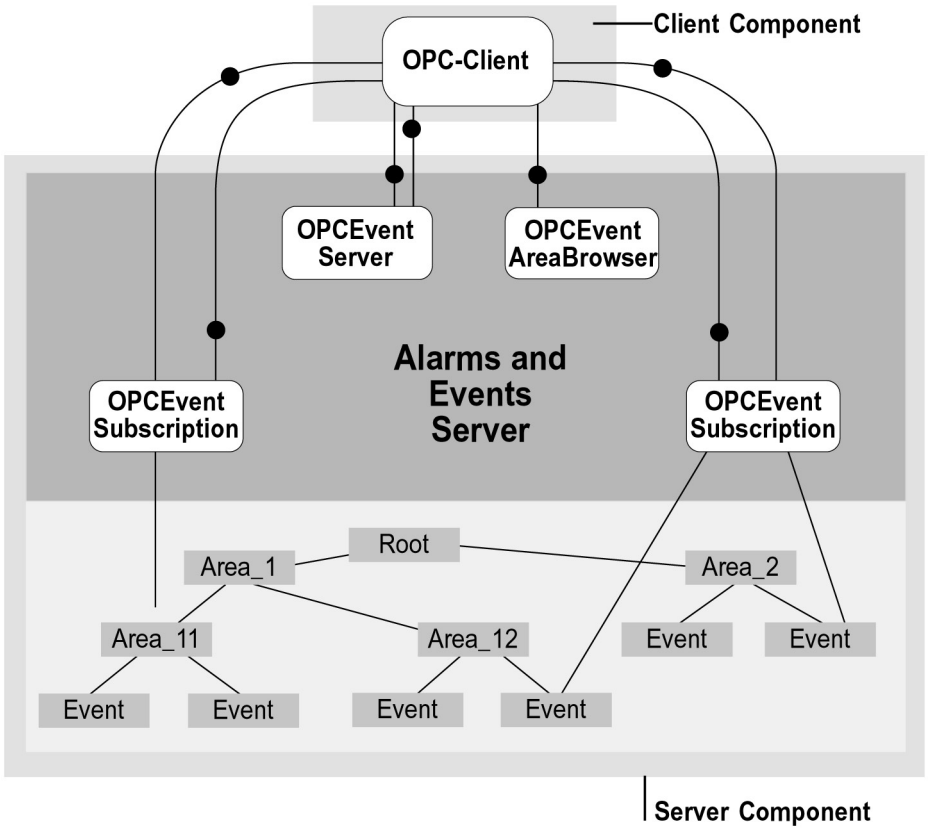

FIGURE 62.11 Components of an Alarms and Events application.

There are three types of events already defined in the specification. An example of a simple event would be a device failure, and that of a tracking-related event, the changing of a setpoint. An example of a condition-related event would be a positive or negative deviation from temperature limit values. For all these three types, there are different categories. The specification proposes only some settings for this value. More categories can be defined based on real application scenarios. For condition-related events, the different categories have conditions and subconditions. The specification already contains some proposals for categories, conditions, and subconditions. Events also have a priority. If necessary, application-specific priorities must be converted into OPC priorities.

A large variety of filters can be defined, for example, <type=condition-related events, category=level, priority=500–700, area=area_1, and source=source_A>.

In case of event occurrence, the server sends an event notification to the client, which has assigned the event to an OPCEventSubscription object via a filter. Depending on the type of event, the notification can have different numbers of parameters. Figure 62.12 shows the mandatory parameters for the various event types. Examples in the figure are related to an event notification informing the client about the occurrence of a condition-related event.

During the notification about a simple event, values for the parameters Source (information from the event space), Time (when did the event occur?), Type, Event Category, Severity, and Message are transferred. The language of the message can be set by means of a method at the general interface mentioned in Part "Common Interfaces and Definitions."

For notification about a tracking-related event, there is the additional parameter ActorId. It contains a numerical identifier to indicate the cause of the event. The creation of the identifier and the meaning of the value are not described in the specification.

© 2005 by CRC Press LLC

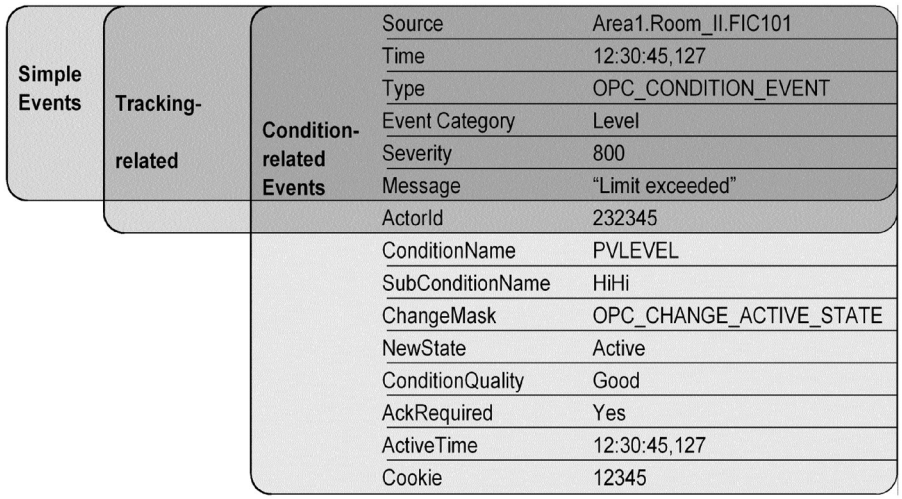

FIGURE 62.12 Structure of an event notification.

The largest number of parameters must be transferred for notification about a condition-related event. The following parameters are added to the ones already mentioned:

- *ConditionName*: Name of the condition from the event area.
- *SubConditionName*: Name of the subcondition, if any.
- *ChangeMask*: Indicates in what way the state of the condition has changed, for example, inactive → active.
- *State*: State of the condition, for example, active, acknowledged, ….
- *ConditionQuality*: The parameter can be compared with the quality of a value from the Data Access Specification. A notification is also sent if the state changes.
- *AckRequired*: The event must be acknowledged.
- *ActiveTime*: Indicates the time at which the state became active. This value is not identical to "Time" since the latter indicates the time of event occurrence. The receipt of an acknowledgment also leads to an event. After the receipt, the values of the parameters differ.
- *Cookie*: Used by the client in the acknowledge and by the server to relate the acknowledge to the event.

There may be other attributes in addition to these mandatory ones. They have to be supported for all events of a category, that is, they are defined for a category.

OPC Historical Data Access [11]

The Historical Data Access Specification defines an API to access historical data. Historical data have been collected over some time frame and is now available. The specification does not define how the data are collected and stored. The recent specification only considers parameter values; access to stored event information is not specified.

Accessing data by using Data Access clients and storing it in a database could be one way to collect data later accessible for Historical Data Access Server. Other possibilities could include other ways of accessing data. Another use of case of interest would be access to data that has been stored over some time in a measuring device and is accessed only once a week, for example, environmental parameter. Figure 62.13 shows the object hierarchy and the relation to the namespace.

Different from Data Access Server, Historical data Access Server will provide access to larger amounts of data. This is caused by the larger number of variables (all variables in a process) and by the amount of

© 2005 by CRC Press LLC

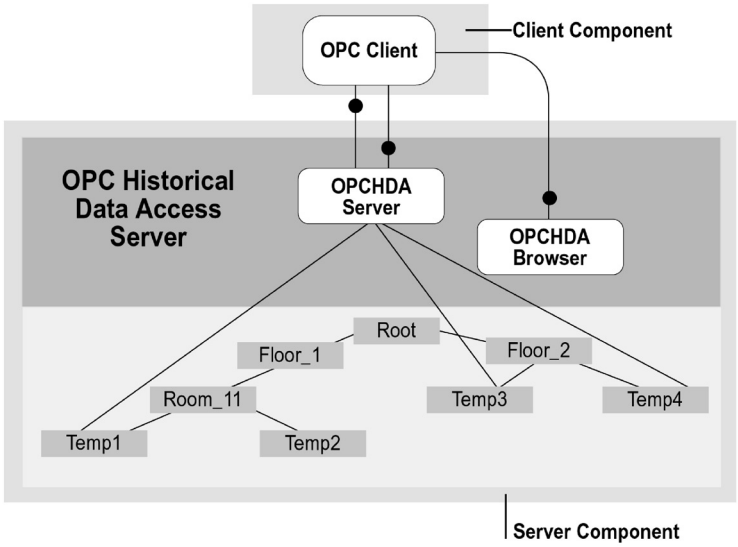

FIGURE 62.13 Components of an HDA application.

values per variable. Stored values do not change. But they can be deleted and new values or attributes can be added. Different from Data Access Server, the access to aggregated values plays an important role (average over a time frame, smallest value over a time frame, ...).

Only two DCOM objects were specified for the server. Immediately after launching of the component, the client has access to the OPCHDAServer object where the entire functionality is available. The OPCHDABrowser object is used for searching the namespace of an HDA Server. This namespace contains all data points for which values are available. Other than with the Data Access Server, there is no explicit object for the access to data points; this is not necessary since access takes place very rarely. For the client, methods for synchronous and asynchronous reading, recording, and changing entries in the database of historical data are available.

The tables in Figure 62.14 show a few aggregates and attributes for stored raw data. For both parameters, the specification already contains default values. The server manufacturer can also provide other possibilities.

An HDA Client can use four different ways to access historical data:

- *Read*: Using this approach, the client can read raw values, processed values, values at a specific point in time (AtTime), modified values, or value attributes. The client can invoke synchronous or asynchronous calls.
- *Update*: The client can insert, replace, or insert and replace values. This can be done for a time frame or for specific values. Synchronous and asynchronous calls are also available.
- *Annotation*: The client can read and insert annotations. Again, this can be performed synchronously and asynchronously.
- *Playback*: The client can request the server to send values with a defined frequency for a defined time frame (every 15 sec values stored over 15 min). This can be applied both for raw and aggregated data.

OPC Batch [13]

The OPC Batch Specification defines an interface between clients and servers for a certain type of application called batch processing. With this procedure, recipes are processed by resources and reports are generated. Functionality that is made available by Data Access Specification is required. For batch

FIGURE 62.14 Relations between Raw Data, Attributes, and Aggregated Data.

processing, there is the international standard IEC 61512-1 defining a model for this kind of data exchange. Many products in this area have been implemented accordingly. Therefore, the idea was to combine the existing functionality of the Data Access Servers with the specifications in this standard. The consequence was an extension of the Data Access Specification, which defines a special namespace and some additional methods adapted optimally to the conditions during batch processing.

Figure 62.15 shows a part of the namespace that is specific to a server used in batch processing. The namespace is defined to be always hierarchical. Specific nodes exist on the highest hierarchy level (OPCBPhysicalModel, OPCBBatchModel and OPCBBatchList). These nodes represent models of IEC 61512-1. Batches contain parameters and results. For each batch, there are corresponding OPCBParameters and OPCBResults nodes. The parameters and results are represented by specific properties.

OPC Security [15]

OPC Clients and Server can run on different PCs. Security aspects have to be considered in such applications. Security settings can be applied in two different ways:

- by using the utility program "dcomcnfg" and/or
- by using the security API functionality of the operating system.

By using "dcomcnfg," security settings are applied to the components, that is, the server or to the overall system. If smaller granularity is necessary (settings for objects, methods, data, ...), the security API must be used. It is the goal of the Security specification to foster interoperability between security-aware applications, that is, applications that use the security API.

The Security Specification defines a model for security, different levels of security, and possibilities of how the client and the server can exchange security information.

© 2005 by CRC Press LLC

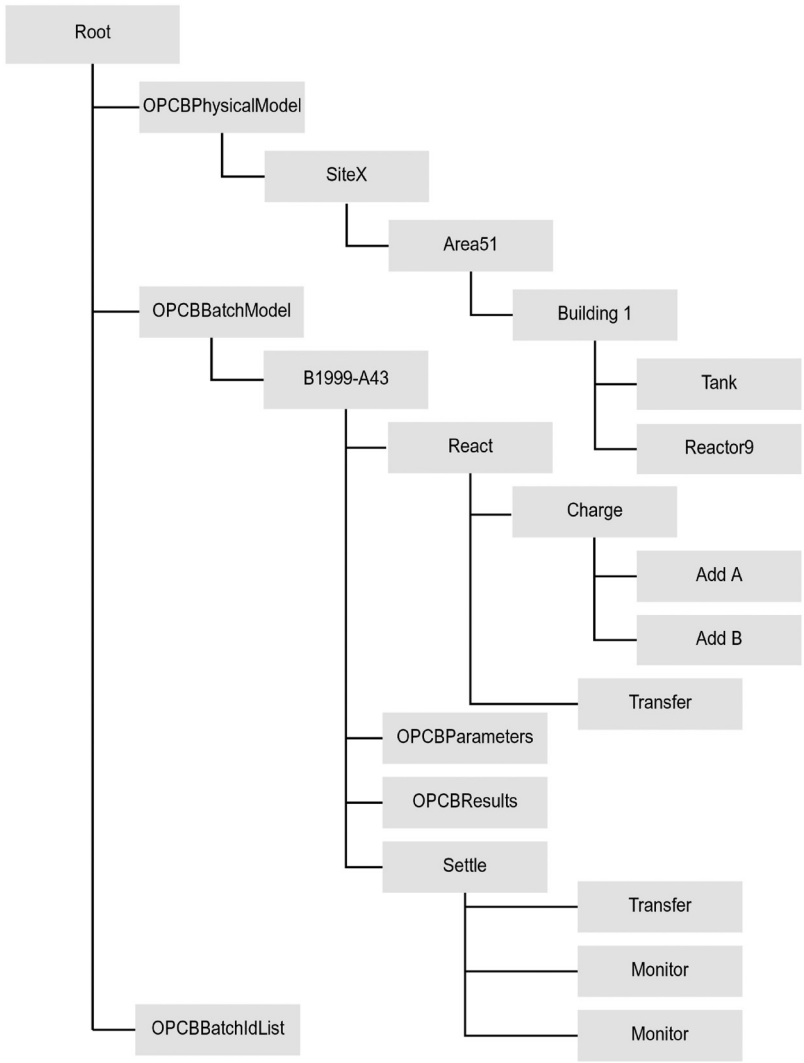

FIGURE 62.15 OPC Batch Server — part of a namespace.

The specification does not define which objects are to be secured and how.

Figure 62.16 shows the Windows NT/2000 security model on which the specification is based.

The model differentiates between principals described by access certificates and security objects. All processes in Windows NT/2000 are principals. If a user logs in, a process is started. Depending on which group a user belongs to (administrators, guests, etc.) and on the corresponding access rights, an access certificate is assigned to the process. This is a kind of "ticket" describing the properties of the principal. On the other hand, there are security objects. These are objects to which access is monitored. If a principal tries to access a security object, the reference monitor decides, using the access control list, whether the principal may do that. If "Dcomcnfg" is used, the ACL is edited by means of this tool, and the reference monitor is part of the DCOM run-time environment. If COM Security API methods are used, the reference monitor and creation of the ACL must be implemented as parts of the server. In this case, security objects of any granularity can be implemented.

© 2005 by CRC Press LLC

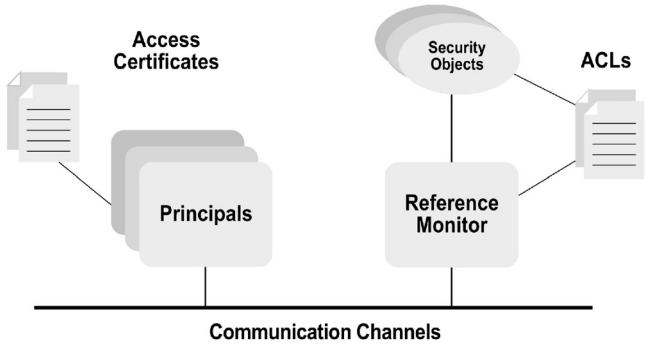

FIGURE 62.16 Windows Security model.

Furthermore, a differentiation is made in the specification regarding the way to characterize principals. Security decisions can be based on access certificates for NT user (NT Access Token) or specific OPC user. NT users are already known in the system. For each of these different certificates, one interface has been specified.

Compliance Test

The OPC Foundation defines compliance testing as a way to verify whether a server implementation conforms to the specification. There are no test tools to check clients!

Compliance testing is based on the following prerequisites:

- *Test cases*: A huge number of test cases have been defined, by generating a number of different parameter values for the method calls. These parameter values can be used to verify the server's behavior in response to valid, invalid, and impossible method calls. Default and extreme values have been defined for the various parameter.
- *Test system*: A Compliance Test Client has been developed by the OPC Foundation.
- Test procedure: During running the Compliance Test Client against a server, test result files are generated. These have to be submitted to the OPC Foundation. It will derive the result. The information is added to a page on the OPC Foundation Web site.

The Compliance Test Client supports the following test possibilities:

- *Stress tests*: Here, it can be determined that a selectable number of objects can be added and removed in the server component to be tested.
- *Logical tests*: Here, it is tested whether the Proxy/Stub-DLLs are installed correctly.
- *Interface tests*: Here, methods are tested at the interfaces of the objects. Valid, invalid, and meaningless parameter values are used for all the methods.

Configuration of the Compliance Test Client has to be carried out prior to starting the test run.

Now, the test run can be started. The results of the proceeded test cases are displayed. If test cases have not been passed successfully, the implementation of the server has to be changed. At the end of the test, after passing all test cases successful, a binary result file will be generated by the test client. This file must be sent to the OPC Foundation. The result is then published on the OPC Foundation Web site. Figure 62.17 shows an example.

Table 62.5 shows the current availability of compliance tests for the different specifications.

XML-DA	Test Specification Release Candidate

62.10 Implementation of OPC Products

With the release of the OPC XML-DA and OPC DX Specifications, not only the implementation of DCOM based Client and Servers have to be considered, it also becomes important to think about implementation based on Web Services.

There are some major differences between these two approaches:

- DCOM is available mainly on Microsoft systems. Portation exists for Unix systems, but only a few OPC products for this area are available.
- OPC XML-DA products can be easily made available everywhere where HTTP and XML are supported. Even if XML support does not exist, products can be implemented. Coding and decoding of XML messages can be implemented without a parser.

In the following paragraphs, first implementation of DCOM-based OPC products is considered and then Web Service-based solutions are considered.

© 2005 by CRC Press LLC

OPC DCOM Server Implementation

OPC Servers can be implemented in three types:

- *InProc Servers*: The server is implemented as a DLL and runs in the process space of the client. In this manner, high-speed data access is possible since no process or computer boundaries have to be overcome. There will only be restrictions if the server needs to access a protected kernel resource.
- *OutProc Servers*: The server is implemented as a stand-alone executable. It can run on the same computer as the client or on a different one. The advantage is that several clients have access if protected resources are used. Since there are process and maybe even computer boundaries between client and server, data traffic is slower than with the InProc solution.
- *Service*: This is a special kind of OutProc Server. Services can be configured in such a way that they are immediately started during booting without the necessity of user log-in. Thus, the initialization of communications links is shifted to the booting process of the computer. The advantage of this solution is that the server is available immediately after booting. The disadvantage is that services are only available for Windows NT/2000/XP. On other operating systems (Windows 98/ME), they run as a "normal" OutProc server.

OPC DCOM Client Implementation

An OPC Client must provide functionality in two phases of the life cycle of an automation system (during commissioning/configuration and on-line operation). It must be possible to:

- Find and start available OPC Servers during the configuration phase. The namespace/eventspace of the servers must be browsed to obtain fully qualified item identifier necessary to add OPCItem objects and to receive filter criteria. The same is true for properties. ValidateItem checks whether the passed parameters would result in a valid OPCItem object. To accomplish this, OPCGroup objects must also be able to be added. The client must query for supported filter criteria. The result of the configuration process can be stored somewhere. Access to other methods also needs to be implemented.
- At runtime, the OPC Client requests that all objects have to be created in the OPC Server. The OPC Client supplies the application with the requested data and monitors communication. During data exchange, it must also be possible to start additional Servers, add and manipulate OPCGroup/OPCEventSubscription objects, as well as add and manipulate OPCItem objects.

Creating OPC DCOM Components by Means of Tools

As far as DCOM knowledge is seen as core competence, the development of OPC clients and servers can be done by means of different developing environments. Detailed knowledge of DCOM and the OPC specifications is necessary for this.

A simpler way to create OPC components is to use toolkits. Toolkits encapsulate the DCOM and OPC functionality. They exchange information through an API with an application using the toolkits. Toolkits are available for client and server components. Most toolkits support Windows 9X/NT/2000/XP. Versions for Windows CE and Linux also exist.

The toolkits can be distinguished by their possibilities of optimization. There are compact solutions intended for a simple server type and more complex toolkits that permit extremely flexible solutions.

Characteristic of complex toolkits is that they can be combined with each other resp. are based on each other. With the OPC Toolbox shown in Figure 62.18 components can be developed that contain both Data Access and Alarms and Events functionality, which can be used on standard Windows operating systems but also on Windows CE.

© 2005 by CRC Press LLC

FIGURE 62.18 OPC Toolkit sample.

There are toolkits for different use cases that are performed as a C++ class library, so-called C++ toolkits and those that provide a more or less complete OPC component in which only some few function calls must be integrated. ActiveX Controls is a special kind of OPC client implementation: the complete OPC Client functionality is provided as OPC Client Controls and can be used in Visual Basic, Excel, or other ActiveX container applications without any programming.

Implementation of OPC XML Servers and Clients

Three approaches can be distinguished for the implementation. They are described below.

- Starting from scratch — the most demanding approach.
  This approach mainly has to be used for impl ementing OPC products on embedded devices. If HTTP and XML support is available, the infrastructure components for receiving and sending of SOAP telegrams and coding of XML messages have to be implemented. These components must be combined with the remaining parts of the client and server application. If this is not available, the necessary parts have to be ported. There are a number of solutions available in the public domain.
- Using toolkits supporting WSDL.
  Toolkits exist in the market that generate the necessary infrastructure components and templates to integrate with parts of client and server application based on the WSDL file.
- Using OPC toolkits — the easiest approach.
  These toolkits not only implement infrastructure components but also internal logic of client and server application.

62.11 Outlook into Future

The huge acceptance and fast penetration of the OPC technology in many areas of automation technology are unique. Many standards, for example, fieldbuses in industrial communication or in the area of PLC programming have established in one decade or more or not at all. OPC has been much more successful. With the defined specifications, multiple areas of application from fast and equidistant data trans-

© 2005 by CRC Press LLC

fer (Data Access) via processing of large amounts of historical data (Historical Data Access) up to the collection and acknowledgement of volatile and critical events (Alarms and Events) can be covered.

The availability of Data eXchange and OPC XML-DA opens up further areas of application in vertical integration and peer-to-peer interaction. On the basis of the specifications, clients and servers can run in the same process on one PC (InProc Server) or in different processes (OutProc Server) on PCs that can be close together or far apart. One or several clients can access a server. A client, in turn, can communicate with one or more servers. With the availability of Web Services-based products, OPC can be used in Embedded Devices or any other kind of devices supporting this technology.

There are a variety of products that translate the OPC specifications into reality. The scope ranges from sample clients and servers to tools for creating OPC components and servers for a wide variety of communication systems and devices. A multitude of visualization systems, systems for data acquisition, and diagnosis have been equipped with OPC Client interfaces. These products are used in a vast number of actual applications. A large variety of programming languages and development environments are available for the creation of OPC components. OPC products can be used on a wide range of hardware and software platforms.

Solutions for the compliance test are available. The use of successfully tested products raises the confidence of end users in product quality and interoperability.

A nonprofit organization, the OPC Foundation is in charge of marketing and developing the technology.

These points characterize the current actual state described in this handbook. One question still remains to be answered — what does OPC's future look like?

62.12 The Future of OPC

There are two issues that drive the future of OPC:

- OPC XML-DA is available. The market will request to also provide other specifications on this technological basis, for example, OPC XML-AE.
- The market will request for migration paths between technologies and solutions.

Microsoft pushes .NET. More and more potential OPC client providers will go this way. A request for an interoperable .NET interface for accessing the legacy DCOM OPC server arises. OPC XML-DA servers and

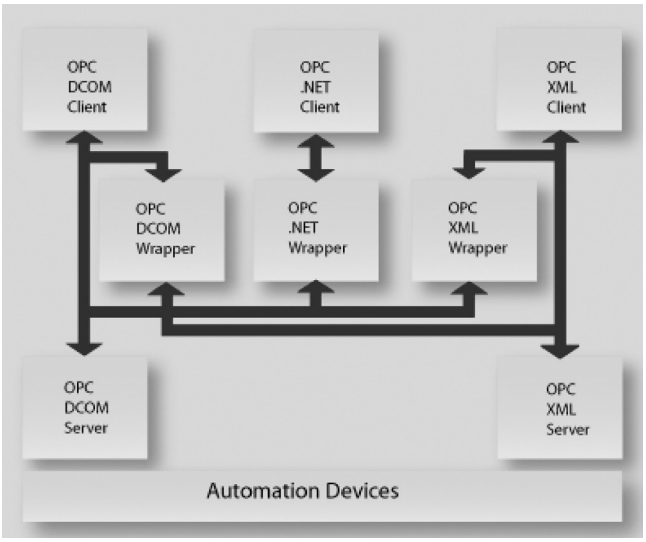

FIGURE 62.19 Migration paths for technologies and specifications.

© 2005 by CRC Press LLC

clients on different platforms will be available in the future. Legacy DCOM clients and servers should be used in mixed applications. Wrappers between these components are necessary. Figure 62.19 shows the different constellations and the necessary wrapper. The OPC Foundation provides a skeleton for a .NET to DCOM wrapper. It implements the DCOM object view and makes it accessible from .NET languages. Wrapper between DCOM and Web Services and vice versa will be provided by different vendors.

It can be foreseen that many more OPC products will be developed in the future and the success story of OPC will continue.

63.1 Introduction New Programming Paradigms in Industrial Automation

Industrial automation is currently characterized by a number of trends induced by the current market situation. The main trends are the pursuit of high flexibility, good scalability, and high robustness of automation systems, the integration of new technologies, and the harmonization of used technologies in all fields and levels of automation. Of special interest is the integration of technologies, which were originally developed for the office-world into the control area. This trend is characterized by the emergence of industrial PCs, operating systems for embedded devices like WindowsCE, embedded Linux, and RTLinux, data presentation technologies like XML, and communication technologies like Ethernet and Internet technologies.

In this context, object-oriented languages like Java have gained importance. Particularly Java, which has evolved with the Internet and related technologies, fits very well in different areas of industrial automation.

In the following sections, the boundary conditions, advantages, and problems of using Java in the area of industrial automation will be described in more detail. A special focus will be on the lower levels of the automation pyramid, where real-time requirements are of significance.

© 2005 by CRC Press LLC

63.2 Requirements in Automation and Typical Application Areas of Java

Java can be characterized as a high-level, consequently object-oriented programming language with a strong type-system. One important feature is the idea of a Virtual Machine abstracting the concrete underlying hardware by translating Java programs to an intermediate language called Bytecode, which is executed on the Java Virtual Machine (JVM). Thereby, the concept "Write Once, Run Anywhere" (WORA) is realized, enabling a platform-independent application design. This means that Java applications are (of course, under consideration of different Java versions and editions) executable on every platform, which can run a JVM. Together with typical concepts of object-orientation, like encapsulation of functionalities in classes, inheritance, and polymorphism, Java opens many possibilities for a reusability of the code. Java also provides high stability of applications. This is realized by extensive checks (e.g., regarding type or array boundaries) during compile-, load- and runtime. Due to the fact that error-prone concepts like direct pointer manipulations are beyond the scope of the language and memory allocation (and deallocation) is realized by an automatic memory management, the so-called Garbage Collection (GC), the efficiency of software development with Java is very high. Although it is not easy to specify this in figures, some sources state at least 20% improvement compared to C/C++ [9]. In contrast to the most used PLC programming languages specified in the IEC 61131, the efficiency increases by more than 50%. The extensive, easy-to-use networking abilities of Java can help to reduce the difficulty of programming distributed systems.

Besides general advantages, the typical potential application areas for Java in industrial automation and their specific requirements have to be considered. On the upper levels of the automation pyramid (ERP and SCADA/MES-Systems), Java is already used as one alternative. The requirements in this area are very similar to typical IT-applications and characterized by powerful hardware. Here, Java2SE (Standard Edition) and Java2EE (Enterprise Edition) with a wide variety of APIs supporting different technologies for communication, visualization, and database access are the proper Java platforms. Examples for Java applications can mainly be found for different interface realizations of ERPs and the implementation of advanced technologies on the MES level [11].

At the field device level, Java is still not a very common language as the requirements here are a problematic issue for standard Java versions. Many features of Java, normally responsible for typical advantages, cause problems at the field device level. The hardware on this level is very heterogeneous and most devices have only limited resources with respect to memory and computing power. For communication purposes, several different field bus protocols are used, although the increasing relevance of Ethernet-based protocols shows potentials for a common communication medium [15].

For indicator and control elements, Java provides powerful APIs for User-Interface programming (ATW and Swing) and there are no special requirements regarding computing power. In contrast to this, for control devices like PLC, SoftPLC, or IPC, there are constraints that do not fit in every case to the features of standard Java. These devices are characterized by:

- real-time requirements for application parts that realize control functionalities (cyclic control program execution with a defined cycle time),
- direct hardware access to the I/O level,
- today's usage of PLC typical programming concepts (e.g., IEC 61131).

A special case are smart I/O-devices where the computing resources are even more limited than in normal PLCs.

63.3 Problems of Using Java at the Field Level Under Real-Time Conditions

It can be stated that for the use of standard Java in non-real-time conditions with limited resources, several problems have to be solved, even if the advantages mentioned above make Java an interesting programming language for control engineering.

© 2005 by CRC Press LLC

Before describing the existing problems, the usual necessities for the design of applications in the field control area will be given. A (distributed) control application requires, of course, real-time behavior as well as the realization of communication with other applications, field I/O and/or remote I/O. Normally, hardware access regarding memory allocation, access to local I/O, and similar things are also necessary. Figure 63.1 gives an overview of the strengths and problems of Java against the background of these requirements. In general, Java provides advantages for tasks like user interaction over an HMI or communication with other applications/remote I/Os over different protocols. The close relation of Java to the Internet world makes it easy to support communication via protocols like http, ftp, or SMTP.

Unfortunately, other features of Java make it difficult to use it in control engineering without modifications or enhancements. This concerns the resource consumption of Java as well as the real-time capabilities and direct access to the hardware [6]. In the following sections, the reasons for these problems shall be described more in detail.

Resource Consumption

With respect to resource consumption, for the use of Java, two requirements have to be taken into account: first, the necessity to run a JVM on the target system (depending on the system architecture) and second, the need for large standard libraries, if the full features of Java are to be used.

To ensure the applicability of Java on different systems in a common way, three Java2 Editions were introduced. One of them, Java2ME (Micro Edition), was specially developed with respect to limited and embedded devices. With Java2ME consisting of two different configurations and offering the possibility to add profiles and optional packages, it is possible to tailor a Java platform to the special needs of devices and application areas. While the Connected Device Configuration (CDC) is used for devices with a memory of 2 MB and more, the Connected Limited Device Configuration (CLDC) was designed for smaller devices. With enhancements like personal profile and RMI-optional package, the CDC provides nearly the same functionality as J2SE. The CLDC-based K(kilo)-VM is much more limited, but runs on devices with memory down to 128 KB.

The more serious problems are the insufficient real-time capabilities of Java. Besides others, especially some features normally providing basic advantages of Java are problematic: the concept of JVM and GC.

Execution Speed and Predictability

Initially, the interpretation of Bytecode by the JVM was the rule. To improve the performance, later techniques such as just-in-time-compiler (JIT) were introduced. In a JIT, methods are translated into

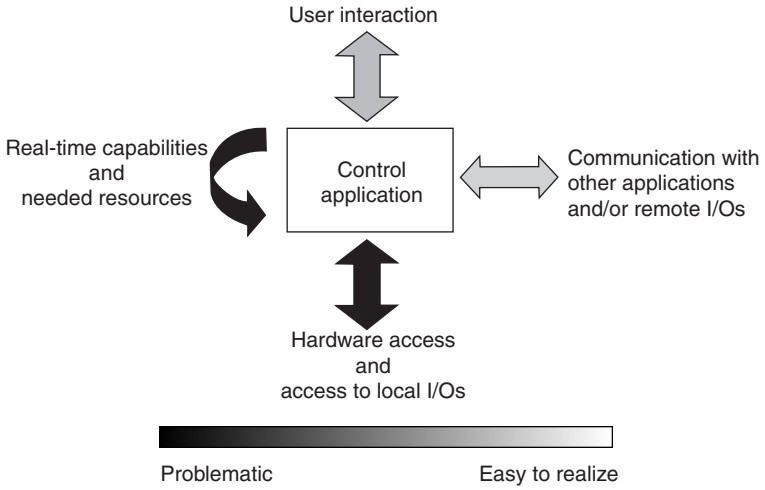

FIGURE 63.1 Requirements around a control application.

© 2005 by CRC Press LLC

machine-code of the current platform during the execution. Hence, at their next invocation they can be executed much faster. For real-time systems, both variants are not sufficient. The interpretation may be too slow (depending on the speed requirements) and the JIT is highly nondeterministic as the execution time of a method can depend on how many times it was performed before! For a real-time system, the worst case is always important and here a JIT compiler is normally not better than an interpreter. Hence, the solution for such systems is to use Ahead-Of-Time compiling (AOT). Here, the application is either translated completely *before* the execution or *during* the class-loading. Both methods enable a considerable optimization and especially the first one reduces the resource consumption on the target system. Unfortunately, with a complete compilation in advance, an important Java feature — the dynamic class loading — is no longer possible. The compilation during class loading retains this possibility, but needs more resources on the target system (class loader).

Garbage Collection

Although the Java Language Specification (JLS) does not require a GC, the most JVM implementations use one for automatic memory management. A GC scans the memory for objects with no references and frees the memory, mostly also followed by a defragmentation of memory.

The GC is normally not interruptible (except incremental GC, which is rarely used) and so it stops any execution of application threads at an unpredictable point of time for an unknown time span. This is an extremely nondeterministic behavior and, of course, not acceptable under real-time constraints.

Synchronization/Priorities

The possibilities for thread scheduling and prioritization offered by Java are insufficient. Real-time systems require a reasonable number of priorities to enable the use of different scheduling strategies. Against this requirement, the number of priorities (the JLS defines 10) is too small. Usually, it is not guaranteed that the Java threads are mapped to threads at the operating system level. However, this is a prerequisite for a correct scheduling in a Real-time operating system (RTOS). Although there is a concept for synchronization of threads (keyword `synchronized`) with monitors, no mechanisms for avoidance of priority inversion[1] are specified by the JLS.

Hardware Access

Finally, as a result of the concept of platform independence realized by the JVM (abstracting the underlining hardware), direct hardware access is not possible in Java. This applies to direct memory access, as well as for specific device functionalities. Although this is no direct requirement for a real-time system, it can be necessary for the I/O-access in control engineering.

All these problems regarding different aspects of standard Java implementations result in the necessity for special modifications or enhancements, if Java is to be used with field-level devices under real-time constraints.

63.4 Specifications for Real-Time Java

Although the creation of a uniform specification for real-time behavior in Java is vitally important right against the background of platform independence, it was not possible to find a common approach of all parties thereto. At the moment, there are suggestions for the enhancement/modification of the standard-Java-specification by two consortia. Both of them have a goal to solve the problems stated above and make Java applicable to real-time systems.

[1]Priority inversion occurs, if a low-priority thread using a resource is pre-empted by a medium-priority thread. If now a high-priority thread also needs the resource, it is blocked until the low-priority thread is executed again and can free the resource.

© 2005 by CRC Press LLC

Real-Time Specification for Java

The first consortium is the "Real-Time for Java Expert Group," under the leadership of Sun Microsystems, which has developed the "Real-Time Specification for Java" (RTSJ) [2]. The formal scope for the development of this specification is the Java Community Process (JCP), where the RTSJ runs as Java Specification Request (JSR)-000001. The JCP defines a procedure that requires an internal and public review of the draft specifications as well as a reference implementation and a test suite called "Technology Compatibility Kit" (TCK).

The JSR-000001 has reached the state of Final Release on 07 January, 2002, and a reference implementation has been developed by TimeSys Corporation [13].

General principles for the development of the RTSJ were to guarantee the temporally predictable execution of Java programs and to support the current real-time application development practice. For the realization of real-time features, the boundary conditions were set so that no syntactic extension of the Language needed to be introduced, and the backward compatibility was to be maintained by mapping Java Language Semantics (JLS) to appropriate entities providing the required behavior under real-time conditions. Furthermore, the RTSJ should be appropriate for any Java Platform.

The more general WORA concept of standard Java is replaced by the so-called Write Once Carefully Run Anywhere Conditionally (WOCRAC) principle. This is necessary because the influence of the platform has to be taken into account. For instance, if the performance of the platform is not fast enough to meet some deadlines (this should normally not be the case, but may be, if the original platform was much faster), this is a serious problem that cannot be ignored.

In this context, the goal of the RTSJ is not to optimize the general performance of a JVM, but to improve the features causing problems for real-time systems like the GC, synchronization mechanisms, and the handling of asynchronous events.

To achieve this, the RTSJ enhances the Java specification in seven areas. All these additions improve critical aspects in the behavior of Java, or add typical programming features for real-time system development [10]. In the following, these enhancements will be explained more in detail.

Thread Scheduling and Dispatching

The RTSJ introduces real-time threads with scheduling attributes to improve the scheduling possibilities compared to Standard-Java. Every real-time thread (implementing the interface `schedulable`) has a reference to a scheduler. Although the RTSJ is open for implementations of various scheduling principles, the only required version is (as default scheduler) a strict fixed-priority pre-emptive scheduling for real-time threads. For these threads, at least 28 unique priority levels are required (plus the ten priorities of the JLS). The assignment of thread-priorities is, as usual in most real-time systems, left to the programmer. The algorithm for the determination of the next thread to run (feasibility algorithm) requires an assignment of priorities following the Rate-Monotonic Analysis.

In the RTSJ the interface `scheduleable` is implemented by `RealTimeThreads` and `AsyncEventHandlers`. It contains several parameters to describe relevant data for the scheduling. For instance, the abstract class `SchedulingParameters` is used as the base class for the `PriorityParameters` describing the priority of a thread. Besides the basic RealTimeThread, which may use memory areas other than the normal heap, the `NoHeapRealtimeThread` must be created with a scoped memory area (see next paragraph) and is able to preempt the GC. Hence, there are strong restrictions regarding the interaction with objects on the heap (no reading or writing, nor manipulations of references except objects in the `ImmortalMemory`).

Memory Management

The RTSJ provides different kinds of memory to allocate objects outside the memory area controlled by the garbage collector. As the JLS does not require a GC (although nearly every JVM-implementation has one), the RTSJ also does not define the necessity for a GC. ScopedMemory is used to define the lifetime of objects depending on the syntactical scope. If such a scoped memory area is entered, every use of a new-statement results in an allocation of memory exclusively within this area. These objects are not garbage collected, but live until the control flows out of this scope. Then the whole memory area will be reclaimed. A scope

© 2005 by CRC Press LLC

(real-time thread or closure) can be associated with more than one memory area and, also, a scoped memory area can be associated with one or more scopes. There are two types of this kind of memory distinguishable by the relation of allocation time to object size: linear for LTMemory and variable for VTMemory.

Objects created within the third kind of memory, the ImmortalMemory, will never be affected by any GC and will exist until the Java runtime terminates. For each JVM, there is only one ImmortalMemory, which is used by all real-time threads together. The RTSJ provides a restricted support for memory allocation budgets, which can be used for defining the maximal memory consumption of a thread.

Synchronization and Resource Sharing

The RTSJ specifies an implementation of the synchronized primitive, which avoids an unbound priority inversion by using the priority inheritance protocol.[2] Using this method, problems can occur when a RealTimeThread is synchronized with a normal thread. A `NoHeapRealTimeThread` generally has a higher priority than the garbage collector, and a normal thread always has a priority below. Thus, a Java thread cannot have the same priority as a RealTimeThread. To solve this problem, the RTSJ introduces special wait-free queue classes with unidirectional data flow and nonblocking read/write methods.

Asynchronous Event Handling

The RTSJ introduces a mechanism to react on events that occur asynchronously to the program execution. Therefore, a schedulable object (`AsyncEventHandler`) is bound to an event (represented by an instance of the class `AsyncEvent`). If an event occurs, the event handler changes its state to "ready" and the event will then be scheduled like any other schedulable object (implementing the interface `Schedulable`).

Asynchronous Transfer of Control

Similar to the normal exception handling in Java, the RTSJ defines the possibility to transfer the flow of control to a predetermined point in the program. It is important to note that the possibility of an interruption has to be declared explicitly before the execution (interface `interruptible`).

Asynchronous Thread Termination

As the current JLS does not provide a mechanism to terminate a thread (the existing method `thread.stop` is marked as deprecated as it can cause inconsistencies), the RTSJ provides such a capability. It is realized by using asynchronous event handling and asynchronous transfer of control, and typically is deployed to terminate a thread when external events occur.

Physical Memory Access

The RTSJ defines two low-level mechanisms for a direct memory access. `RawMemoryAccess` represents a direct addressable physical memory. The content of this memory can be interpreted, for example, as byte, integer, or short (`RawMemoryAccessFloat` can be used for floating point numbers). The classes `ImmortalPhysicalMemory` and `ScopedPhysicalMemory` provide the possibility to allocate Java objects in the physical memory.

For practical use, the RTSJ has several powerful easy-to-use mechanisms. Other features like the immortal memory are potentially dangerous and have to be used very carefully. As objects in the immortal memory never free their allocated memory (until the runtime is shutdown), continued or periodical object creation can easily lead to a situation where the system runs out of memory.

Combining the RTSJ with a real-time GC [5], as explained in [7], can overcome some limitations. In doing so, it is possible to access the heap from the real-time part without limitations and to directly synchronize real-time and non-real-time parts of an application. Unfortunately, the resulting application will not be executable on each RTSJ-compliant JVM.

Also, some conceptual problems of the RTSJ have to be noticed. While the RTSJ provides a defined API, some aspects of the behavior can depend on the underlying RTOS. The API is the same, but the semantics

[2] If a low-priority task holds a resource and therefore blocks a high-priority task, its priority is increased to the same as the high-priority task.

© 2005 by CRC Press LLC

may change! This particularly applies to scheduling and the possibility of implementing scheduling strategies other than the primary scheduler.

The reference implementation (RI) of the RTSJ is provided by TimeSys Corporation. The RI runs on all Linux versions, but the priority inheritance protocol is only supported by TimeSys Linux — a special real-time-capable Linux version. The JVM is based on the JTime-system VM (corresponding to the J2ME-CDC). As the JVM works in an interpreting mode, it is a good system for testing and getting experiences. For product development, one of the available commercial implementations of the RTSJ would be a better choice. Meanwhile, several companies have developed RTSJ-compliant platforms or implemented at least some of the basic concepts of the RTSJ [7, 13, 14].

Real-Time Core Extensions

The second consortium working on real-time specifications for Java is the JConsortium. One group within the JConsortium is the Real-Time Java Working Group (RTJWG). This working group has created the Real-Time Core Extensions (RTCE), finished in September 2000 [2].

The general goal of this specification can be characterized by reaching real-time behavior for Java applications with a performance regarding throughput and memory footprint comparable to compiled C++ code on conventional RTOS. Thus, this specification aims at providing a direct alternative to the existing real-time technologies. It was assumed that for typical applications in this field, the cooperation between the real-time part and the non-real-time part is limited.

As a result of these requirements, the general idea of the RTJWG was to define a set of standard real-time operating system services wrapped by a Java API (the "Core"). In doing so, the standard JVM was not changed, but extended by a Real-Time Core Execution Engine. The components of the core are portable, can be dynamically loaded, and may be extended by profiles providing specialized functionalities. Consequently, all objects implementing real-time behavior are derived from `org.rtjwg.CoreObject`, which is similar to `Java.lang.object`. This means the separation between real-time ("Core") and non-real-time ("baseline Java") is type based.

Following the concept of limited cooperation between core components and baseline Java, the core objects have some special characteristics regarding memory management, synchronization, or scheduling. These will be described in the following subchapters in more detail.

Memory Management

All real-time objects are allocated the core-memory area and are not affected by the GC until the appropriate task[3] terminates. The RTCE also specifies a stack allocation of objects, which provides a more efficient allocation and better reliability and has a performance that is easier to predict. To allocate an object on the stack, it has to be declared as "stackable" and some restrictions have to be observed, for example, a value of a stackable variable cannot be copied to a nonstackable variable. If a task terminates, all objects of this allocation context may be eligible for reclamation, but as there might still be references from the baseline objects, the core engine has to verify if this is the case or not. If not, the objects can be reclaimed.

Synchronization

To avoid priority inversion, the RTCE supports two protocols: the typical priority inheritance protocol and the priority ceiling for "protected objects." The problem of synchronization between baseline and core components (as described for real-time tasks in the RTSJ section) occurs here in the form that the synchronization protocols must not cause unpredictable delays in the real-time tasks. The mechanism to avoid this is the usage of a BufferPair (write/read buffer) in combination with the priority ceiling protocol.

[3]In the RTCE, mainly the term "task" is used instead of "thread," which is not unusual for real-time systems.

© 2005 by CRC Press LLC

Scheduling

The RTCE defines 128 priorities, which are all above the normal Java priorities, so that the GC cannot preempt core tasks. The assignment of priorities is done by the programmer and typically a preemptive priority-based scheduling is used.

Cooperation with Baseline Java Objects

As core objects are not garbage collected before release, they must not access baseline Java objects. In contrast, objects in the baseline heap may invoke some special methods to access core objects (although the most fields and methods of core objects are not visible for baseline objects).

Besides this basic behavior, the RTCE provides a set of further features, which are useful for the programming of real-time systems like signaling and counting semaphores as well as interrupts and I/O ports with integrity. For the practical handling of the RTCE, it has to be noticed that the specification was developed under the assumption that core programmers are "trusted experts" (in contrast to baseline Java programmers), who are aware of the typical problems and pitfalls of real-time systems and can benefit from the functionality provided by the RTCE.

Real-Time Data Access

Another working group within the JConsortium is the RTAWG. The focus of this group is the application field of industrial automation. Hence, the resulting "Real-Time Data Access" (RTDA)-specification focuses on an API for accessing I/O-data in typical industrial and embedded applications rather than on features supporting hard real-time requirements.

Analyzing the typical requirements for the usage of Java in industrial applications, the general idea behind the RTDA is that the support of real time is a basic requirement, but that hard real time with sophisticated features is only needed in a few cases. More important is a concept for a common access to I/O data for real time and non-real-time parts of an application as well as the support of typical traditional procedures regarding configuration and event handling in this domain.

Following these conditions, the RTDA considers real-time capabilities as a prerequisite, assuming that the real-time and non-real-time applications run on a real-time-capable JVM.

Real-Time Aspects

The RTDA supports real time by using permanent objects and creating an execution context for these objects. Permanent objects are not garbage collected and have to implement the interface `PermantentMemoryInterface`, or the "permanent memory creation" has to be enabled (by invoking the method `enable()` of the class `PermantentMemory`). As the main intention is to create all these objects in a setup phase, the permanent objects can also be created by a non-real-time thread. This principle simplifies real-time programming, as the problems of memory allocation for object creation under time constraints and availability of memory are not critical for such a procedure.

The RTDA requires 32 priorities and a system priority for Interrupt Service Routines (ISR) and non-Java threads. The ranges are defined by the constants MIN_PRIORITY – MAX_PRIORITY (typically 1–10) for the non-real-time threads and MIN_RT_PRIORITY – MAX_RT_PRIORITY for real-time threads (12–32); the GC runs typically with priority 11.

The existing `synchronized` keyword will be used, but with different behavior depending on the context: usage of the priority inheritance protocol for real-time threads and permanent objects and raising the priority for permanent objects in normal threads to block out the GC.

Event Handling and I/O-Data Access

As the event handling and the I/O-access are the core components of the RTDA, it defines a dynamic execution model supporting asynchronous as well as synchronous access to I/O-data. The main instances responsible for creation of appropriate objects are the Event-Managers (asynchronous) and the Channel-Managers (synchronous). Every Event-Manager is created out of a `DataAccessThreadGroup`,

© 2005 by CRC Press LLC

which controls the priority of this Event-Manager. Depending on the type of event, there are different Event-Managers like:

- IOInterruptEventManager (InteruptEvent)
- IOTimerEventManager (PeriodicEvent or OneShotEvent)
- IOSporadicEventManager (SporadicEvent)
- IOGenericEventManager (all types of events, more than one event)

For the realization of a hardware-independent I/O-data access, three components are important: "Device-Descriptions," the classes `IONode/IONodeLeaf`, and the I/O-Proxy classes.

A DeviceDescription specifies a hardware component (static in a native DLL or as Java class). As this description does not represent a concrete instance of a hardware, but describes the type of a device, the concrete instantiation is realized by an `IONodeLeaf`-object.

The complete overall (hierarchical) structure of a given I/O-system is described by a tree of `IONodes`. It represents the concrete configuration of a system where the leafs of this tree are objects of the type `IONodeLeaf`. The configuration realizes a mapping on memory addresses as well as on I/O-space. The access path of an `IONodeLeaf` can be described in a way starting from the root node down to the `IONodeLeaf`. During the configuration, which is executed in the setup phase of the Java system, the instances of the `IONodes` (describing a device node) are created and a mapping regarding the addresses is executed.

The entity to access the I/Os in the application is the I/O-proxy, representing physical or software entities. These proxies are generated out of a `IOChannelManager` and can be identified by a physical or a symbolic name. The mapping between both these names takes place in a name map table of the appropriate `IOChannelManager`. Thereby, the design of hardware-independent applications is enabled if only symbolic names are used. Hence, changes in the hardware require only changes within the map table and not within the application.

`IOChannel` is the superclass for all types of I/O-proxies. Every I/O-proxy has a cache for holding the appropriate I/O-data and provides methods for updating the cache from the input channel as well as flushing the cache to the output channel. Furthermore, there is a common error handling.

As the concept of using I/O-proxies in the control application is an important part of the RTDA, there are different types of proxies. Hardware proxies represent a concrete hardware-I/O-device and therefore have a physical name corresponding to the respective entry in an `IODeviceDescription`. Furthermore, there are two different types of software proxies: Empty I/O-channels and generic Software I/O-channels. Empty I/O-channels give a generic possibility for I/O-data access and can be used by manifold non-RT Java components (e.g., HTTP-server). The generic Software I/O-channels provide the possibility to extend the existing I/O-classes by new functionalities without changing the RTDA implementation. Examples for such possible extensions, given in the specification [3], are, for instance, I/O-proxies for remote access, simulation, or accessing legacy software.

As the superclass `IONode` is the base for all I/O-channels and events, the basic concept for the handling of events is similar to the concept of I/O-handling; a similar mechanism for the handling of events are specified.

Although there is no direct reference implementation for the RTDA, the Java package for SICOMP industrial-PCs by Siemens closely follows this specification of the J-Consortium. This particularly applies to the JFPC system (Java for process control) in relation to the I/O concept of the RTDA [3,8] (The resulting structure of RTDA is given in Figure 63.2).

Comparison

Comparing all three specifications, it can be stated that all of them follow different approaches, but also focus on different application areas. The RTSJ and RTCE have the goal to provide a more general way of enabling Java to become usable in the real-time domain, while the RTDA focuses on the special application field of industrial automation and understands real-time capabilities only as one of several requirements, which are typical for this area.

© 2005 by CRC Press LLC

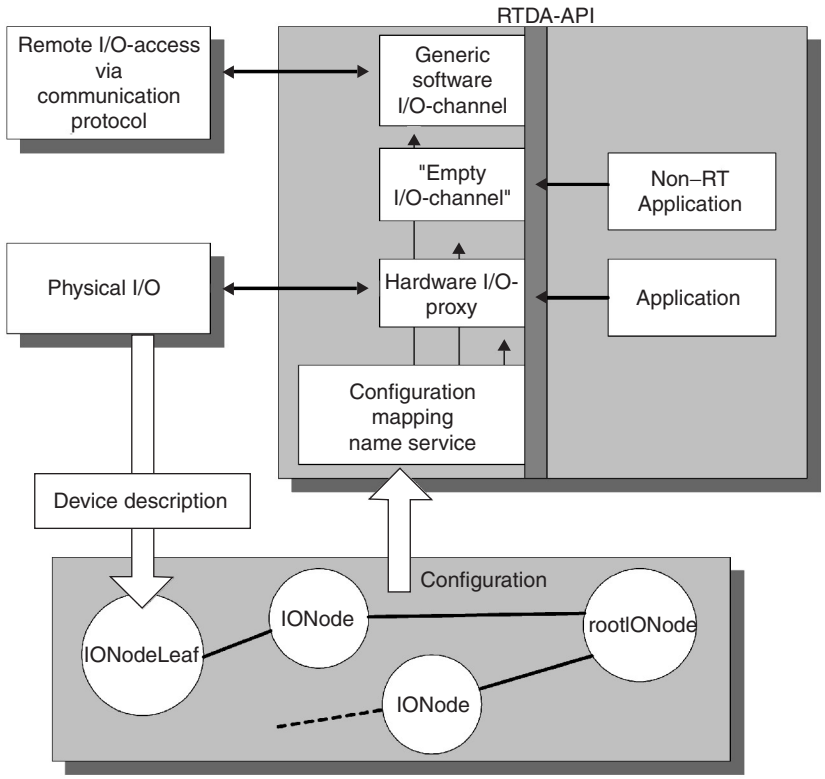

FIGURE 63.2 RTDA — overall archirecture.

The RTSJ is the most general approach, following the idea of "making Java more real-time." Therefore, the RTSJ can be used well by experienced Java programmers, as all enhancements are close to common Java concepts. Considering the number of products implementing the specification, currently, the RTSJ has the highest acceptance.

In contrast, the RTCE follows other premises, focusing on providing a performance comparable to the state of the art (e.g., C++) solutions on commercial RTOS for hard-real-time requirements. The JVM was not changed, but extended by a separated "core," which realizes the real-time features. The RTCE provides real-time functionality following the typical concepts of today's real-time application development and therefore it is assumed that it will be used by experienced real-time programmers. Hence, the RTCE is the first choice for problems dealing with hard-real-time constraints and high-performance requirements, although, at the moment, the lack of a sufficient number of available products reduces the applicability.

The RTDA provides a complete concept for the application development in industrial control engineering. Real-time capabilities are seen only as a needed prerequisite for such applications, but the main part deals with the handling of I/O-data and interrupts. The concept is very similar to typical concepts used in conventional control systems and is therefore easy to understand for programmers working in that domain. Nevertheless, the RTDA is a very "closed" world and therefore it is not easy to adapt all ideas of using reusable components when programming control applications in Java according to the RTDA. Besides the JFPC system, which is available only for very powerful and expensive hardware (a Linux implementation will be developed and opens here new possibilities [12]), the RTDA also lacks a wide range of products.

Currently, it is still not clear if there ever will be *the* one specification, or if each of these specifications will find acceptance in a certain area.

63.5 Java Real-Time Systems

To ensure the real-time capability of a Java application, independent from the used JVM, the underlying operating system (OS) has to be real-time capable as well. Therefore, in particular in the area of embedded systems, different possibilities of combining JVM and real-time-OS exist. In general, there are four different categories:

- *Real-time JVM on conventional RTOS*
  In this case, a real-time JVM is running on a "normal" RTOS. This is typical for systems where the possibility to execute Java is an additional feature (of course, it can be the only feature that is used) and where the resources allow to run a JVM with sufficient execution time. Normally, this is the case for systems like IPCs and SoftPLCs, less for conventional PLCs because the operating systems and processors of conventional PLCs make the integration of a real-time JVM difficult. Examples of such systems are the SICOMP-IPC with JavaPackage [8] or the Jamaica-VM [7].
- *JVM and RTOS as one integrated system*
  If the only function of the RTOS is to run a JVM (this means the whole RT-application is written in Java), it can be useful to integrate both, JVM and RTOS, as one product and tailor the RTOS exactly to the needs of the JVM. Such systems can be a basis for full Java-PLCs.
- *Conventional RTOS with Java-co-processor*
  If the resources of the system are limited with respect to the requirements of a JVM, it can be useful to have a special Java-co-processor for the execution of the Java-Bytecode. This results in an increased execution speed, and also in an increased complexity of the system hardware and software.
- *Java processors*
  Finally, there are systems with a processor the executes Java-Bytecode directly as native processor code. Here the JVM is realized in "hardware," so that the conventional OS level can be dropped. This results in a very efficient (and therefore fast) Bytecode execution, but the flexibility of such systems is reduced due to the fact that non-Java applications cannot be executed. The typical application for the last two combinations are intelligent I/O devices.

63.6 Control Programming in Java

Requirements of Control Applications and New Possibilities in Java

Today, IEC 61131-compliant languages are typical for programming control applications. Although there are concepts for encapsulation of functionalities and data (e.g., function blocks provided in IEC61131-5), the main advantage of Java, compared to these languages, is the possibility to use object-oriented features like encapsulation and inheritance. Of course, networking abilities and stability also play an important role, but object orientation enables completely new ways for code reusability and increases the efficiency of application developments in control programming.

As it is not efficient to implement the whole application from scratch for every new project, it is important to encapsulate functionalities in classes for reasons of reuse. Depending on the concrete device, by means of these classes (or interfaces), generic functions like specific communication protocols or easy access to specific devices can be realized. These existing classes can (if necessary) be modified or extended and then be integrated into the application.

Hence, notable potentials result for industrial automation. Based on the platform independence of Java, parts of applications can be easily reused. Manufacturers of components like I/O-devices or intelligent actors/sensors can deliver classes (representing their components) together with the hardware. Instances of these classes can then be used in the concrete application and provide methods for using the device functionality, concealing the concrete hardware access. In doing so, the manufacturer can provide a clear simplification for the programmer and reduce the danger of improper use of his own hardware.

© 2005 by CRC Press LLC

For complex applications, the concrete hardware access (I/O), communication functions, or other basic functions can be abstracted on different levels. Here, special tailored classes are imaginable, for instance, the usage of IEC 61499 function blocks. A simple example for such a concept shall be explained now more in detail.

Structure of a Control Application in Java — An Example

The goal of the following is to give recommendations for the structure of an application to support efficient programming. This can be ensured on the one hand by as much as possible device-independency, and on the other, by using a consistent procedure for the handling of I/O-variables, independently if these variables represent local I/Os or remote I/O-devices, which are accessible over different communication protocols. The communication can be realized by conventional bus-systems (e.g., CANBus), or via Ethernet (e.g., Modbus/TCP or EtherNet/IP). How should an application for these requirements be structured? In general, it is advantageous to use several levels for the encapsulation of functionalities in Java classes (see Figure 63.4). To explain the structure, a simple example shall be used. The hardware structure of this example is shown in figure 63.3. A conveyer system consisting of several belts and turntables is controlled by a PC-based Java-PLC. As I/Os, two Modbus/TCP-Ethernet-coupler are used.

Objects of the lower level, called here communication level, realize the access to the concrete hardware. For local I/O access (e.g., memory access or GPIOs of a processor), these classes are device-specific. In contrast to this, for the communication with remote I/O-devices or other controls, generic classes (availability of appropriate hardware assumed) can be used on different platforms. Today, such Java classes are available for the Ethernet-based protocols Modbus/TCP and EtherNet/IP. In our example, the Ethernet

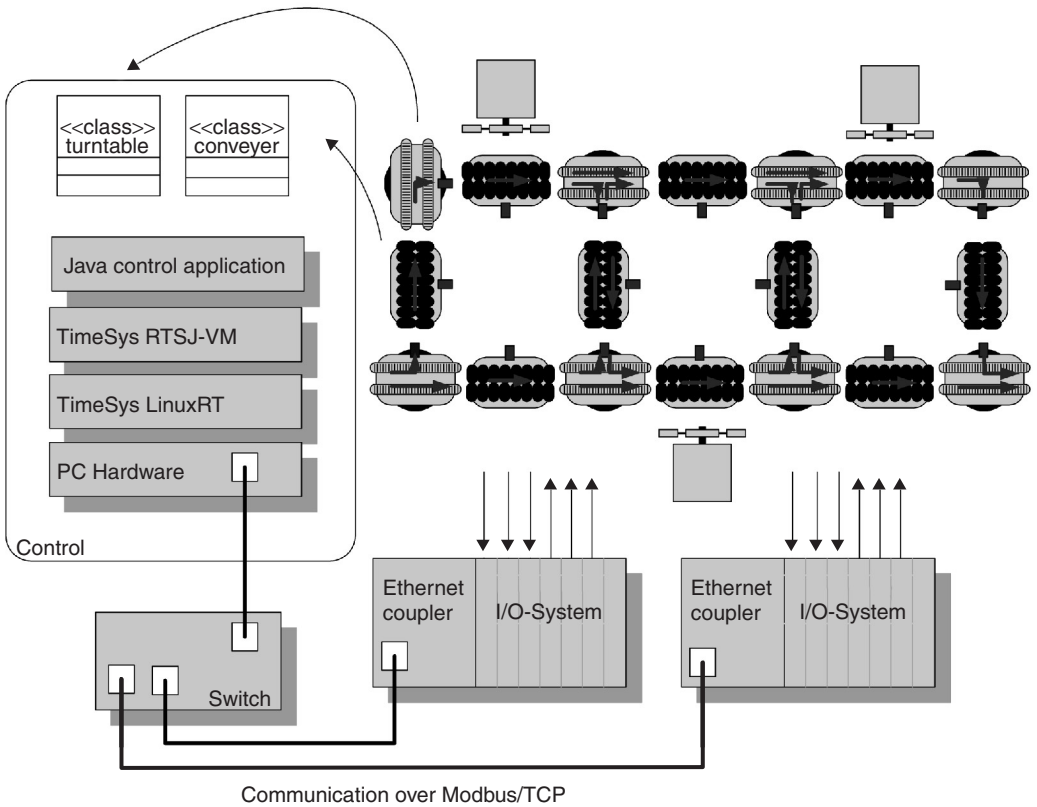

FIGURE 63.3 Hardware structrure of the example.

© 2005 by CRC Press LLC

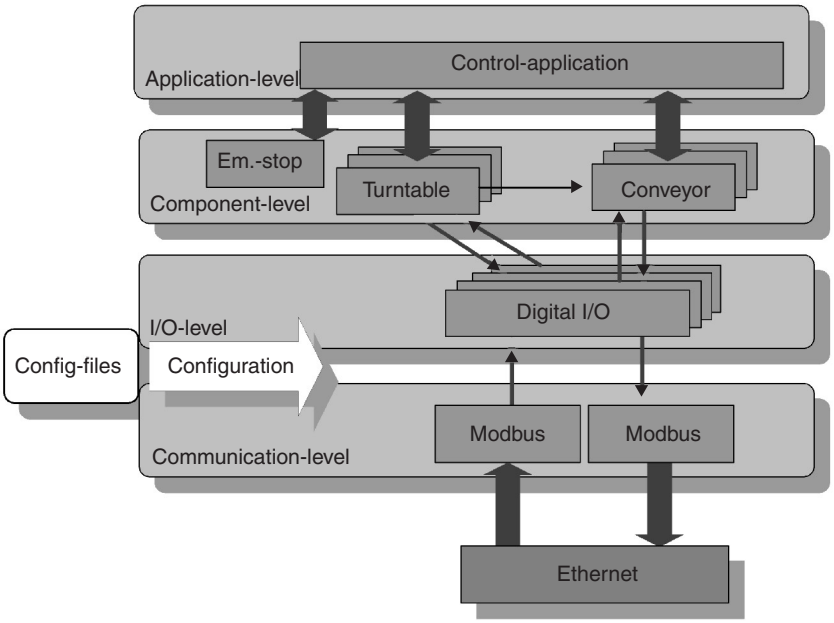

FIGURE 63.4 Structure for control applications in Java.

coupler (and its I/Os) are represented by two instances of a class `Modbus`. These objects ensure the read- and write-access to all I/Os of the appropriate coupler and make it possible to read and write the I/Os. These objects, basically realizing a communication, can be used by classes of the next level (I/O-level), which represents the logical I/O-variables (e.g., digital or analog inputs or outputs). Here, a mapping from physical variables (representing physical I/Os) to logical variables is realized. If this mapping is flexible by using configuration information, for example, stored in a configuration file or as an input from an IDE, the control application can be implemented device-independently. In the example, every input or output is represented by an object of the class `DigitalIn` or `DigitalOut`, which is linked with the help of a configuration file to the appropriate Modbus-objects.

On the third level, complex control functionalities (e.g., emergency-stop) as well as representations of parts of the plant control system (e.g., components like conveyors, drives, or generically usable actors) can be encapsulated in classes. Objects on this level, as well as groups of I/O-variables on the I/O-level, typically run in their own real-time thread. In the example, there are objects for each element of the transport system as instances of the classes `Conveyor` and `Turntable`. These objects provide methods for controlling these elements (e.g., `start()`, `stop()`, `turnleft()`, `turnright()`,...).

This structure simplifies the reusability of huge parts of the control application. Thus, on the highest level (application level), an application can be implemented in a more abstracted, function-related way.

Integration of Advanced Technologies

The use of Java for control programming at the field level shows advantages especially in systems where Java is also used for non-real-time applications. This applies for visualization or remote access for specific functions like maintenance and code download/distribution. In this context, new technologies, also in the area of industrial automation such as agent-systems or plug-and-participate technologies, play an important role.

For implementing such systems, special attention has to be paid to restrictions regarding the mutual interactions of the control application running under real-time conditions and the non-real-time application. If the real-time-Java platform provides support in this respect (like the software I/O-proxy of the

© 2005 by CRC Press LLC

RTDA), this can be realized very easily. Unfortunately, most real-time-Java products and specifications do not follow the requirements of industrial control applications; hence, special attention has to be paid to these aspects.

As a general rule, it can be said that time-critical parts of the application will run with a higher priority, while non-real-time parts have priorities below the GC and will be executed as normal Java applications and, of course, restrictions like synchronous calls from real-time to non-real-time part have to be observed.

For this case, an architecture is reasonable, which decouples the control part and allows a synchronization at certain states of the system. The loose coupling of both parts, allowing the access to the control only in exact defined states, can be implemented by a connection layer using, for example, a finite state machine. This allows to load, parameterize, and start control applications.

As an example for such a system, the so-called "Co-operative Manufacturing Unit" (CMU) shall be mentioned. It was developed within the international research project PABADIS [11]. This project aims at creating a highly flexible structure for automated production systems, replacing parts of the traditional MES-layer by concepts using technologies like mobile agents and plug-and-participate technologies. The CMU is the entity in the system providing the functionalities of automated devices (e.g., welding, drilling) to the PABADIS-system. Although it is also possible to connect conventional controls (e.g., PLCs) to the system, the fully Java-based CMU is the most advanced concept. It avoids the additional communication effort from the object-oriented Java-world to IEC 61131-compliant languages and provides all the advantages of Java stated before. The outcomes of the PABADIS-project give an idea of the possibilities that technologies like Java can bring to future automation systems.

Migration Path for the Step from Conventional Programming to Java Programming

As mentioned before, it is necessary to provide a possibility to migrate in a certain way from the conventional IEC 61131-based programming to Java programming. This way can be opened by applying the ideas of IEC 61499 and the definition of special function blocks for the application parts given in the component level, IO level, and communication level of Figure 63.4. Based on these predefined structures and self-designed control application blocks programmed in IEC 61131-compliant dialects (which can be automatically translated to Java), a new way of programming can be established.

63.7 Conclusion

Summarizing, it has to be stated that Java technology has reached a status where the technical prerequisites regarding use in industrial automation even in the area of control applications on limited devices are fulfilled. There are Java2 Editions allowing an adaptation to the requirements of the platform and several products using different approaches provided real-time capabilities in Java are available. This allows for the use of Java on nearly all types of devices at the field level. A common standard for real-time-Java is important against the background of retaining platform independence of Java also for real-time devices. Now the development of concepts regarding how the advantages of object-oriented high-level languages can best be used for increasing the efficiency of application development (by supporting reusability and providing abstract views on the Java application) is momentous. Besides this, Java opens new possibilities for an easy integration of technologies like XML, Web-services, (mobile) agents, and Plug-and-participate technologies [11].

64.1 Introduction

Due to the complexity of automated systems and the increasing application requirements, the use of appropriate modeling tools becomes essential to achieve a correct system design. These tools must be capable of simultaneously specifying the system behavior in a concise and unambiguous manner, and of validating this specification. Support of a method to easily map the formal model into the final implementation, on possibly varying hardware, is also required.

For several years, the absence of a common modeling tool led system designers to use different methodologies, each supported by a specific tool. This approach resulted in a large number of problems, such as higher development costs, incompatible specifications, absence of formal validation techniques, and difficulties in translating specifications into implementations.

GRAFCET was initially proposed by several academic and industrial research groups, and later standardized by International Electrotechnical Commission (IEC), in the hope that it would be accepted as the common modeling tool. Its aim is to allow the designers to describe and specify a control system's sequential behavior.

This chapter presents a description of the GRAFCET language, from an automated systems' perspective. All aspects of the language are described, although the number of application examples was reduced

© 2005 by CRC Press LLC

to a minimum due to space constraints. Interested readers are encouraged to refer to [3][5][6] for more detailed examples.

64.2 The GRAFCET Standards

In 1975, a working group called Logical Systems from AFCET (*Association Française pour la Cybernétique Economique et Technique*) decided to create a committee in charge of defining the requirements an automated system's modeling tool should fulfill. Having evaluated the state-of-the-art modeling tools of that time — flowcharts, petri nets, and state graphs — they concluded that a new more appropriate modeling language was required. In 1977, GRAFCET (*Graphe Fonctionnel de Commande Etapes-Transitions*), which is translatable to Functional Graph of a Step-Transition Command, was proposed to fill the gap [4].

In 1982, a French initiative created the first GRAFCET standard: NF C 03-190 — *Diagramme fonctionnel "GRAFCET" pour la description des systèmes logiques de commande*. Later, the widespread use of GRAFCET led IEC to promote a standardization process, which resulted in 1988 in the first international GRAFCET standard: IEC 848 Ed. 1 — *Preparation of function charts for control systems*. This document was later revised, and a second edition was published in 2001: IEC 60848 (2001) Ed. 2 — *Specification Language GRAFCET for Sequential Function Charts* [1].

Since the IEC 60848 Ed. 2 does not define how to implement GRAFCET in control systems, other initiatives were adopted to implement it as a programming language for programmable logic controllers (PLCs). These efforts resulted in the definition of the language SFC — *Sequential Function Chart*, which is part of the IEC 61131-3 (2001) *Programmable Controllers — Programming Languages* standard [2].

64.3 The GRAFCET Context

A system can be defined as a set of organized interacting components that work together to achieve some defined objective, which is to confer an added value — physical modification, particular arrangement, position change, data processing — to a group of raw materials — products, energy, data, people — in a specific environment. When the operations necessary to achieve the system objective are executed automatically under the control of computational resources, the system is defined as an *automated system*.

From a conceptual viewpoint, the structure of an automated system is usually considered as being composed of two cooperating parts: *operative* and *control* (Figure 64.1). The *operative part*[1] represents the physical process that creates the added value. It is composed of a set of elements such as sensors, actuators, machines, robots, transportation systems, etc. The *control part* is composed of computational resources that coordinate the sequence of operations performed by the operative part. Additionally, it interacts with other external systems in its environment, such as human–machine interfaces and communication networks. All interactions may be modeled by the sending of commands and the reading of data.

The implementation of an automated system requires a formal, accurate, and complete description of its behavior. Without this understanding, the system designer could introduce faults during the development and implementation phases, which could lead to serious problems during system operation. It is important to notice that automated systems are commonly found operating in very sensitive areas — nuclear power plants, railways, industrial facilities — where a design fault could have a catastrophic impact on people and the environment.

The description of any system component's behavior is performed by first defining a virtual interface that isolates it from the external elements with which it interacts, followed by characterizing the interactions that occur across that interface. Therefore, interactions with the control part, which control engineers will typically be focusing on, can be functionally represented by isolating it from other system elements. Data and commands exchanged with both the operative part and the environment are, respectively, represented by *input* and *output variables* (Figure 64.2).

[1]Also commonly referred to as the controlled part.

© 2005 by CRC Press LLC

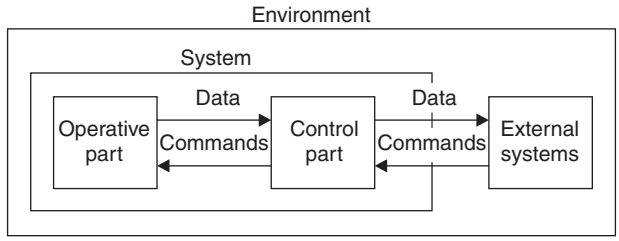

FIGURE 64.1 Automated system structure.

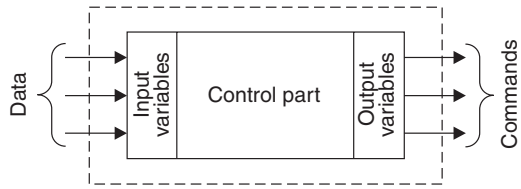

FIGURE 64.2 Control part interactions.

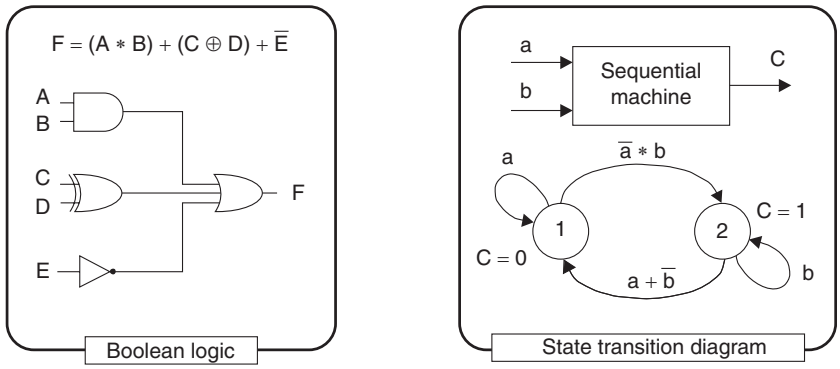

FIGURE 64.3 System behavior modeling.

The control part behavior may be described by the way in which the output variables depend on the input variables, which is necessarily different among distinct system types. Nevertheless, it is possible to find behavioral patterns common to every system and to use appropriate modeling tools to describe it. Among these patterns, two of them are distinguished by being present in any automated system and by representing the majority of interactions related to the control part — *combinational* and *sequential behaviors*. Both of them assume that system inputs and outputs are boolean variables, but other variable types can also be considered within specific contexts.

The *combinational behavior* is characterized by system outputs being a logical combination of their inputs at any given instant. Several modeling tools are available to describe this behavior — boolean logic, Karnaugh maps — which can be easily implemented (Figure 64.3).

The *sequential behavior* introduces the notion of state to describe the system evolution. At any given instant, the system outputs are logical functions of the inputs and the internal system state. This behavior can be modeled as a *sequential machine* by means of a *state transition diagram.*

The diagram is a simple directed graph consisting of circles and arcs, where circles represent the system states (Figure 64.3). At any given instant, only one state is active, representing the current system state, referred to as *situation*[2]. For each system state, a group of actions operating on the output variables

[2]Adopting the IEC 60848 Ed. 2 terminology.

© 2005 by CRC Press LLC

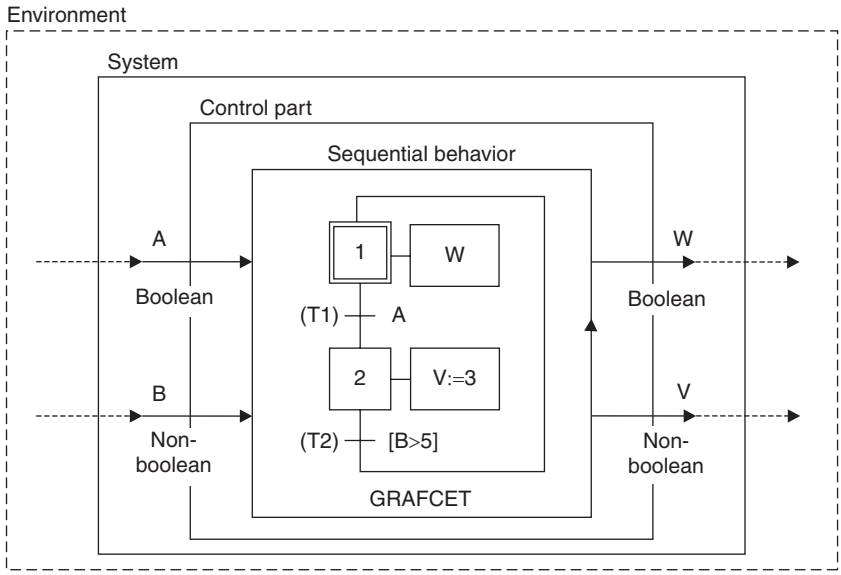

FIGURE 64.4 GRAFCET and system behavior.

may be defined, which are only executed while the state is active. The evolution between system states is modeled by directed arcs connecting the states. A boolean expression composed of input variables is associated to each arc, representing an evolution condition. When this condition is true, a transition from one state to another occurs. The definition of output variables and evolution conditions imply that the combinational behavior is embedded in the sequential behavior.

Although a state transition diagram could describe any type of sequential behavior, they are difficult to use when it becomes necessary to model behaviors commonly found in automated systems, which usually involve a certain degree of complexity, such as synchronization, parallelism, hierarchical relationships, and different detail levels.

In order to overcome these limitations, a new formalism is required, with the same descriptive power as sequential machines, but also capable of representing complex behaviors in a simple, concise, and intuitive way. It should also be well-adapted to represent the sequential evolutions of a system, which will potentially ease the mapping to the final hardware/software implementation. With all these properties, it becomes the appropriate tool for both automated system designers and end users.

These requirements resulted in the specification of the GRAFCET standard — IEC 60848 Ed. 2 [1].

GRAFCET's aim can be synthesized as to describe and specify, in a consistent and unambiguous manner, the sequential behavior of the system control part (Figure 64.4). The description is performed by using a graphical language composed of charts, which includes graphical elements to represent the system states and possible evolutions, associated with an alphanumerical representation of the system input and output variables. Therefore, it can be said that GRAFCET is a *behavior specification language* for sequential systems.

Although any kind of system that exhibits a sequential behavior can be modeled by using GRAFCET, until now its main application domains have been in the specification of control applications running on PLCs.

64.4 Basic Elements

Introduction

In a sequential system at any given instant the output variables are established from the system state and the input variables[3]. Since GRAFCET models the behavior of these systems, it becomes necessary that it includes

[3]Both variables are assumed to be of the boolean type, unless otherwise stated.

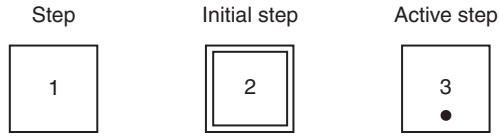

FIGURE 64.5 Step representation.

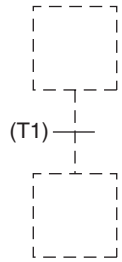

FIGURE 64.6 Transition representation.

all system data in its representation. This is accomplished by producing a chart (or group of charts), referred as *Grafcets*[4], using a set of graphical elements that represent different, but complementary, viewpoints of the system behavior. This representation distinguishes two perspectives: *structure* and *representation*.

Structure

The structure models the system evolution between situations. It is represented as a graph composed of *steps* and *transitions*, disposed in alternating mode, which are interconnected by *directed links*.

Steps

A *step* represents part of the system state. It may have two states: *active* or *inactive*. The set of active steps at any given instant represents the system, and *Grafcet,* situation at that instant.

A step is graphically represented by a square box, which is identified by means of a distinct label (Figure 64.5). The initial situation, *initial step,* represents the state of the system at the initial time ($t = 0$). The corresponding steps are represented by a double box. During the *Grafcet* evolution, the active states, at any given instant, are represented with a small dot inside the box.

Transitions

A *transition* represents a possible system *evolution* from one step to another, which is a change in the *Grafcet* situation. The evolution is performed by *clearing*[5] the transition. It is graphically represented by a thin horizontal bar (Figure 64.6), and it is identified by means of a distinct label, between brackets, placed to the left. This is known as its *designation.*

Directed Links

A *directed link* is used to connect steps to transitions and vice versa. Therefore, two steps cannot be directly connected, unless a transition exists between them. This property is known as the *alternation step-transition* rule.

A directed link is graphically represented by a line, with the direction of evolution path, assumed from top to bottom (Figure 64.7). An arrow can be used to avoid misunderstandings.

---

[4]We have adopted "GRAFCET" to refer to the language in general, and "*Grafcet*" to refer to a particular chart model.
[5]Also commonly referred to as *firing*.

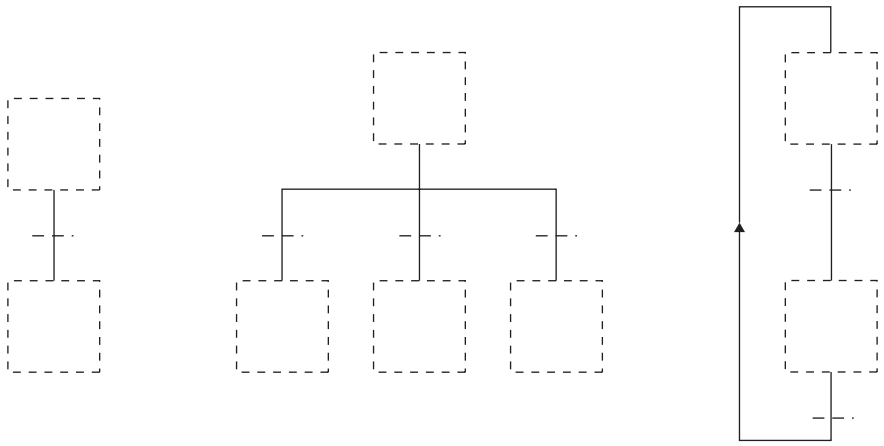

FIGURE 64.7 Directed link representation.

Interpretation

The interpretation establishes the relationships between the input and output variables and the *Grafcet* structure. It is composed of alphanumerical elements — *transition-conditions* and *actions* — representing the functional aspect of GRAFCET.

Transition-Conditions

A *transition-condition*[6] is a logical expression composed of input variables and/or *internal variables* (Section 64.5) representing an *evolution condition*. This condition is associated with a transition and establishes the necessary conditions to its clearing. Input variables are provided by both the operative part and the environment, while internal variables represent data internal to the system control part.

Transition-conditions are graphically represented by a logical expression placed at the right of the transition (Figure 64.8). A condition that is always true is represented as '1'.

Actions

An *action* represents an operation performed on an output variable, corresponding to a command that is sent either to the operative part or to the environment. The action is executed only while the associated step is active. Several actions can be associated to the same step.

Actions are graphically represented by a rectangle connected to the associated step (Figure 64.9). A literal or symbolic label inside it designates the output variable that takes the true value.

Evolution Rules

Since GRAFCET specifies the behavior of a dynamic system, it is necessary to define a set of rules that establish, without any ambiguity, the system evolution from one situation to another. The following five rules apply:[7]

- *Rule 1 — Initial Situation*. This situation is defined by the system designer and represents the state of the system at initial time ($t = 0$).
- *Rule 2 — Clearing of a Transition*. A transition is cleared if and only if both the following conditions occur:
  - All immediately preceding steps, linked to the transition, are active. The transition is said to be *enabled*.
  - The condition associated with the transition is true.

[6]Also commonly referred to as *receptivity*.

[7]According to IEC 60848 Ed. 2.

© 2005 by CRC Press LLC

- *Rule 3 — Evolution of Active Steps*. The clearing of a transition results in the simultaneous deactivation of all immediately preceeding steps and the activation of all immediately succeeding steps.
- *Rule 4 — Simultaneous Evolutions*. All transitions that can be cleared simultaneously are simultaneously cleared.
- *Rule 5 — Simultaneous Activation and Deactivation of a Step*. If during rule 4 phase, an active step is simultaneously deactivated and activated, it remains active.

The systematic application of the previous rules to a *Grafcet* describes all possible evolution situations, which helps the system designer to verify if the model's behavior diverges from the initial specification. Application examples are presented in Figure 64.10.

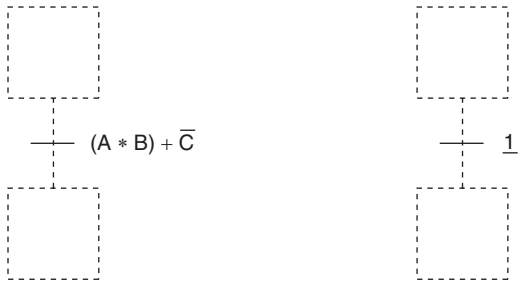

FIGURE 64.8 Transition-condition representation.

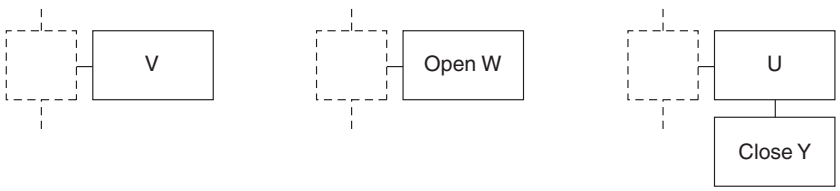

FIGURE 64.9 Action representation.

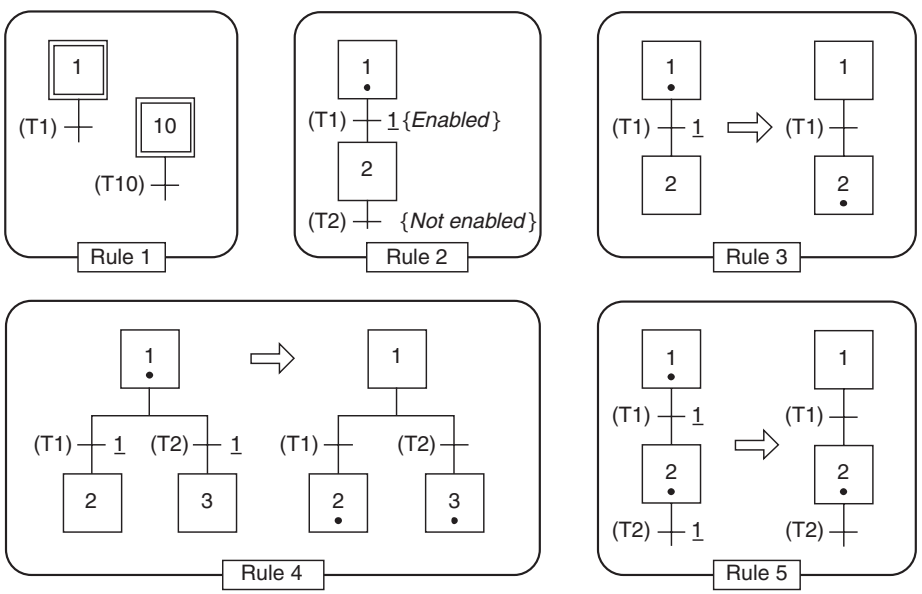

FIGURE 64.10 Evolution rules.

© 2005 by CRC Press LLC

Unstable Situations

The application of the evolution rules, combined with the existence of particular situations, may lead the *Grafcet* to a scenario where an *unstable situation* will occur.

As an example, consider the *Grafcet* presented in Figure 64.11, where at a given instant the situation is defined by: **step 1** is active, **A**=0 and **B**=1. Now assume that **A** changes to **1**, initiating the *Grafcet* evolution (Figure 64.11). From the instant where **A** changes to **1**, the *Grafcet* situation instantaneously changes from **step 1** active to **step 3** active. The simultaneous activation and deactivation of **step 2** is referred to as an *unstable situation*. Actions associated to steps in unstable situations are not executed, unless they are *stored actions* (Section 64.5).

Evolution Algorithm

The evolution rules establish a simple algorithm that defines the GRAFCET evolution:

1. Initialization (assumed stable). All initial steps are activated and the actions associated are executed.
2. Define the set of cleared transitions.
3. Clear all cleared transitions, until a stable situation occurs. During this phase, execute eventual stored actions associated with transitions clearings, step activations, and deactivations, including unstable situations.
4. Execute the actions associated with the active steps.
5. Goto to step 2.

Tank Filling Example (I)

The following example was chosen to demonstrate the basic GRAFCET capabilities, when used to specify the behavior of an automated system.

The system represented in Figure 64.12 is composed of a tank that must be filled with a liquid stored in a reservoir. Two valves (**V** and **W**), respectively, control the input and output of liquid in the tank. Two level sensors (**H** and **L**) monitor the tank level. A button (**S**) is used to start the system operation.

The tank is empty when the level is less than **L** (i.e., **L**=0) and is full when the level is greater than **H** (i.e., **H**=1). Initially, the tank is empty. When button **S** is pressed (i.e., **S**=1), the tank is filled by opening **V** and closing **W**. The filling operation stops when the tank is full, by closing **V**, and its contents are drained by opening **W**. When the tank is empty, **W** is closed. Filling may only restart when **S** is pressed again. The valves are open when the respective outputs are true, otherwise are closed.

A *Grafcet* that meets these specifications is also presented in Figure 64.12. It has three input variables: **L**, **H**, and **S**, and two output variables: **V** and **W**. Initially, the system waits for button **S** to be pressed. Only **step 1** is active — the initial step — without any associated action. Therefore, both valves will be closed. When the button is pressed, **S** becomes true, **T1** is cleared, and **step 2** is activated. The associated action — open **V** — is executed. When **H** becomes true, transition **T2** is cleared and **step 3** is activated. In this situation, **W** is opened and **V** is closed. The system is maintained in this situation until **L** becomes true. When this happens, **T3** is cleared and **step 1** is activated, returning to the initial situation.

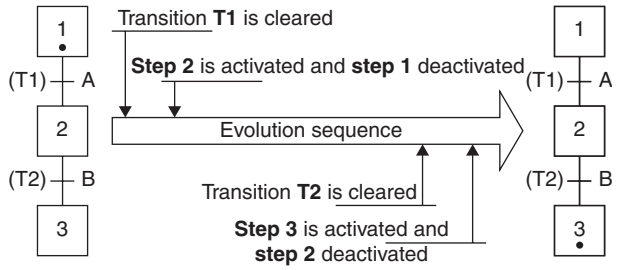

FIGURE 64.11 Unstable situation.

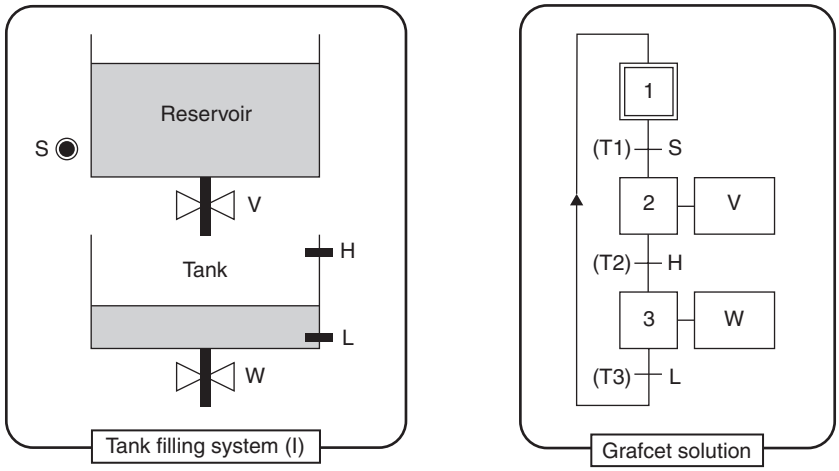

FIGURE 64.12 Tank filling example (I).

64.5 Advanced Elements

The GRAFCET elements already described are not a significant improvement to state transition diagrams. This may be easily understood considering that the GRAFCET basic elements are in fact based on these diagrams; therefore, the modeling capabilities must be similar. The introduction of a new set of advanced elements becomes necessary to enhance the GRAFCET modeling power.

Sequence Structures

A sequence consists of a succession of steps, where each step has only one preceding and succeeding transition, and represents the simplest sequential behavior that can be found. However, the behavior of an automated system is frequently more complex, requiring the use of advanced modeling structures. GRAFCET provides this by defining extensions to the graphical notation that are able to represent those behaviors:

- *Selection*. This structure is intended to represent a choice between alternative sequences. Example (Figure 64.13): transitions **T1**, **T2,** and **T3** are simultaneously enabled. One or more can be cleared simultaneously. Mutually exclusive transition clearing can only be achieved if their transition-conditions behave accordingly.
- *Parallelism*. This structure is intended to describe the behavior of parallel sequences. It is graphically represented as a double bar after a transition. Example (Figure 64.13): when transition **T4** is cleared, step **5** is deactivated and steps **6**, **7,** and **8** are simultaneously activated. After their simultaneous activation, the evolution of the active steps in each parallel sequences becomes independent.
- *Synchronization*. This structure can be interpreted as the inverse of parallelism, since its intention is to join parallel sequences. It is graphically represented as a double bar before a transition. Example (Figure 64.13): transition **T5** is only enabled when all previous steps (**9**, **10,** and **11**) are simultaneously active. When transition **T5** is cleared, steps **9**, **10,** and **11** are simultaneously deactivated and step **12** is activated.

Variable Type Extensions

The interactions between the control part and the remaining system elements have been formalized by means of boolean input and output variables. Nevertheless, in a real system not all the variables are of the

© 2005 by CRC Press LLC

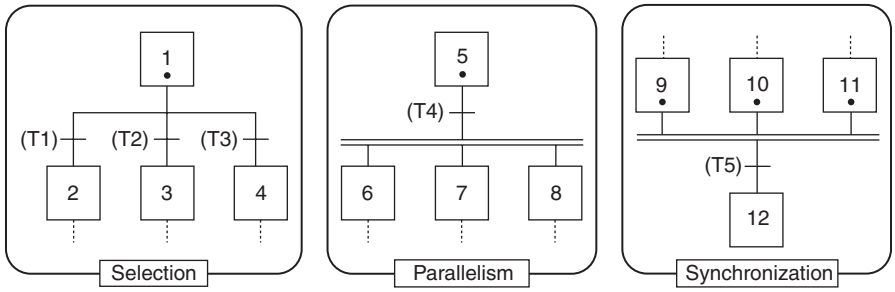

FIGURE 64.13 Sequence representation.

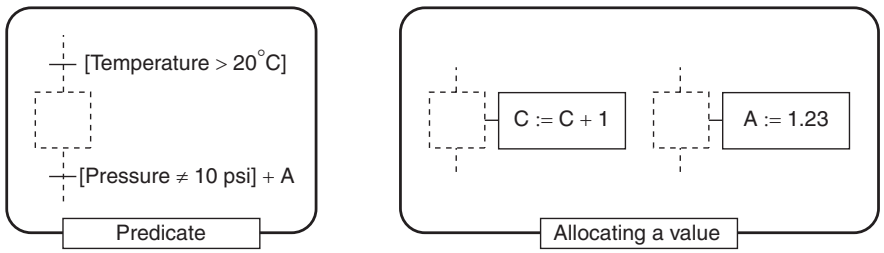

FIGURE 64.14 Predicate and allocation representation.

boolean type (e.g., temperature, pressure, counters, etc.). The system specification must include references to these non-boolean variables; otherwise, it would become inconsistent.

To overcome this limitation, GRAFCET provides an extension to the types of variables supported, without, however, establishing a formal definition of their type (e.g., integer, float, string) as classic programming languages do. Support for the extended types was achieved by naturally extending the use of boolean variables.

Since input variables are associated with transition-conditions, which are logical expressions, supporting these non-boolean input variables only requires that they be included as boolean *predicates*, graphically represented as a logical condition between square brackets (Figure 64.14).

Output variables are associated with actions. When an action is executed, a value is assigned to the variable. In the case of a boolean variable, the inclusion of its label is sufficient to establish its true value. Non-boolean variables are processed in a straightforward way, by *allocating* them a value (Figure 64.14).

Internal Variables

Another extension related with variables reflects the possibility of accessing data that are internal to the *Grafcet* structure. This is performed by distinguishing between *external* and *internal* variables:

- *External variables* are those that are external to the control part — the previously defined input and output variables.
- *Internal variables* are associated with the GRAFCET structure. For each step, a boolean variable is defined with the following syntax: **X***step_label*. When the corresponding step is active the variable takes a true value; otherwise, it is false (Figure 64.15). These *step variables* have the same application scope as boolean input variables and they are used to access the step state. They become useful when synchronizing several *Grafcets* (Section 64.6).

The logical value of a boolean expression that comprises one or several boolean variables — input variables, predicate, step variables, partial *Grafcet* variables or macrostep variables (Section 64.6) — can be represented by a *logical variable*.

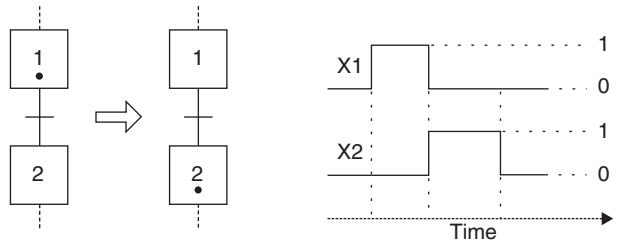

FIGURE 64.15 Step variable behavior.

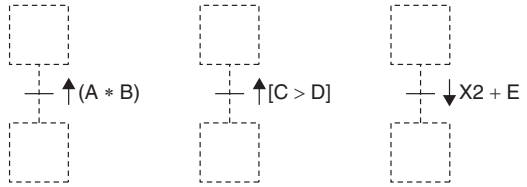

FIGURE 64.16 Input event representation.

Events

At first, it may seem that the input variable definition is sufficient to represent all the conditions that enable the *Grafcet* evolution. Nevertheless, there are scenarios where this representation is insufficient — for example, how would it be possible to express the rising edge of a variable? To overcome this, GRAFCET introduces the notion of *event*. An event is characterized by the falling or rising edge of a variable and takes a boolean value.

It is possible to distinguish between two types of events:

- *Input events*, associated with the falling or rising edge of a logical variable. When the respective edge occurs, this event takes a true value; otherwise, it is false. Since this event is related to logical variables, it has the same application scope. It is graphically represented as a ↑ (rising edge) or ↓ (falling edge) symbol, followed by the associated logical variable (Figure 64.16).
- *Internal events*, associated with a step activation, deactivation, and transition clearing. These events are closely related with *stored actions*. They are interpreted as follows: when the internal event occurs, the associated action is executed. A detailed explanation is presented in the Stored Actions Section.

Time Representation

Time plays a central role in the operation of automated systems, intervening in many aspects of their evolution. In order to track time, GRAFCET defines a *time-dependent condition*. This is a boolean condition related with an input or internal event by the notation: **T1**/*variable*/**T2**. The semantics is at follows: the condition is true after a time **T1** of the occurrence of the rising edge of the logical variable, and becomes false after a time **T2** from the occurrence of the falling edge (Figure 64.17). **T2** may be omitted. The logical value of this condition can be represented by a *timed variable*.

Time-dependent conditions have the same application scope as standard boolean conditions — transition-conditions and timed *continuous actions*.

Action Types

Actions represent the connection between the GRAFCET evolution and the system outputs. Although the action types presented until now are capable of describing the behavior of the most common output

© 2005 by CRC Press LLC

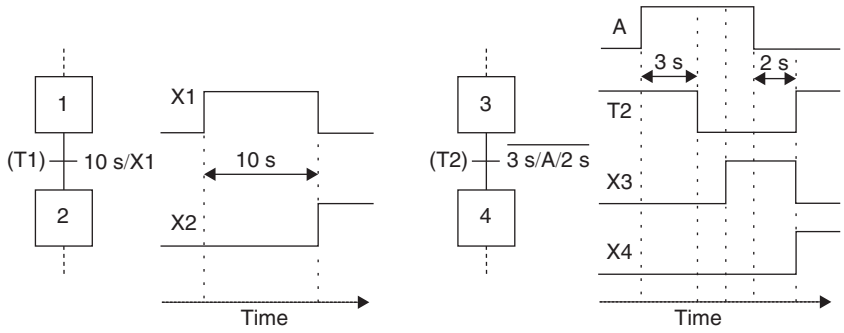

FIGURE 64.17 Time-dependent condition behavior.

types — on, off, assigning a value — they cannot represent more complex behaviors, such as timed or event actions. GRAFCET approaches this issue by extending the basic action definition into *continuous* and *stored actions*.

Continuous Actions

Continuous actions are continuously executed while an associated *assignation condition* is true. This boolean assignation condition has the same characteristics of a logical or timed variable. When the assignation condition is true, and the step associated to the action is active, a true value is assigned to the boolean output variable referenced in the action. Otherwise, the output variable value is considered false. If the assignation condition is omitted, it is considered as always true, which corresponds to the basic action definition.

A continuous action is graphically represented as a basic action with the assignation condition placed at the right of a vertical line, which is connected to the action. Some application examples are presented in Figure 64.18.

Stored Actions

Stored actions are only executed when an event occurs. A value is allocated to the output variable indicated in the action whenever the event occurs. The output variable remains unchanged until a new allocation modifies its value. Typically, this kind of action is used to process non-boolean data such as incrementing/decrementing counters, computing expressions, starting of internal tasks, etc.

A stored action is graphically represented as basic action with symbols referring to the event type. Some application examples are presented in Figure 64.19.

Output Values

From the previous discussions, the output variables behavior results as follows:

Continuous actions. For a given situation, the value of the outputs variables is assigned:

- to the true value, for each output related to an action associated with an active step for which the assignation condition is true.
- to the false value, for the remaining outputs.

Stored actions. The output variable is allocated to a value when the associated event occurs, and remains unchanged until a new allocation is performed.

When an output variable is referred in more than one action, a conflict could occur if there are actions being simultaneously executed and if a contradictory assignment or allocation is performed. This problem can only be circumvented if the system designer takes the necessary measures to avoid it; otherwise, an inconsistent behavior results.

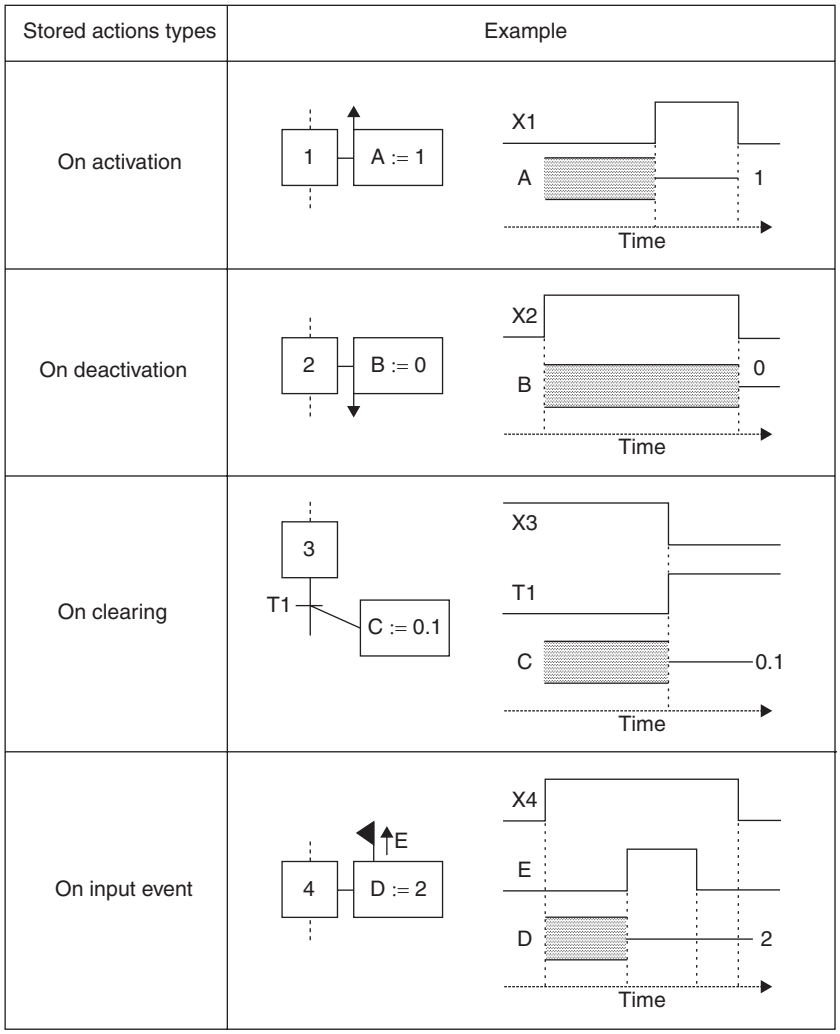

FIGURE 64.19 Stored actions.

Particular Structures

Some GRAFCET structures represent an exception to the *alternation step-transition* rule (Figure 64.20). Their use is associated with the implementation of hierarchical *Grafcets* (Section 64.6), and can be classified as follows:

- *Source step*, is characterized by the absence of any preceding transition.
- *Pit step*, is characterized by the absence of any succeeding transition.
- *Source transition* does not have any preceding step. It is assumed that it is always enabled, being cleared when its condition-transition is true.
- *Pit transition* does not have any succeeding step.

Graphical Composition

Like any other language, GRAFCET includes some elements that help the reader to have a clear description of the charts either textually, using *comments,* or graphically – using *page references* (Figure 64.21).

© 2005 by CRC Press LLC

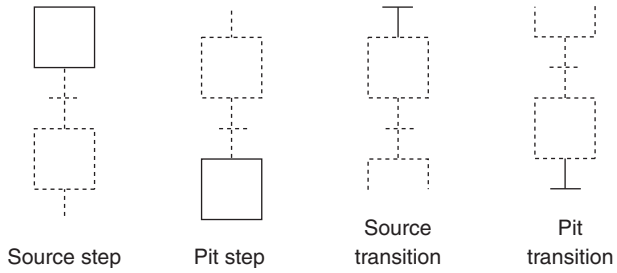

FIGURE 64.20 Particular structures.

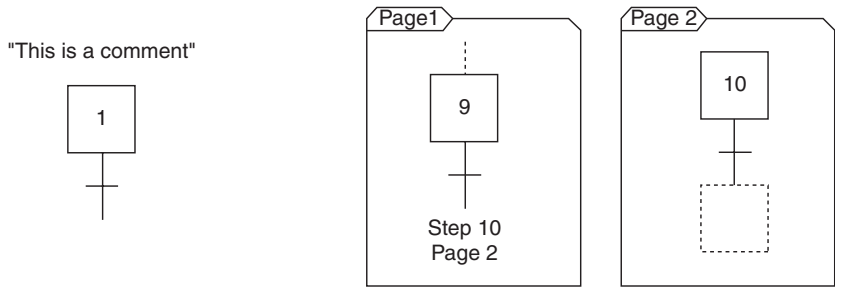

FIGURE 64.21 Graphical composition.

Tank Filling Example (II)

Let us now consider the following extensions to the specifications of the tank system presented previously. The system is now composed of two tanks used in a similar way (Figure 64.22), with the following changes:

1. The filling process is triggered by the rising edge of **S**.
2. Both tanks are filled simultaneously.
3. Filling may only start up again when both tanks are empty.
4. **V1** is closed only 2 seconds after **H1** becomes active.
5. **W2** is opened only 10 sec after **H2** becomes active.

A *Grafcet* that meets these specifications[8] is presented in Figure 64.22. Initially, with **step 1** active, the system waits for button **S** to be pressed. When this occurs, the event ↑**S** becomes true, and **steps 2** and **6** are simultaneously activated. This initiates two parallel sequences where both tanks are filled.

On the left sequence, **step 2** is activated and a stored action is used to open **V1**. When **H1** becomes true, **V1** is closed 2 seconds after that. This delay is represented by **step 3** and the time-dependent condition-transition **T3**. When **T3** is cleared, **V1** is closed by a stored action. Immediately, **step 4** is activated and the associated action, open **W1,** is executed. The tank **1** is maintained in this situation until **L1** becomes true. When this happens, **step 5** is activated and **W1** is closed. This is a waiting step required to allow synchronization between tanks.

In the sequence on the right, **step 6** is activated and the associated action, open **V2,** is executed. When **H2** becomes true, **step 7** is activated and **V2** is closed. This step has a delayed action, open **W2,** which is only executed 10 seconds after its activation. The tank **2** is maintained in this situation until **L2** becomes true. When this happens, **step 8** is activated and **W2** is closed. Just like with the sequence on the left, a waiting step is required to synchronize behaviors.

[8] Our aim is to present several alternative solutions, and not necessarily the simplest one.

© 2005 by CRC Press LLC

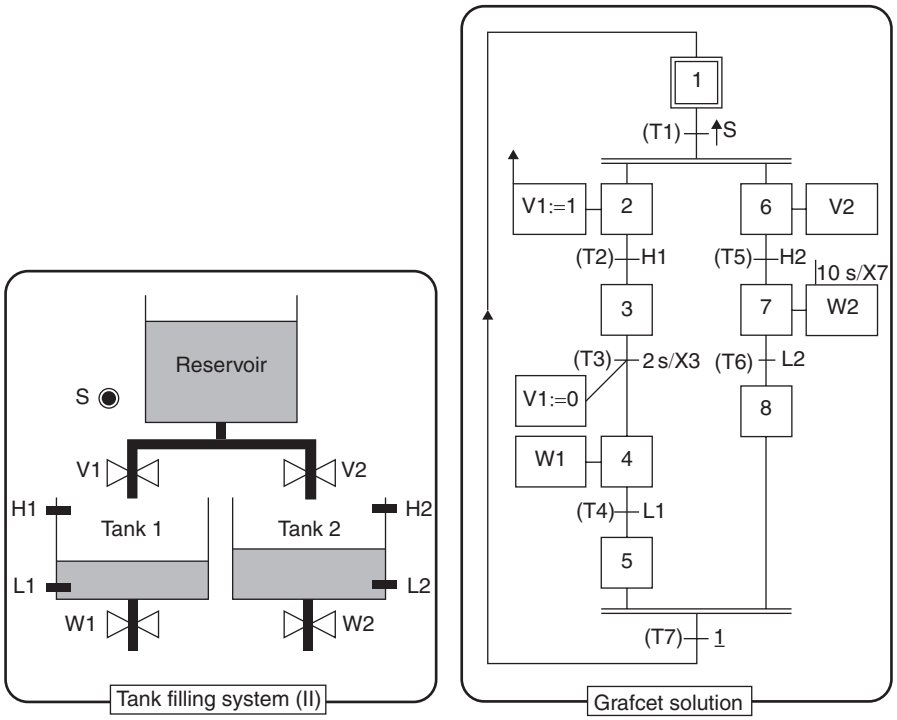

FIGURE 64.22 Tank filling example (II).

When both tanks are empty — **steps 5** and **8** are both activated — the system immediately returns to the initial situation. This is achieved by using a synchronization structure associated to a transition, **T7,** with a condition that is always true.

64.6 Hierarchical Grafcets

Some automated systems present very complex behavior. In these cases, an attempt to model the behavior using a single abstraction level results in a model almost impossible to understand. To overcome these scenarios, system designers usually use a methodology based on a top-down approach, which decomposes a single complex system in several less complex subsystems. This results in several advantages, such as: (i) better specifications, since the behavior of any subsystem is easier to understand; (ii) definition of different detail levels, which helps to identify the relationships between subsystems; and (iii) reuse of specifications — if a subsystem is replicated, a single specification suffices.

In order to support this methodology, GRAFCET defines *hierarchical Grafcets*. Using this approach, a complex *Grafcet* is decomposed into smaller ones, *partial Grafcets,* each representing part of the system behavior. Since a hierarchical relationship exists between *Grafcets,* it is naturally asymmetrical, with high-level *Grafcets* sending commands to the lower ones, and accessing their internal situation. These mechanisms allow the *Grafcets* to synchronize their evolutions (Figure 64.23).

A partial *Grafcet* is formed by one or several *connected Grafcets*. A connected *Grafcet* is one where there is always a continuity of links between any pair of elements (steps or transitions). It is identified by means of a name, with the following syntax: G*name*. Figure 64.24 presents two partial *Grafcets*, G1 with a single connected *Grafcet* and G2 with two connected *Grafcets*.

The global state of a partial *Grafcet* is represented by a boolean variable, **XG***name,* which is true if at least one of their steps is active. Their internal situation is represented by G*name*{*steps*}, where *steps* is a list of the currently active steps. Some application examples are presented in Figure 64.24.

© 2005 by CRC Press LLC

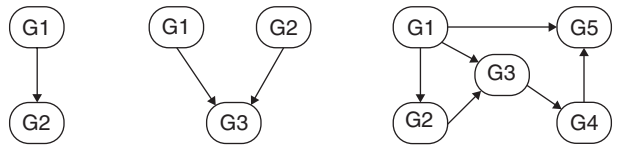

FIGURE 64.23 Hierarchical *Grafcets*.

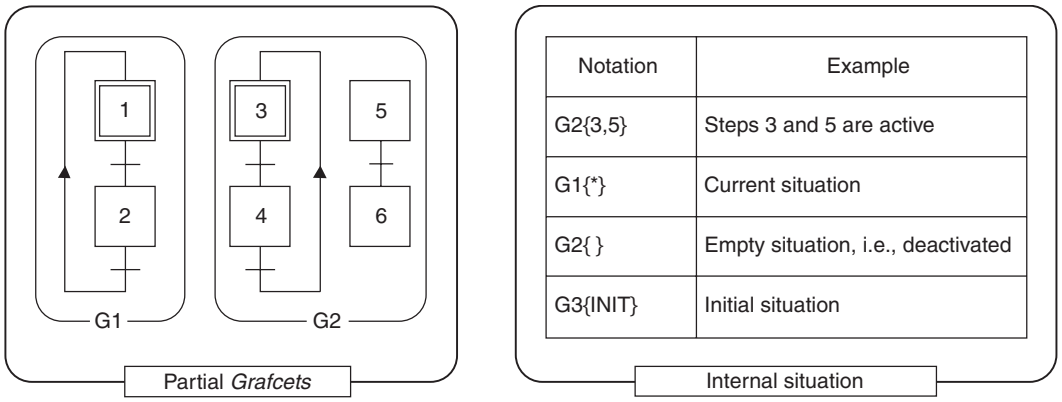

FIGURE 64.24 Partial *Grafcet* representation.

As stated previously, structured *Grafcets* need to synchronize their evolution. The GRAFCET notation was therefore extended in order to allow a partial *Grafcet* to modify the current situation of another partial *Grafcet*. The following subsections present the three distinct mechanisms that were defined to support this feature.

Forcing

With this approach, a partial G*rafcet* forces another to a specific situation. This is accomplished by associating a *forcing order* to a step. While the step is active the order is continually executed. It has precedence over the evolution rules and during their execution the forced *Grafcet* cannot evolve. This is referred as a *frozen Grafcet*.

A forcing order is graphically represented as a basic action, but with a double rectangle to distinguish it. Some application examples are presented in Figure 64.25.

Enclosure

An enclosure is an alternative to forcing. It is more powerful, although a bit more complex. The concept is based on the definition of an *enclosure* — a set of steps that are enclosed in an *enclosing step*. The set of enclosed steps can be considered a *partial Grafcet*.

The enclosing step has the same properties of a basic step and a similar graphical representation, but with an octagon inside it (Figure 64.26). The enclosure is graphically represented as partial *Grafcet* inside a rectangle, which has two labels referring to the enclosing step and the enclosure name.

When the enclosing step is activated, the steps in the enclosure identified by an *activation link* are also activated. This activation initiates the evolution of the partial *Grafcet*. When the enclosing step is deactivated, all steps in the enclosure are also deactivated. The activation link is graphically represented by an asterisk "*"at the left of the enclosed steps (Figure 64.26). This behavior is analogous to the release of a task in a programming language.

© 2005 by CRC Press LLC

Forcing orders types	Description
	While step 1 is active, Grafcet G2 is forced to a situation where steps 1, 2, and 3 are active.
	While step 2 is active, Grafcet G3 is forced to the same situation it was in when step 2 became active.
	While step 3 is active, Grafcet G4 is deactivated, i.e., it is forced to the empty situation.

FIGURE 64.25 Forcing orders.

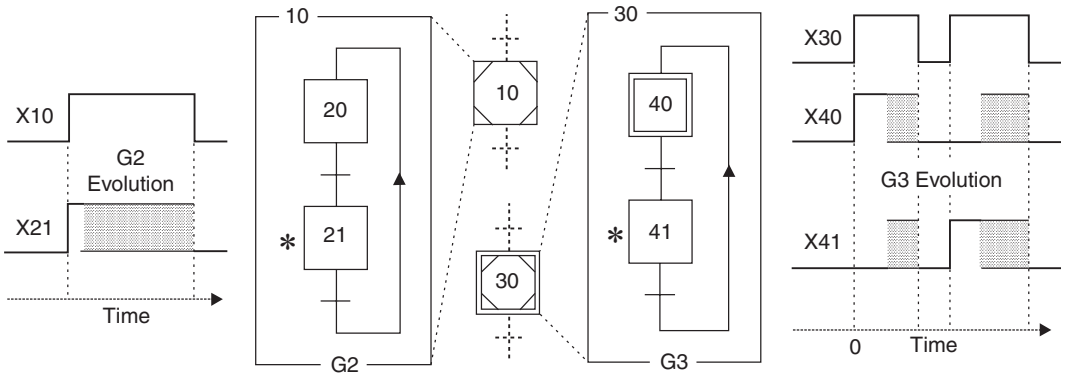

FIGURE 64.26 Enclosure representation.

An enclosure participates in the initial situation if, at least, one of the enclosed steps in each of its enclosures is also an initial step. In this scenario ($t = 0$), only the initial steps are activated (and not the activation links), the enclosure evolution being defined by the standard *Grafcet* rules. However, if the initial enclosing step is deactivated, the enclosure is also deactivated. Posterior reactivations of the enclosing step follow the defined enclosure activation rules (Figure 64.26). Its graphical representation results from merging both the initial and enclosure step representations.

An enclosing step can contain several enclosures simultaneously, which enables the parallel execution of several partial *Grafcets*. An enclosure can itself contain other enclosures, enabling the modeling of hierarchical abstraction layers.

MacroSteps

A partial *Grafcet* may be encapsulated by a special step, referred as a *macrostep,* which when activated, is expanded and substituted by the partial *Grafcet* (Figure 64.27). This encapsulation allows a gradual

© 2005 by CRC Press LLC

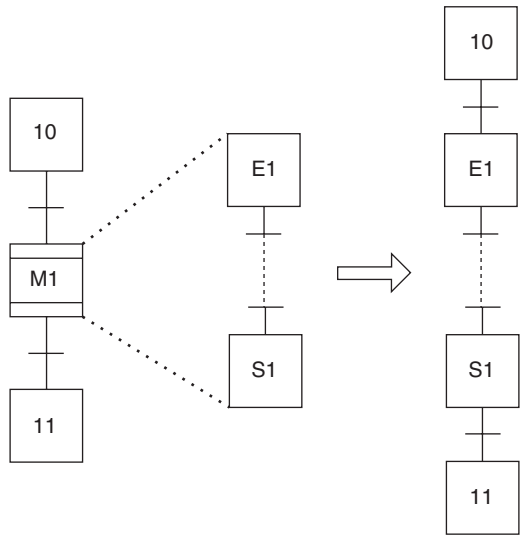

FIGURE 64.27 Macro-step representation.

description from general to particular, with a behavior analogous to the execution of a subroutine in a classical programming language.

To perform this expansion, the partial *Grafcet* must have a particular structure, being initiated by an *entry step*, and terminated by an *exit step*. The entry step becomes active when one of the preceding transitions of the macrostep is cleared. The succeeding transitions of the macrostep are enabled when the exit step becomes active. The expansion of a macrostep can have initial steps, and can recursively include other macrosteps.

A macrostep is graphically represented as a basic step with two horizontal bars inside, and is identified by means of a label with the following syntax: M*label*. Their global state is represented by a boolean variable, XM*label,* which is true if at least one of the encapsulated steps is active.

Tank Filling Example (III)

Consider the following extensions to the system specified in Tank filling example (II):

(i) A suspend–resume button (**SR**) that when activated suspends the filling operation. If **SR** is once again activated, the operation is resumed.
(ii) An emergency button (**EM**) that when activated forces the system to the initial situation. This button has priority over all others.

The *Grafcet* that meets these specifications is presented[9] in Figure 64.28. The system behavior is structured through the use of three *Grafcets* in a hierarchical relationship — **G1**, **G2,** and **G3**.

The *Grafcet* **G1** is at the highest level, and related to the operation of the emergency button (**EM**). On the second level, *Grafcet* **G2** describes the operation of the suspend-resume button (**SR**). Finally, *Grafcet* **G3** describes the tank filling operation. Initially **steps 1**, **21,** and **31** are active. This initiates the independent evolution of *Grafcets* **G1**, **G2,** and **G3**.

When the emergency button (**EM**) is pressed, **step 2** is activated, which disables the enclosure **G2** and executes a forcing order on *Grafcet* **G3**, forcing it to its initial situation. During this period, any activations of the start button (**S**) or the suspend–resume button (**SR**) are ignored, since **G3** is frozen and **G2**

[9] Our aim is to present several alternative solutions, and not necessarily the simplest one.

© 2005 by CRC Press LLC

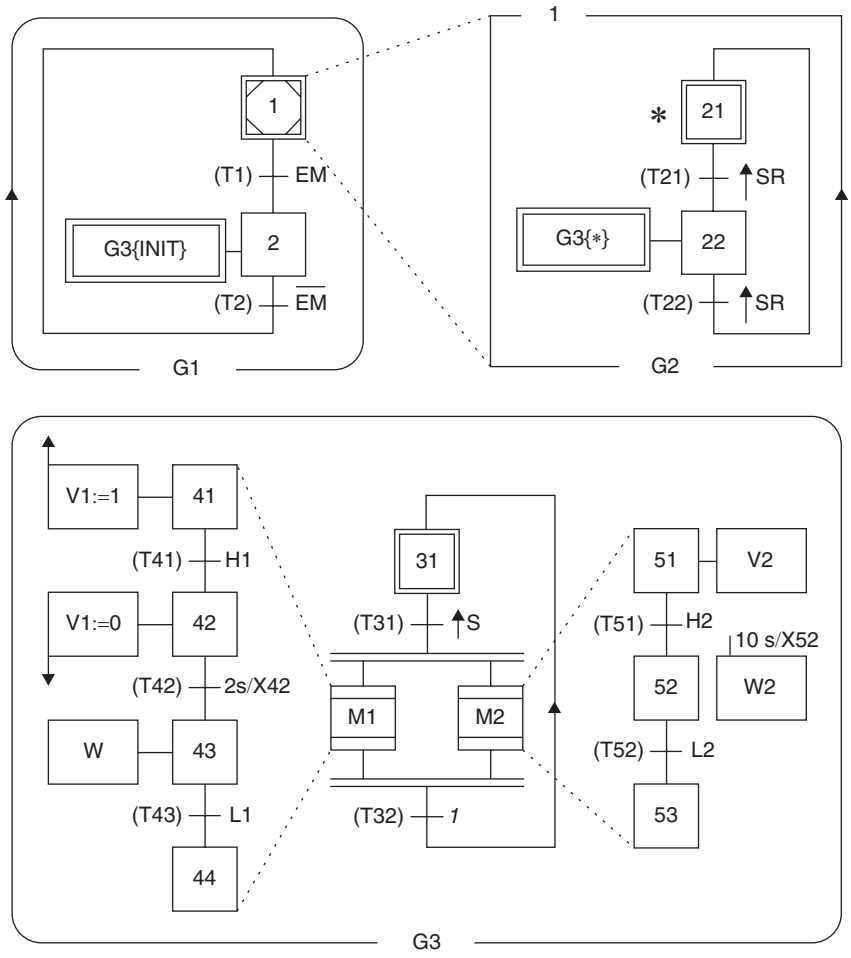

FIGURE 64.28 Example (III): *Grafcet* solution.

is deactivated. When the emergency button (**EM**) is released, the system returns to the initial situation. Since **step 1** is also an enclosing step, its activation initiates the evolution of enclosure **G2** by activating **step 21**.

If during normal system operation the suspend–resume button (**SR**) is pressed, **step 22** is activated. Since its associated action is a freezing order, *Grafcet* **G3** cannot evolve and maintains the current situation. If during this order it is necessary to disable all output variables, then the use of *conditional actions* must be employed. Therefore, the internal variable XZZ should be used as an *assigmation condition* of the actions in steps 41, 42, 51 and 52. For clearance reasons this is ommited. When the suspend–resume button (**SR**) is pressed once again, *Grafcet* **G3** is allowed to resume its normal evolution.

Grafcet **G3** has a structure similar to the example presented in the Tank filling example (II) section, with the exception that the parallel sequences were replaced by macrosteps.

65.1 Introduction

The proliferation of Programmable Logic Controllers (PLCs) used in an industrial setting is indicative of their usefulness. These have evolved with the times, to the point that many modern top-of-the-range PLCs are actually full-fledged computers in disguise, executing modern operating systems. The programming languages with which the PLCs are programmed have also evolved with time, simultaneously becoming more powerful and complex. Nevertheless, and unlike the hardware, the programming languages used between different vendors were diverging, leading to longer learning times for the programmer when switching between PLCs.

To this end, the International Electrotechnical Commission (IEC), an international standards body, has approved a collection of standards with the intention of creating a common user experience when configuring and programming industrial controllers. One of the components of this standard, namely the IEC 61131-3 [1], refers to the programming languages.

This chapter is an introduction to the IEC 61131-3 programming languages, but assumes that the reader has previous knowledge of other procedural programming languages. Although the main aspects

© 2005 by CRC Press LLC

of the languages are described, a complete description of the languages' syntax is beyond the scope of this chapter. Readers wishing to program using these languages may use the examples in this chapter as a starting point, but are nevertheless advised to read a manual or book [2, 3] with a complete description of the IEC 61131-3 languages.

The IEC 61131 Standards

The IEC 61131 standard has its origins in 1979, when an international committee was formed with the intention of generating a standard for a common user interface for PLCs. In 1982, this committee came up with a draft that was so complex that it was then decided to divide it into five parts. The IEC 61131 standard may therefore be better described as a general framework that tries to establish the rules to which all PLCs should adhere to, encompassing mechanical, electrical, and logical aspects, and consisting of five parts: part 1 — general information; part 2 — equipment and testing requirements; part 3 — programming languages; part 4 — user guidelines; and part 5 — communications.

The third part (IEC 61131-3) deals with the programming aspect of the industrial controllers and defines the programming model, composed of three program organization units and five programming languages. The first version of part 3 was approved in March 1993. This was later revised and extended, resulting in a second edition of the standard being published in early 2003.

65.2 IEC 61131-3 Programming Basics

The IEC 61131-3 standard, which shall henceforth be referred to as simply the standard for brevity, specifies four distinct programming languages. Additionally, it also defines a state machine specification language, which is considered by many as a fifth programming language.

More importantly though, the standard also specifies basic building blocks (referred to as Program Organization Units in the standard), which may be composed into other more complex building blocks, and ultimately, the intended program. The building blocks fall into one of three types: functions, function blocks, or programs. An IEC 61131-3 programming environment comes with predefined functions and function blocks, commonly referred to as basic building blocks. A user may also program new building blocks, of any type, using any of the programming languages.

All languages support the same data types. This allows the programming language used to program the building blocks to be decoupled from the programming language used to access the building block. In other words, a building block written in one language may be called from any other programming language, without having to deal with issues of converting data types between the two languages.

It should be noted, however, that the languages are not completely interchangeable. Although a one-to-one mapping between any two languages may be defined for most of the syntax of these languages, each programming language has some features that do not map directly to the syntax of the others. This, of course, implies that some languages are better suited to specific tasks than others.

Building Blocks

As already mentioned, there are three variations of building blocks: functions, function block types, and program types. All three consist of a variable declaration part, and a code part. Variables may have local scope, that is, they are only accessible from within the building block in which they are declared, or may be input and output parameters of the building block. The code part is specified using the programming languages defined in the standard. The code may contain calls to other building blocks, with the restriction that functions may only call other functions, while programs and function blocks may call other functions or function blocks (Figure 65.1). In any of the three types of building blocks, the code part may not include recursive calling of the building block itself, either directly or indirectly through the call of another building block.

Functions have semantics similar to those in traditional procedural languages, and directly return a single output value. However, besides one or more input values (equivalent to variables passed as values),

© 2005 by CRC Press LLC

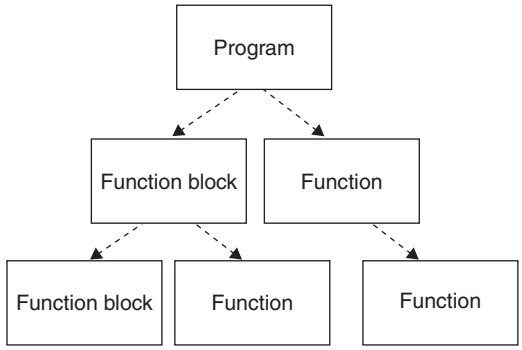

FIGURE 65.1 Calling of building blocks from within other building blocks.

the function may also have parameters used as outputs (equivalent to passing variables as references), or as input and output simultaneously. Functions may also have local private variables. This is a change from the first version of the standard, which only allows a function to have input parameters and local private variables.

Function semantics state that they are idem potent, that is, all invocations of the same function with the same input values should always yield the exact same result, whatever the state of the rest of the system, including the time at which the function is executed. When calling a function, it is not necessary to specify all the function parameters. Unspecified parameters are automatically set to their default values.

Function block types are similar to classes in object-oriented languages, with the limitation of not supporting inheritance, and having a single default public member function and no constructors or destructors. Function blocks are instantiated as variables, each with their own copy of the function block state. The default function of a function block does not directly return any value, but, like functions, may have parameters to pass data as input, output, or bidirectional. Since the function block has only a single function, calling this function is commonly referred to as "calling the function block." Likewise, this function's parameters are often referred to as the function block parameters.

When calling a function block, it is once again not necessary to specify all the parameters. Nevertheless, unlike functions, unspecified parameters are not reinitialized to their default parameters but rather retain their values of the previous call (unless it is the first time the function block is being called, in which case the default values are used). The function block parameters may therefore be said to be persistent between calls. The output and bidirectional (simultaneously input and output) parameters may be read directly from outside the function block, but may not be written to. On the other hand, input parameters may only be given new values during a function block call.

Internal variables may be persistent or temporary, but may only be accessed from within the function block itself. Temporary variables are initialized to their default values every time the function block is called, unlike persistent variables whose values remain unchanged between calls.

Since a function must be idem-potent, it can neither instantiate nor call a function block instance. It may, however, access the current values of the output or bidirectional parameters of a function block. Note that in this case the function block instance must be passed to the function as an input parameter, since a function may not instantiate a function block itself.

Program types are very similar to function blocks, with the exception that these may only be instantiated inside a configuration, and not inside other functions, function block types, or program types. Configurations are described in more detail in Section 65.7.

Figure 65.2 shows an example of interface definitions of a function, function block, and program. The text delimited by "(*' and '*)" are comments, and are ignored by the compilers. Variable declarations may be appear in any order, with local, temporary, and interface variables intermingled. Nevertheless, these appear separated in the examples to make it easier to identify the building block parameters.

FIGURE 65.2 Examples of building block declarations.

Language Overview

The five programming languages are

ST — Structured Text
IL — Instruction List
LD — Ladder
FBD — Function Block Diagram
SFC — Sequential Function Chart

Of these, LD and FBD are graphical-based languages, while ST and IL are text based. Programming with SFC may be either graphical or text based, although the text version is hardly ever used. It should be noted that the IL language is also commonly referred to as STL (Statement List). This latter nomenclature, however, is not defined in the standard, and its use should therefore be deprecated.

Programming in LD is similar to designing a relay-based electrical circuit. In fact, this language exists specifically to accommodate electrical technicians with little to no programming knowledge and skills. It can be said that LD is a historical artifact. The first PLCs were competing with existing control equipment based on hardwired relay circuits, and therefore adopted a language similar to the electrical circuits in order to ease platform acceptance by the existing technicians.

An LD program is composed of horizontal rungs connecting two vertical power rails. A rung consists of one or more relay contacts connected in series or parallel, in essence expressing a logic function, and at least one relay coil (see Figures 65.3 and 65.4), representing the variable in which the result of the logic function will be stored. The standard has also extended the language to allow calling of other building blocks (functions or function block instances), and to handle referencing data in variables more powerful than the simple Boolean type, such as analog values, counters, and timers.

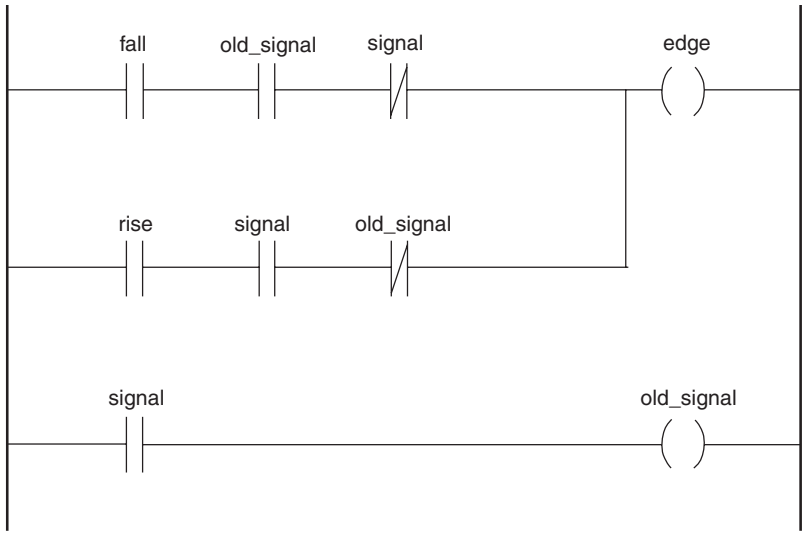

FIGURE 65.4 Example of an LD program.

The graphical FBD sits at the other extreme; a very high-level language where the user simply places boxes representing the building blocks (functions or function blocks), and defines data exchange between these blocks by drawing lines connecting the outputs and inputs of the boxes (see Figures 65.3 and 65.5). Inputs are typically drawn on the left-hand side of the boxes, while outputs are drawn on the right-hand side. Bidirectional parameters (input and output) appear on both sides, and are connected by a line within the box. The standard specifies basic building blocks that implement the basic logic operations,

© 2005 by CRC Press LLC

counters, and timers, which makes this programming language somewhat similar to designing a digital electrical circuit based on logic gates, counters, and timers.

The IL language is a low-level programming language similar to assembly. It consists of a list of simple instructions, with an optional parameter. The instruction is an operation on the value stored in a default register, and using the optional parameter, with the result being stored back in the same default register (see Figures 65.3 and 65.6). Like LD, this language has also been extended to handle calling of functions and function blocks, and deal with complex data variables.

ST caters to the user with more knowledge in Computer Science. It is a procedural language consisting of a list of statements (see Figures 65.3 and 65.7). Assignment statements may contain expressions on the right-hand side. In turn, expressions may contain calls to functions, while function block calls, which do not return a value, constitute a single statement. Iteration statements such as FOR, WHILE, and REPEAT as well as flow control statements such as IF THEN, ELSE, and CASE are supported.

Both text-based languages (ST and IL) share the same syntax for declaring the interfaces to programming building blocks, as well as for the declaration of derived data types.

The SFC is a graphical language for specifying state machines, mostly based on Grafcet. Grafcet originated in France in the 1970s and was later standardized by the IEC itself in IEC 60848 (See Chapter 64). In SFC, states of the state machine are called steps. Any number of steps may be active or deactivated at any one time. Directed links between the steps convey the step activation sequence. Between any two linked steps, exactly one transition must be placed. Likewise, between any two linked transitions, exactly one step must be found. A transition is enabled when all the preceding steps (connected to the transition by directed links) are simultaneously active. A transition may fire only when it is enabled, and when a condition associated with it is true. Firing of a transition has the effect of deactivating all preceding steps, and simultaneously activating all successor steps. One or more actions may be associated with each step. Actions are only executed while the step is active. The conditions associated with the transitions, as well as the actions associated with the steps may be specified in any one of the remaining IEC 61131-3 languages, that is, in IL, ST, FBD, or LD. Additionally, actions may also be specified using another SFC. It should be noted that without reverting to the other languages it is not possible to write a complete program using only an SFC chart.

Data Types

As stated previously, all programming languages support the same data types. Supported elementary data types, along with their size, are listed in Figure 65.8.

Note how the standard supports data types to handle time and the passing of time. The TIME_OF_DAY data type is used for absolute times in the day, such as the time to sound the siren marking the end of the shift. The TIME data type is used for relative times, such as periods, offsets, and the difference between two TIME_OF_DAYs.

All data types have a default value. This default value is used when variables are created (unless otherwise specified), and when calling a building block for parameters for which no explicit value is specified.

Derived data types are also supported. The most simple of these is a data type based on a previously defined data type and with a new default value. Besides these, the user may define subranges, enumerations, arrays, and structures. The standard does not include syntax for declaring derived data types in

Data Type	Size (bytes)	Default Value
Boolean		FALSE
Byte	1	0
Word	2	0
DWord	4	0
LWord	8	0
SINT / USINT	1	0
INT / UINT	2	0
DINT / UDINT	4	0
LINT / ULINT	8	0
Real	4	0
LReal	8	0
String	1 (per character)	'' (empty string)
WString	2 (per character)	"" (empty string)
Time	(implementation dependent)	T#0S
Time_of_Day	(implementation dependent)	TOD#00:00:00
Date	(implementation dependent)	D#0001-01-01
Date_and_Time	(implementation dependent)	DT#0001-01-01-00:00:00

FIGURE 65.8 Data types.

© 2005 by CRC Press LLC

graphical languages, from which one may surmise that these must therefore be defined using the syntax defined for the text-based languages. In practice, however, existing programming environments allow the programmer to define the new data types through the use of graphical interfaces such as pull-down menus, lists, etc. This, of course, is not standardized.

Subranges may only be defined based on elementary integer types. Subranges based on derived integer types are not supported, including subranges of subranges. Their default value is the lowest value in the subrange, unless otherwise specified.

Data types consisting of an enumeration of possible values use the first value for the default, unless otherwise specified. The names of the values in an enumeration may be reused for other constructs such as variable names, function names, etc. In these cases, and when being used in an expression, the enumeration value may be qualified by the enumeration type in order to resolve any ambiguities.

Structures are aggregates of variables of possibly different types, and arrays sequences of variables of the same type, both similar to constructs available in other languages such as C and Java. Default values for arrays may contain different values for each element of the array. Arrays may be defined of any data type, which excludes arrays of a function block type, as function blocks are not considered a data type.

Variable Location

Before the IEC 61131-3 standard, it was common for the PLC memory to be divided into blocks, and the physical inputs and outputs to be mapped onto specific memory blocks. When using variables while programming these PLCs, the variables had to be explicitly mapped onto a memory offset in a specific memory block by the programmer.

The IEC 61131-3 standard replaces this with a programming model where the programmer merely declares the variables required, and memory allocation is done automatically by the underlying operating system, or the compiler/interpreter. Nevertheless, in order to be able to access the physical inputs and outputs of the PLC (which are still mapped to memory locations), the standard allows the explicit declaration of the memory location of variables that are declared in function blocks, programs, and configurations. Functions may not access these directly mapped variables as their value may change between calls, destroying the idem-potency property of functions. Directly mapped variables may nevertheless be passed as parameters to functions.

Variables may also be explicitly declared to be retainable or nonretainable. Retainable variables will not lose their values after a power-off/power-on cycle, while nonretainable variables are guaranteed to be reset to their default values after a PLC reset.

65.3 Programming in ST

An ST program consists of a sequence of statements, each ended by a semicolon. The most basic statements are the function block call, and the assignment statement (i.e., assigning the value of an expression to a variable).

Variables may be replaced by expressions in most locations except on the left-hand side of an assignment statement. Expressions may contain logic operators (including exclusive or), comparison, and arithmetic operators (including an exponentiation operator), besides function calls. They are evaluated from left to right, and Boolean expressions may be evaluated only to the extent necessary to determine the resultant value.

A function or function block call may follow either the formal or the nonformal method of specifying parameters. In the nonformal method, the parameters are attributed values in a comma-separated list, in the same order in which they were declared in the function or function block type declaration.

In the formal method, the parameters are assigned values in a comma-separated list of assignment statements, where the assignment symbol changes from ":=" for input and in_out parameters, to "=>" for output parameters. In this case, the parameters may be given values in any order, and a full parameter list is not required. In function calls, the remaining parameters are given their default values, while in

© 2005 by CRC Press LLC

function block calls the parameters retain their previous values. Additionally, calls to functions require at least one parameter, while calls to function blocks may be made with an empty parameter list.

The language includes two selection statements, if and case, whose syntax may be found in Figure 65.9, expressed in BNF.

Three iteration statements are also supported: for, while, and repeat. Their syntax may be found in Figure 65.10. All selection and iteration statements have similar semantics as found in other languages such as Pascal, C, and Java.

The last two statements of the ST language allow early exiting from a building block (RETURN) and early exit from the innermost iteration loop (EXIT).

An important consideration is that PLC programs are executed cyclically, and therefore should run to completion as soon as possible. For this reason, the while and repeat iteration loops should not be used for synchronization purposes, for example, by waiting on a physical input until it changes state. Synchronization should only be implemented using SFC (with conditions associated to transitions), this because an SFC program is typically compiled to test the conditions on each execution cycle, and not block on that condition.

A further issue is that, unlike the first version of the standard, the second version does not define the IL operators as reserved words. This means that it should be possible to declare variables, functions, and function block types with names that clash with the IL operators such as LD, LDN, ADD, etc. Current IEC 61131-3 compilers were based on the first version of the standard and do not accept such use of these keywords, even though the generated error messages may be somewhat cryptic and difficult to understand. We strongly recommend not using IL operators as described above, even in compilers based on the standard's second version, since using it may lead to ambiguities.

```
IF <expression> THEN <statement_list>
{ELSEIF <expression> THEN <statement_list>}
[ELSE <statement_list>]
END_IF

CASE <expression> OF
<case_list> : <statement_list>
{<case_list> : <statement_list>}
[ELSE <statement_list>]
END_CASE

case_list: <value> {, <value>}
```

65.4 Programming in IL

An IL program consists of a sequence of instructions, one per line. Each instruction may be preceded by an optional label, and followed by an optional instruction modifier and an optional parameter. Each instruction typically executes an operation on the value stored within a default register, and possibly the optional operand, and stores the result back in the same default register. The operand may take the form of a variable name or a literal value.

The most basic instructions copy the operand to the register (LD), or the value in the register to the operand (ST). Other simple instructions may be executed or not, depending on the current value in the default register. This is the case of the set (S) and reset (R) instructions that will set or reset the operand if the register contains the Boolean true value, or simply not do anything otherwise.

Binary logic instructions (AND, OR, XOR, ANDN, ORN, XORN) operate on the register and the operand, and store the result back in the register. The same occurs with the arithmetic instructions (ADD, SUB, MUL, DIV, MOD) and comparison instructions (EQ, NE, GT, GE, LT, LE). For these instructions, the type of value currently stored in the default register has to match the type of value of the operand, for example, it is an error to try and execute a logical instruction (AND, OR, ...) when the default register does not currently contain a boolean value.

The above instructions may be followed by the "(" modifier, in which case the operand is not required. This will result in the current value of the register being pushed onto a last-in-first-out stack, and a new sequence of instructions executed. Only when the corresponding ")" is found by itself in a line is the instruction behind the "(" modifier executed, using as operands the value at the top of the stack and the value in the default register.

The sequence of instruction execution may be changed with the JMP <label> instruction, which jumps to the instruction that is preceded by the specified label. Similarly, the RET instruction exits from the current building block. Both these instructions may be modified by the C (e.g., JMPC) or CN (e.g., RETCN) modifiers, in which case they will only be executed if the default register currently contains the boolean true value in the case of C, or false value if CN is used.

In IL, a function is called by placing the function name in the operator field, followed by a parameter list (see Figure 65.11). Similar to ST, a function may be called using either the nonformal or formal

```
(* Calling function LIMIT *)
(* assume LIMIT requires 3
 * parameters...
 *)

(* Using formal argument list *)
LIMIT (
  in  := 1,
  min := 2,
  max := 3
)
ST result

(* Using non-formal argument list *)
LD 1
LIMIT 2, 3
ST result
```

FIGURE 65.11 Calling functions from IL.

© 2005 by CRC Press LLC

method. However, and unlike ST, in the nonformal method the first parameter is taken from the value stored in the default register. In either case, the value returned by the function call will be stored back in the default register.

Function blocks may be called using one of four options (see Figure 65.12). Three of these options require the use of the CAL operator, which may be followed by the C or CN modifiers. Using CAL, the function block parameters are passed using: (1) a formal argument list, (2) a nonformal argument list, and (3) storing of the parameters in the input variables, followed by reading of the output variables. The third option is an exception to the previously mentioned rule stating that values to the input parameters may only be attributed during a function block call.

The fourth option only supports calling any of the following function blocks defined in the standard library: R_TRIG and F_TRIG (rising and falling edge detector, respectively), CTU, CTD, CTUD (up, down, and up-down counter, respectively), TP, TON, TOFF (pulse, on-delay, and off-delay timers, respectively), SR and RS (bi-stable flip-flops, set and reset dominant, respectively). This fourth option uses the following special input operators that replace the CAL operator: S, S1, R, R1 (set and reset for SR and RS), CLK (clock for R_TRIG and F_TRIG), CU, CD, R, PV (count up/down, reset, and present value for counters), IN, PT (input and pulse time for timers). In this case, the value in the default register is given to the function block parameter with the same name as the input operator, all other function block parameters remain unchanged, and the function block is called. Using this method, only a single parameter of the function block may change its value between consecutive calls.

```
(* Calling function block *)
(* assume function block COUNT
 * is an instance of the CTU
 * function block type.
 * CTU has 3 input parameters: CU, R, PV
 * and 2 output parameters: Q, CV
 *)

(* Using formal argument list *)
CAL COUNT (CU:=%IX3, Q=>OUT)

(* Using non-formal argument list *)
CAL COUNT (%IX3, FALSE, A, OUT, B)

(* Using pre-loading of values *)
LD %IX3
ST COUNT.CU
CAL COUNT
LD COUNT.Q
ST OUT

(* Use of special input operators *)
LD %IX3
CU COUNT
LD COUNT.Q
ST OUT
```

65.5 Programming in FBD

As stated previously, an FBD is composed of boxes representing functions and function block instances, with lines connecting data inputs with data outputs. Data are transferred from the outputs to the inputs without any associated data retention.

The body of a function block type may contain an FBD consisting of several networks, where each network is self-contained and does not exchange data with the other networks. In this case, the order by which these networks are evaluated is either implementation defined, or may be explicitly set by the user using an implementation-defined method.

Each network is evaluated according to the following rules:

1. A function or function block is only evaluated once all the values of its inputs have already been evaluated.
2. The evaluation of a network is not complete until all its outputs have been evaluated.

Networks containing loops are allowed, that is, networks where a function or function block output is connected to one of its inputs, or the input of another function or function block that precedes it in the network. In this case, the sequence of evaluation may be defined using an implementation-dependent method. Another alternative is to explicitly specify a feedback variable in one of the output to input connections in the loop. In this case, the evaluation of the network will use the previous value of the feedback variable to determine a new value.

A name that terminates in a colon ":" may be associated to each network. This allows the transfer of program control from one network to another. Transfer of control (conditional or unconditional jump) is indicated by a Boolean signal line terminated in a double arrowhead pointing to the name of the network to which execution shall be transferred. The jump is only executed if the Boolean value of the line is true.

Return from a building block is similarly indicated by a Boolean signal line terminated by the symbol "<RETURN>." The return statement is also only executed if the value of the signal line is true.

65.6 Programming in LD

An LD diagram is composed of two vertical "power" rails, connected by horizontal rungs. A rung consists of contacts and coils connected in series or parallel (resembling an electrical circuit). The left vertical power rail is considered having "power," that is, at logical state 1. Like an electrical circuit, "power" flows from this rail to each rung.

The semantics of a contact resembles the workings of a contact in an electrical relay. It receives power from one side and, depending on the logical state of the variable associated with the contact, it may or may not allow the power to flow onwards to the other side on the right.

Similarly, the semantics of a coil resembles the workings of a coil in an electrical relay. If it receives power from the left, it activates the variable associated with the relay, and allows the power to flow onwards to the right. By connecting the contacts appropriately, and choosing the variables associated with each contact and coil, it is possible to define logical expressions.

Several variations of contacts and coils are accepted, as described in the table of Figure 65.13.

Just like FBD, LD diagrams may also be given a name terminated by a colon ":", and transfer of program control is also indicated using the same symbols (with the same semantics) as those used in FBD.

65.7 Configurations

With the building blocks described thus far, it is already possible to write complete PLC programs. While this may be sufficient for many simple applications that are controlled by a single program, applications that require a PLC with multiple CPUs also require multiple programs executing concurrently.

The standard takes this into account by defining a new modeling layer at a higher abstraction level (see Figure 65.14). This new modeling layer allows the programmer/user to specify a configuration for the

PLC with possibly multiple CPUs. A configuration contains enough information to completely specify which programs should execute in which CPUs, as well as new variables with global scope. It does not contain executable code, but rather instantiates programs and/or function blocks, creates tasks, and assigns these programs and/or function blocks to tasks.

More specifically, a configuration contains the definition of all the resources it requires, and the type of each resource. In reality, a resource is nothing other than a CPU on the PLC rack, while a resource type defines the CPU model. Each vendor is expected to provide a library of resource types that it supports.

Each resource may be attributed one or more tasks. Tasks are similar to processes in common operating systems, but are intentionally very poorly defined by the standard, which limits itself to defining how tasks should behave, but not how they should be implemented by each PLC vendor. In reality, these may be implemented as processes running on an operating system, as threads in a single process, or ultimately not at all. Tasks may be configured to execute periodically, or to execute upon the occurrence of the rising edge of a specified Boolean variable.

Each task is configured to execute one, or more, program or function block instantiations. The number of tasks a resource type supports, as well as the properties that may be applied to it (such as the period), are implementation dependent. Most simple CPUs support a single fixed task, while some may support a fixed number of two or three tasks. Currently, few CPUs permit the programmer/user to define large numbers of new tasks, which the standard allows.

Besides programs and function blocks, variables may also be instantiated inside a configuration, or inside a resource within the same configuration. The scope of variables, programs, or functions blocks instantiated within a resource is limited to that same resource.

The standard refers to variables created within a configuration or a resource as global variables. These may be accessed by the programs and function blocks created in the same configuration. Nevertheless, from the point of view of the programs or function blocks, these variables are external to them, and must be declared in the program or function block type declarations as external variables before they may be accessed. The mapping between external and global variables must be explicitly specified when instantiating a program or function block in a configuration. External variables may therefore be better viewed as references to variables instantiated outside the program or function block type.

65.8 Programming Example

The example we have chosen is a small part of a real industrial application, and consists of a conveyor that crosses three ovens. Each oven is composed of a heat exchanger, where the temperature is controlled by opening or closing a valve that regulates the amount of hot oil entering the heat exchanger. The oil is heated in a single gas burner and pumped to the ovens. To simplify matters, we consider that the valves have an analog input to control their state.

The system may work in manual or automatic mode, and may also be stopped. Manual mode allows the operator to control the position of each valve directly. This is done by using a pair of up/down pushbuttons for each valve. In automatic mode, the temperature of each oven is controlled by a PID loop, as is the temperature of the oil leaving the heater. The same up/down pushbuttons are now used to change the target temperature of each PID loop. From the above description, it is fairly obvious that the system has two main modes of operation, which should be handled at the highest level of our program. This shall be a building block of the program type, and is basically a state machine; hence, we use an SFC to define its algorithm (see Figures 65.15 and 65.16).

Notice how we have given the interface and body separately. This is because the standard itself does not specify a method to simultaneously represent both the building block interface and graphical body, which means that the method of doing so is implementation-dependent. In reality, and in most programming environments, instead of writing out the interface with the correct textual syntax, the environment allows the programmer to specify the building block interface using a graphical user interface, for e.g. a list of variables. The programmer is then expected to simply insert the variable names and use drop-down menus to choose the data types, data direction (input, output, or in_out), etc. Defining the body usually involves

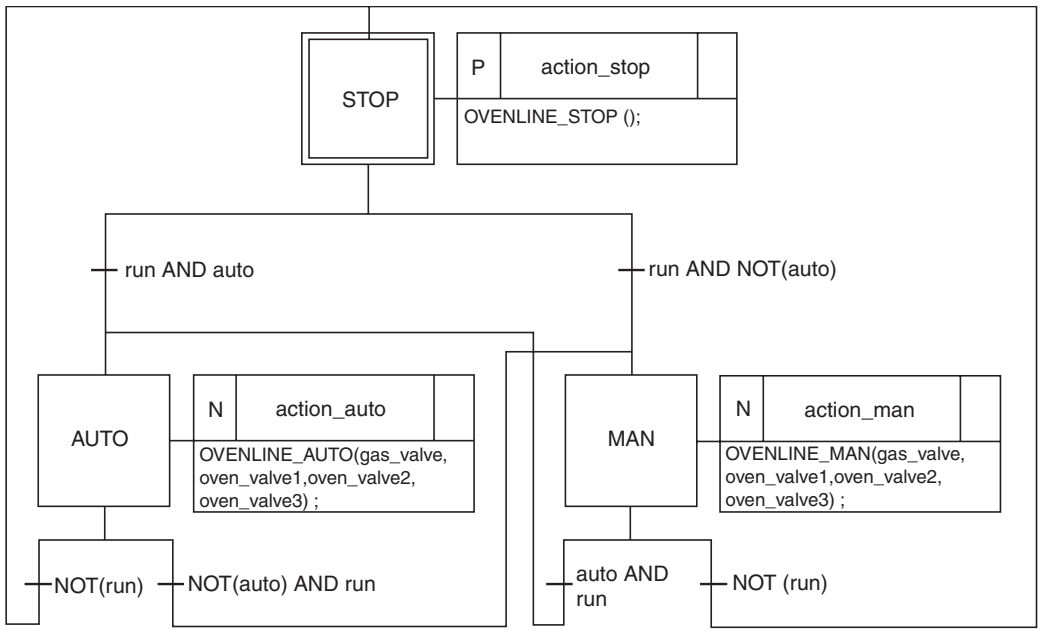

FIGURE 65.16 Body of the main program.

double-clicking the icon representing the building block (or some other similar action on the part of the programmer), choosing the language (SFC, FBD, LD, IL, or ST), and actually writing or drawing the body.

The SFC of Figure 65.16 contains three steps or states (STOP, AUTO and MAN), of which only STOP is active upon startup. From this step, the SFC will evolve to AUTO if the "run" button is activated while the "auto" switch is on, or to the MAN mode if the "run" button is pressed while the "auto" switch is off. In this case, "on" and "auto" refer to the variables declared in Figure 65.15, which are themselves mapped onto digital inputs of the PLC.

© 2005 by CRC Press LLC

From the AUTO mode, the SFC may evolve to either the STOP or MAN modes. Notice how the condition associated with the transition from AUTO to MAN mode contains a test to verify if "run" is still True. If this were not the case, a situation could occur whereupon both the transitions from AUTO (to STOP and MAN) could be simultaneously fired. If this were allowed to happen, then the SFC would evolve to a state where both the STOP and MAN steps would be simultaneously active, which is not desirable in our example. The same may be said of the transitions from AUTO to MAN and STOP.

The action "action_stop" is associated with the STOP step, which consists of calling the ovenline_stop building block. This building block will be called once, and once only, whenever the STOP step is activated, due to the pulse (P) association of the action with the step. The ovenline_stop building block is expected to shut down the production line, such as stopping the oil pump and the conveyer, and closing all the valves if required.

Similarly, associated with the AUTO step is the action "action_auto," which consists of calling the ovenline_auto building block. Unlike the ovenline_stop building block, the ovenline_auto building block will be called continuously, as long as the AUTO step is active, due to the nonstored (N) association of the action with the step.

We now have to write the building blocks that are called from the main SFC. The ovenline_man building block (for the manual mode) will consist of reading up/down pushbuttons for several valves, and changing the state of those valves accordingly. Although the standard up/down counter function blocks could be used for this purpose, we will write our own for demonstration value (see Figure 65.17). We will then instantiate one counter function block for each valve.

```
1         FUNCTION_BLOCK UPDOWNCOUNTER
2           (* Interface *)
3           VAR_INPUT
4             up   : BOOL;
5             down : BOOL;
6           END_VAR
7           VAR_OUTPUT
8             counter : INT := 0;
9           END_VAR
10          (* Body in IL *)
11          LD up
12          JMPC inc
13          LD down
14          JMPC dec
15          RET
16        inc: LD 1
17             ADD counter
18             ST counter
19             RET
20        dec: LD -1
21             ADD counter
22             ST counter
23             RET
24        END_FUNCTION_BLOCK
```

FIGURE 65.17 Up/down counter building block.

© 2005 by CRC Press LLC

The up/down counter function block maintains a counter (line 8) that starts off with the value 0. Since this building block will be called once every iteration, it will continually increment (decrement) its value while the up (down) Boolean input is True. Line 11 loads the default register with the value stored in the up variable. The next line will then jump to line 16 (labelled inc) if the Boolean value currently in the default variable is True. On line 16, the default register is loaded with the value 1. This is then added to the value stored in counter (line 17), and the result stored back in the default register. Line 18 then copies the result in the default register into the counter variable, and the function returns (line 19). The remaining code is similar to the lines previously explained.

The continuous increment or decrement of the counter value will allow the user controlling the factory floor to control the position of a valve by simply keeping a pushbutton pressed. This function could be further augmented to allow for an increasing rate of change, starting off slowly at first, and increasing as time goes by.

The building block that will control the ovens while these are in manual mode (see Figure 65.18) simply instantiates an up/down counter for each valve, and calls these counters once every iteration with the appropriate pushbuttons as parameters.

The automatic mode requires that we implement several PID loops. Although it is common for vendors to supply functions that implement these loops, we implement them ourselves for demonstration purposes, starting off by writing an open-loop PID controller. Due to the mathematical operations that need to be programmed, it is best to use the ST language (see Figure 65.19). The KP, KI, and KD are the proportional, integral, and derivative parameters of the PID controller, respectively. The controller is expected to be called continually every delta_time time units. It ends by storing the current value of the input (in the prev_in variable); hence, the rate of change may be determined in the next iteration (which is stored in D). The I variable contains the integral of the input, which is constantly updated every iteration.

We are now prepared to define the function block to handle the automatic mode. Since it will have to close the PID loops, using the PID function block, it is probably easiest to program it using FBD (see Figures 65.20 and 65.21).

FIGURE 65.20 Interface to the auto building block.

© 2005 by CRC Press LLC

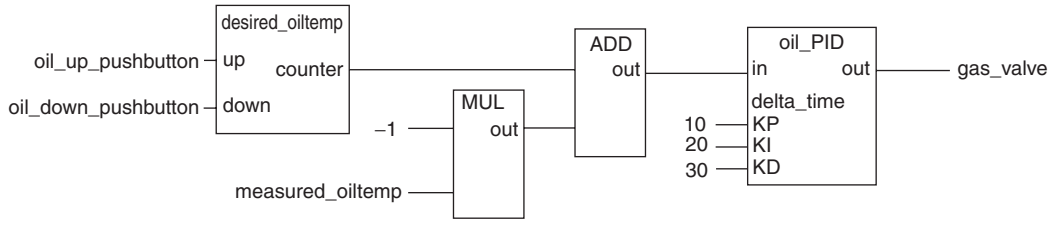

FIGURE 65.21 Body of the ovenline-auto-t building block.

The "desired_oil_temp" function block in Figure 65.21 is declared in Figure 65.20 as being an "updowncounter" (see Figure 65.17). The "up" and "down" inputs of this function block are connected to variables declared in Figure 65.20. These variables are mapped onto the digital inputs of the PLC to which the relevant pushbuttons must be physically connected. The user can then change the target temperature for the oil by simply pressing these up and down pushbuttons.

The difference between the desired temperature and the current oil temperature consists of the error, which the PID loop must eliminate. The error value, computed with the help of the MUL and ADD standard functions, will be the input to the PID block, along with the P, I, and D constants. The output of the PID block is sent to the gas_valve variable, once again declared in Figure 65.20, and mapped to an output.

65.9 The Future

The IEC 61131-3 standard, along with its programming languages, is already well understood and widely used in the industrial world. Nevertheless, this standard relates only to PLCs working in isolation. The companion standard IEC 61131-5 specifies the mechanism of reading and writing of specific values remotely over a network, but it falls short of defining a framework in which PLCs may cooperate in a networked environment.

The IEC soon recognized that the future belongs to networked equipment, and therefore started the IEC 61499 standard [4], which defines a framework for configuring cooperating devices connected by a data network. In this framework, each PLC is considered a device. The framework allows each device to contain zero or more resources (i.e., CPUs), which is in accordance with the IEC 61131-3 standard. Nevertheless, the framework now considers applications that span multiple resources and multiple devices, which means that an application may be distributed among several PLCs, and the same PLC may be executing several applications or subapplications.

Applications are composed of a group of cooperating subapplications or function blocks, with inputs and outputs connected like a network (similar to an FBD). Subapplications are a network of function blocks. Function blocks themselves may be composed of a network of other function blocks. Unlike IEC 61131-3, the framework does not contemplate other building blocks such as functions and programs.

The IEC 61499 function blocks have substantial extensions in relation to the IEC 61131-3 function blocks. Besides normal data passing through input and output variables, information may also be transferred through events. Each function block defines input ports through which it may receive events, and output ports through which it may generate events. A network of function blocks is comprised of several function blocks with output event ports connected to input event ports, and output data variables connected to input data variables.

Basic function blocks (i.e., those that are not composed of a network of other function blocks) may also have several execution states. An execution state chart defines the state transitions and when certain actions or algorithms will be performed. The algorithms are specified using one of several programming languages, including all the languages specified in IEC 61131-3, such as ST and IL.

© 2005 by CRC Press LLC

Applications interact with the real world through specialized function blocks known as service interface function blocks. The standard defines service interface function blocks to access the physical inputs and outputs of the PLC, to access the data network connecting the distributed PLCs, and to manage the state of the user's applications and the PLC itself. This means that access to the PLC's physical inputs and outputs is no longer achieved through the use of located variables, as is done in IEC 61131-3.

The standard merely specifies the interface and the semantics of each service interface function. It does not specify their implementation, leaving this to the PLC vendors. This allows, for example, the coexistence of several network service interface function blocks, each implementing a specific network protocol, but all furnishing the exact same interface to the application. The network service interfaces defined in the standard support the publish/subscribe and the client/server models. As long as the application only accesses the network through these service interface function blocks, the application itself does not have to change in order to use a new network protocol.

65.10 Advantages of the IEC 61131-3 Languages

The main advantage of the standardization of the PLC programming languages is the portability between PLC vendors of both the software itself, as well as the programmers writing the software. Nevertheless, PLC vendors have still been able to lock users into their product family by simply saving the software into a nonstandard file format. This is allowed since the standard merely specifies the language syntax, and not the format of saving the programs in a file. This is currently being worked on by the IEC, which will shortly release a standard specifying a common file format based on XML.

Apart from the standardization advantage, the languages themselves include features that greatly ease the development process, such as automatic memory allocation for data variables, strong consistency of data types, complex data structures, and the definition of the programming blocks, which allow better code structuring and code reuse.

65.11 The MatPLC Project

The MatPLC is the result of a project that is creating a PLC to run on any POSIX-compliant operating system (OS). The entire source code is distributed under the GPL license (GNU Public License), and may be obtained from http://mat.sf.net.

The MatPLC [5] is composed of several modules, each of which is executed by its own OS process. The modules all access the same shared PLC state, which stores the internal PLC coils, or points. Modules may be configured to run periodically, and synchronized among themselves using a Petri Net model. Examples of currently implemented modules are the modbus master, the hilscher module (that interfaces with industrial network interface cards, such as Devicenet, Profibus, ASI, etc.), digital signal processor (including PID controllers and digital filtering), IEC ST and IL compiler, and tcl- or gtk-based graphical interfaces.

The authors have implemented the IEC 61131-3 ST and IL compiler for the MatPLC [6]. This compiler executes in four plus one stages: lexical analyzer, syntax parser, semantics analyzer, code generator, and binary code generator. At the time of writing, the semantic analyzer had not yet been coded, and only a C++ code generator existed for the fourth stage. The last stage of the overall compiler generates the final executable from the C++ code. In our case, we are currently using the GNU C/C++ compiler (gcc) to generate the final executable.

A few conflicts were found in the syntax definition given in the standard. These were mostly due to the existence of more than one route for reducing several constructs. All of these conflicts were easily resolved, as the expected semantics of either route were identical. Other more thorny issues were related to the fact that the language requires more than one look-ahead token to be correctly parsed, while the bison utility we used generates a parser that uses a single look-ahead token.

© 2005 by CRC Press LLC

We also found that the syntax does not contain sufficient redundancy to allow it to be parsed successfully without the help of a symbol table that keeps track of the type of construct to which an identifier (name) refers to. Before any parsing commences, the global table is initialized with the names of all the default functions and functions blocks defined in the standard. The use by the standard of the identifiers "NOT" and "MOD" as either keywords or standard functions, added considerable complexity to the parser, as these identifiers may be correctly interpreted as one of two different tokens by the lexical parser.

66.1 Reasons for a New Standard

The development of the IEC 61499 has been stimulated by new requirements coming mainly from the manufacturing industry and by new concepts and capabilities of control software and hardware engineering.

To survive growing competition in more and more internationalized global markets, the production systems need to be more flexible and reconfigurable. This demand is especially strong in highly developed countries with high labor costs and individual customer demands. Acting successfully in such markets means decreased lot sizes and therefore frequent changes of manufacturing orders that may require changes of the manufacturing system itself. This means either a change of parts of the machinery or a change of the interconnection of subsystems by flow of material.

Each change corresponds to a partial or complete redesign of the corresponding control system. The more frequent the changes are, the more time and effort has to be spent on the redesign. As a consequence, there is a growing economic need to minimize these costs by application of appropriate methodologies of

© 2005 by CRC Press LLC

control system engineering. The desire of control engineers is to reach so-called "plug and play" integration and reconfiguration.

When the production systems are built from automated units, the control engineers naturally try to reuse the software components of the units. This is especially attractive in case of a reconfiguration, when the changes of units functionality may seem to be minor. However, the obstacles come from the software side.

The currently dominating International Standard IEC 61131 for programming of Programmable Logic Controllers (PLCs) [2] is reaching the end of its technological lifecycle, and its execution semantics does not fit well into the new requirements for distributed, flexible automation systems. The IEC 61331 systems rely on the centralized programmable control model with cyclically scanned program execution. Integration of this kind of systems via communication networks may require quite complex synchronization procedures. Thus, overheads of the integration may be as complex as the startover system development. Furthermore, even different implementations of the same programming language of IEC 61131 may have different execution semantics. Moreover, PLCs of different vendors are not interoperable and require vendor-dependent configuration tools.

For dealing with distributed nonhomogeneous systems, it would be convenient to define control applications in a way that is independent from a particular hardware architecture. However, the architectural concept for such a definition is missing.

These are severe obstacles toward the plug-and-play integration and reconfiguration of flexible automation systems.

The newly emerging International Standard IEC 61499 [1] is an attempt to provide the missing architectural concept. The standard defines a reference architecture for open, distributed control systems. This provides the means for real compatibility between automation systems of different vendors. The standard incorporates advanced software technologies, such as encapsulation of functionality, component-based design, event-driven execution, and distribution. As a result, specific implementations of different providers of field devices, controller hardware, human–machine interfaces, communication networks, etc. can be integrated in component-based, heterogeneous systems. The IEC 61499 standard stimulates the development of new engineering technologies that are intended to reduce the design efforts and to enable fast and easy reconfiguration.

This chapter provides an overview of the concepts and design principles of the standard. For the internal details of the standard, the reader is referred to [1], for a more systematic introduction into the subject to [4], and to [7] for the evolution of the idea. Since the design principles differ considerably from those of the well-known IEC 61131, the general issues are introduced in a rather intuitive way. To illustrate the design principles and new features, an example is presented in this chapter. Real applications — although sparse — do exist but are too complex to be explained here in detail. The interested reader is referred to [9]. This chapter is based on the Publicly Available Specification (PAS) of the IEC TC65 from March 2000. As of July 2004, the parts 61499-1 "Architecture" and 61499-2 "Software Tools Requirements" were voted and approved as IEC Standards. The texts are expected to be published by the end of 2004.

66.2 Basic Concepts of IEC 61499

The standard defines several basic *functional* and *structural* entities. They can be used for specification, modeling, and implementation of distributed control applications. Some of them stand for pure software components. Others represent logical abstractions of a mixed software/hardware nature. The main functional entities are function block types, resource types, device types, and applications that are composed of function block instances. System configurations include instances of device types and applications that are placed (mapped) into the devices. The following subsections will briefly discuss all these entities.

The specification of functionality of a control application and the specification of a system architecture can be performed independently. An implementation of an application on a given system architecture is done by mapping of its function blocks onto the devices and their resources. Each function block must be mapped to a single resource and cannot be distributed over different resources.

© 2005 by CRC Press LLC

Thus, the next section discusses the means to define the functionality of a distributed control application, and the section "Specification of the system architecture" shows how a particular system configuration can be defined.

Describing the Functionality of Control Applications

Overview of the Function Block Concept

The basic entity of a portable software component in IEC 61499 is a so-called *function block*. The new standard defines several types of blocks: basic function blocks, service interface function blocks, and composite function blocks. Although the term function block is known from IEC 61131, a function block of IEC 61499 is different from IEC 61131 function blocks. Figure 66.1 shows a *function block interface* following the standard (note that the graphical appearance is not normative). The upper part is often referred to as the "head" and the lower as the "body" of the function block. A block may have inputs and outputs. There is a clear distinction between data and event input/output signals. Events serve for synchronization and interactions among the execution control mechanisms in interconnected networks of function blocks. The concept of data types is adopted as in any programming language. In particular, the standard refers to the data types of IEC 61131. In the graphical representation in Figure 66.1, the event inputs and outputs are associated with the head of the function block, and the data inputs and outputs are associated with the body.

The IEC 61499 defines a number of standard function blocks for manipulations with events, such as splitting or merging events, generation of events with delays or cyclically, etc.

The definition of the function block external interface also includes an association between the events and relevant data. It is denoted by vertical lines connecting an event and its associated data inputs/outputs in the graphical representation. The association literally means that the values of the variables associated with a particular event (and only these!) will be updated when the event occurs.

The IEC 61499 standard uses the typing concept of function blocks that is similar to that in IEC 61131 and in the object-oriented programming. Once a function block type is defined, it can be stored in the library of function block types and later instantiated in applications over and over again.

The standard does not determine in detail the languages to define the internal functionality of a function block. However, for each type of blocks, the ways of structuring the functionality are identified. These will be discussed in the following sections.

Basic Function Blocks

Basic Function Blocks are software structures intended to implement basic functions of distributed control applications. The standard says that in addition to inputs and outputs, the internal structure of a basic function block may include *internal variables*, one or several *algorithms,* and an *execution control chart*.

An algorithm is a structure of finest granularity. It represents a piece of software code operating on the common input, output, and internal data of the function block. The algorithms can be specified, for

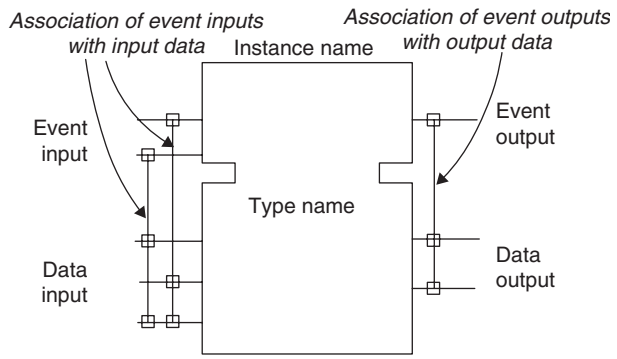

FIGURE 66.1 External interface of a function block.

© 2005 by CRC Press LLC

example, in languages defined in IEC 61131. But, in general, they can be given in any form supported by the implementation platform. It is important to note that an algorithm has to be implemented in one programming language. The internal data of a function block cannot be accessed from outside and can only be used by the internal algorithms of the particular function block (Figure 66.2).

The execution control function specifies the algorithm that must be invoked after a certain input event in a certain state of the execution control function. It is specified by means of Execution Control Charts (ECC for short). Figure 66.3 shows an example. An ECC is a finite state machine with a designated initial state. An ECC consists of states with associated *actions* (designated by ovals in the Figure) and of state transitions (designated by arrows). The actions contain algorithms to invoke and output events to issue upon the completion of the algorithms' execution.

Each state transition is labeled with a BOOLEAN condition that is a logic expression utilizing one or more event input variables, output variables, or internal variables of the function block. The event inputs are represented in the conditions as BOOLEAN variables that are set to TRUE upon an event and cleared after all possible state transitions (initiated by a single input event) are exhausted.

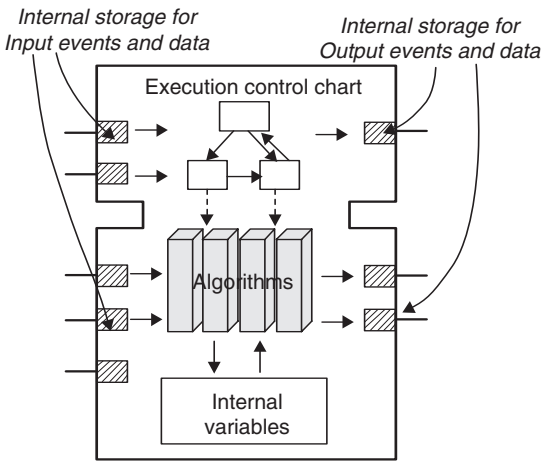

FIGURE 66.2 A basic function block.

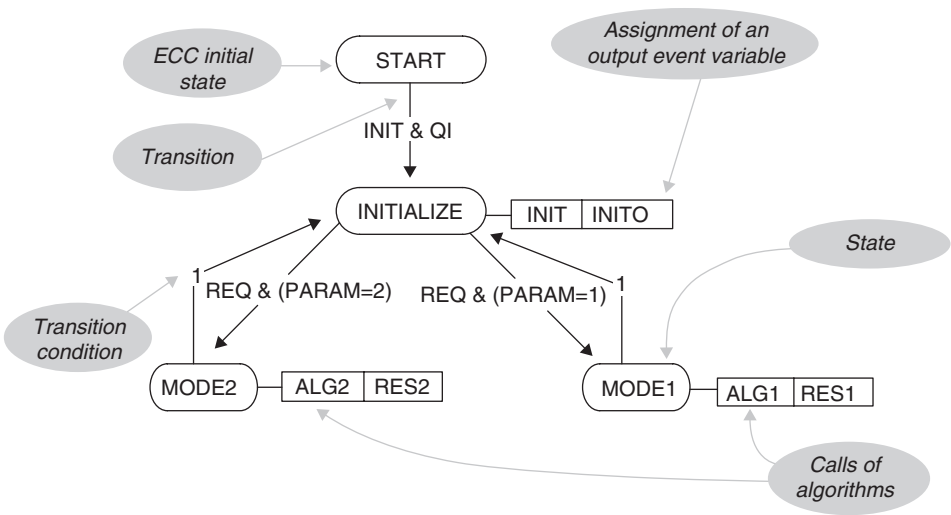

FIGURE 66.3 An example of the ECC [1].

© 2005 by CRC Press LLC

An input event causes the *invocation of the execution control function* that in more detail is as follows (see Figure 66.4):

Step 1: The input variable values relevant to the input event are made available.

Step 2: The input event occurs, the corresponding BOOLEAN variable is set, and the execution control of the function block is triggered.

Step 3: The execution control function evaluates the ECC as follows. All the transition conditions going out of the current ECC state are evaluated. If no transition is enabled, then the procedure goes to the Step 8. Otherwise, if one or several state transitions are enabled (i.e., if the corresponding conditions are evaluated to TRUE), a single state transition takes place.[1] The current state is substituted by the following one. The algorithms associated with the new current state will be scheduled for execution. The execution control function notifies the resource scheduling function to schedule an algorithm for execution.

Step 4: Algorithm execution begins.

Step 5: The algorithm completes the establishment of values for the output variables.

Step 6: The resource scheduling function is notified that algorithm execution has ended.

Step 7: The scheduling function invokes the execution control function. The procedure resumes from Step 3.

Step 8: When some of the output event variables were set during this invocation of the execution control function, then the execution control function signals the corresponding event output and clears the BOOLEAN variables corresponding to the triggered input and output events.

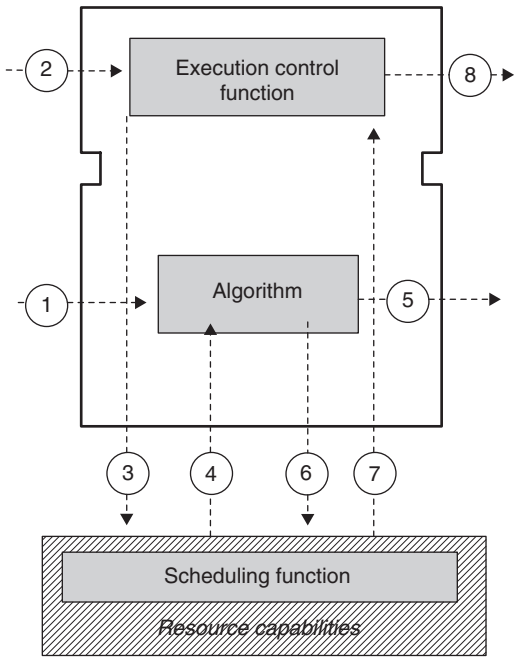

FIGURE 66.4 Execution of a function block.

[1]The standard does not determine a rule regarding how to choose a state transition if several are simultaneously enabled.

© 2005 by CRC Press LLC

First conclusions can be drawn at this point:

- A Basic Function Block is an abstraction of a software component adjusted for the needs of measurement and control systems. Its execution semantics is event-driven and platform independent. Basic Function Blocks are intended to be main instruments of an application developer.
- The standard implies separation of the functions, implemented by algorithms, from the execution control. The algorithms encapsulated in a function block can be programmed in different programming languages.
- The execution of function blocks is event-driven. This means that algorithms are executed only if there is a need to execute them in contrast to the cyclically scanned execution in IEC 61131. The need has to be indicated by events. The source of events can be other function blocks. Some of them may encapsulate interfaces to the environment (controlled process, communication networks, hardware of a particular computational device).
- The execution function of a Basic Function Block is defined in the form of a state machine that is available for documentation and specification purposes even if the algorithms are hidden.
- The function block abstracts from a physical platform (the resource) on which it is located. This means that the specification of the function block can be made without any knowledge of the particular hardware on which it will be later executed.

Composite Function Blocks

The standard also defines Composite Function Blocks, the functionality of which, in contrast to Basic Function Blocks, is determined by a network of interconnected function blocks inside. Figure 66.5 shows the principle.

More precisely, members of the network are instances of function block types. These can be either Basic Function Blocks or other Composite Function Blocks. Therefore, hierarchical applications can be built.

It is important to note that Composite Function Blocks have no internal variables, except for those storing the values of input and output events and data. Thus, the functionality of Composite Function Blocks completely depends on the behavior of the constituent function blocks and their interconnections by events and data.

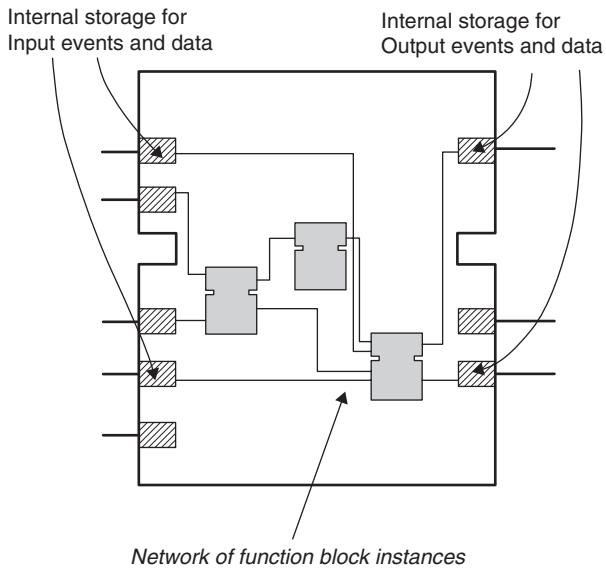

FIGURE 66.5 Composite Function Block.

© 2005 by CRC Press LLC

Along with Basic Function Blocks, the Composite Function Blocks are intended to be main instruments of an application developer.

Service Interface Function Blocks

In contrast to Basic and Composite Function Blocks, Service Interface Function Blocks are not intended to be developed by an application developer. These have to be provided by vendors of the corresponding equipment, for example, controllers, field buses, remote input/output modules, intelligent sensors, etc. The application scope determines the differences of this kind of function blocks from the previously considered ones.

To conceal the implementation-specific details of the system from the application, the IEC 61499 defines the concept of services that the system provides to an application. A service is a functional capability of a resource that is made available to an application. A service is specified by a sequence of service primitives that define properties of the interaction between an application and a resource during the service. The service primitives are specified in a graphical form of the time-sequence diagrams described in Technical Report 8509 of the International Standard Organization (ISO) [3]. This is rather a qualitative specification form as it does not specify exact timing requirements to the services. An example of time-sequence diagrams is presented in Figure 66.7 and will be briefly discussed later in this section.

A Service Interface Function Block is an abstraction of a software component implementing the services. Figure 66.6 shows an example of a Service Interface Function Block REQUESTER that provides some service upon request to an application (examples of possible services: read the values of sensors, increase the memory used by a resource, shut down a resource, send a message, access remote database, etc.). The standard predefines some names for input/output parameters of Service Interface Function Blocks such as INIT for initialization, INITO for confirmation of the initialization, QI for input qualifier, etc.

Some of the services provided by this block are specified in the form of time-sequence diagrams in Figure 66.7. These are "normal establishment" of the service, "normal service," and "application initiated termination" of the service.

The input event INIT serves for initialization/termination of the service, depending on whether the BOOLEAN input QI is true or false. The notation INIT+ means the occurrence of the event INIT with the qualifier value QI=true, and INIT-correspondingly with QI=false.

The input parameter PARAMS stands for the service parameters that have to be taken into account during the service initialization. At the end of the initialization/termination procedure, the Service Interface Function Block responds by event INITO its completion and indicates by the BOOLEAN data output QO whether initialization/termination was successful (QO=true) or not (QO=false).

The input data needed to perform the service are denoted as inputs SD_1 ... SD_m. Note that these data are associated with the event input REQ. The data outputs RD_1 ... RD_n stand for the data computed as a result of the service. These data are associated with event CNF that represents confirmation of the service. The output STATUS provides information about the status of the service upon the occurrence of an event output.

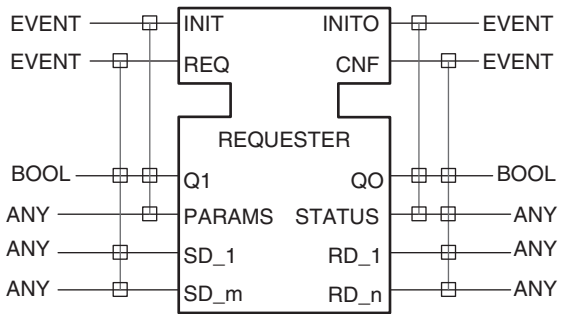

FIGURE 66.6 Generic REQUESTER [1].

© 2005 by CRC Press LLC

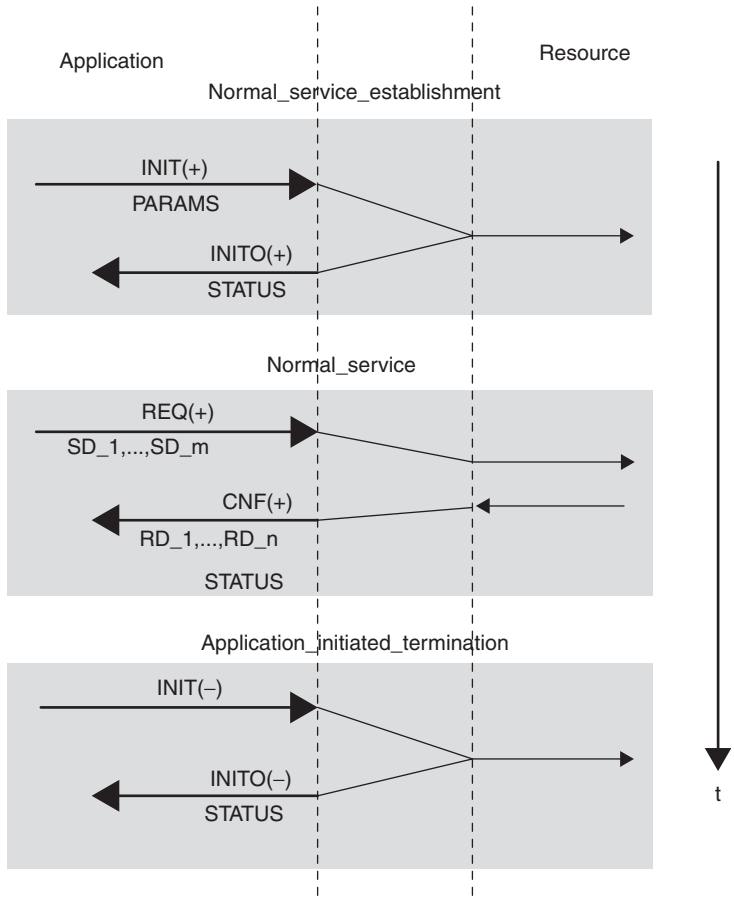

FIGURE 66.7 Diagrams of service sequences for application-initiated interactions.

The execution of Service Interface Function Blocks is initiated by input events. The internal structure of Service Interface Function Blocks is not specified as firmly as for Basic Function Blocks. For example, a programming implementation of a Service Interface Function Block can be done in the form of several encapsulated algorithms (methods, procedures) that are invoked upon a particular event (say algorithm **init** stands for the event INIT). The algorithms may check the value of the qualifier QI and then call either the subroutine responsible for the "normal service establishment" (if QI=true) or the one responsible for the "application initiated termination" (if QI=false). Note that the concept of Service Interface Function Blocks does not presume the need for internal variables — the conditions for initiating services are described by input events and data (qualifiers).

A particular case of Service Interface Function Blocks are Communication Interface Function Blocks. The standard explicitly defines two generic communication patterns: PUBLISH/SUBSCRIBE for unidirectional transactions and CLIENT/SERVER for bidirectional communication. These patterns can be adjusted to a particular networking or communication mechanism of a particular implementation. Otherwise, a provider of communication hardware/software can specify his own patterns if they differ from the above-mentioned ones. Figure 66.8 illustrates the generic PUBLISH and SUBSCRIBE blocks performing unidirectional data transfer via a network.

The PUBLISHER serves for publishing data SD_1 ... SD_m that come from one or more function blocks in the application. It is therefore initialized/terminated by the application in the same way as described above.

Upon the request-event REQ from the application, the data that need to be published are sent by the PUBLISHER via an implementation-dependent network. When this is done, the PUBLISHER informs the publishing application via event output CNF.

© 2005 by CRC Press LLC

The SUBSCRIBER function block is initialized by the application that is supposed to read the data RD_1 ... RD_m. Normal data transfer is initiated by the sending application via the REQ input event to the PUBLISHER. This is illustrated in Figure 66.9 by means of time-sequence diagrams. The PUBLISHER sends the data and triggers the IND-event at the outputs of the SUBSCRIBER to notify the reading applications that new values of data are available at RD_1 ... RD_m outputs of the SUBSCRIBER. The reading application notifies the SUBSCRIBER by the RSP-event that the data are read.

In summarizing this subsection, one can see that Service Interface Function Blocks implement the interface between an application and the specific functionality that is provided by control hardware or system software. The content of Service Interface Function Blocks can be concealed, but the means are reserved to specify their functionality in a visual form.

Application

An *application* following IEC 61499 is a network of function block instances whose data inputs and outputs and event inputs and outputs are interconnected (see Figure 66.10).

An application can be considered as an intermediate step in the system development. It already defines the desired functionality of the system completely, but it does not specify the system's structure in terms of computational devices where the function blocks can be executed. The next step in the engineering process is to define a particular set of devices and to "cut" the application, assigning the blocks to the devices as illustrated in Figure 66.11.

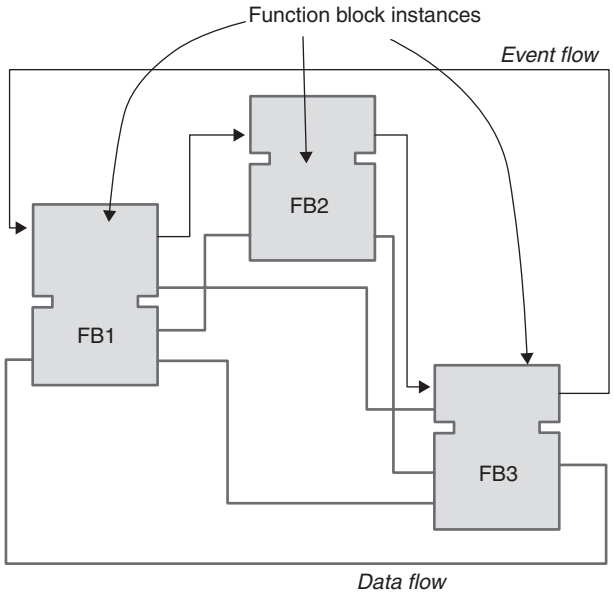

FIGURE 66.10 An application.

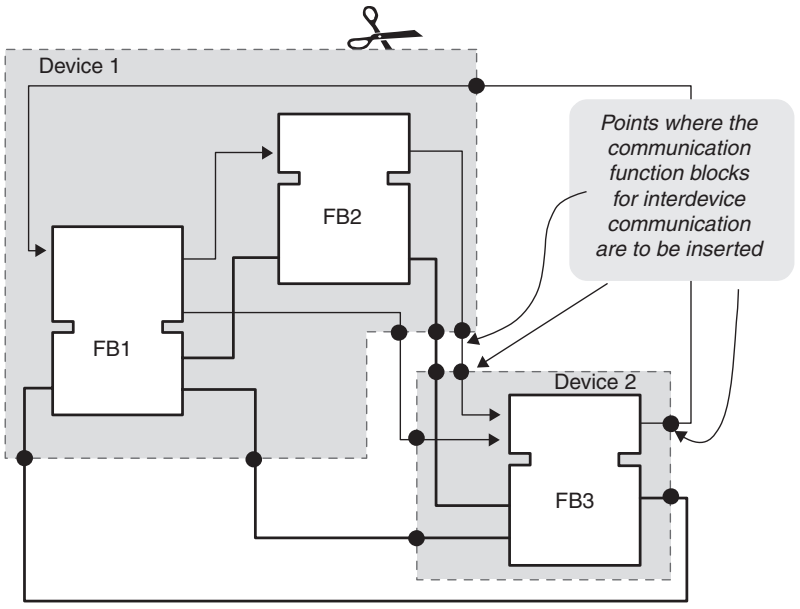

FIGURE 66.11 The application distributed onto two devices.

© 2005 by CRC Press LLC

The way in which the separated parts of the distributed applications communicate with each other has to be explicitly defined. This can be done by adding Communication Function Blocks in the places where the "cut" took place (see Figure 66.12).

A network of function blocks (forming the application) can be encapsulated in a Composite Function Block if needed. In this case, however, it could not be distributed across several devices or resources as a function block can be executed only in a single resource.

In fact, the standard provides a structure (called *subapplication*) that combines features of Composite Function Blocks and of applications. The content of a subapplication can be distributed across several devices. However, the practical applicability of this structure is quite questionable.

The following subsection will show the concepts and specifications of a system following IEC 61499 as a platform for implementation and execution of an application.

Specification of the System Architecture

Resources and Devices

A device in IEC 61499 is an atomic element of a system configuration. The standard provides architectural frames for creating models of devices, including their subdivision in computationally independent resources.

A device type (Figure 66.13) is specified by its process interface and communication interfaces. A device can contain zero or more resources (see the description below) and function block networks (this option is reserved for the devices having no resources).

A "process interface" provides a mapping between the physical process (analog measurements, discrete I/O, etc.) and the resources. Information exchanged with the physical process is presented to the resource as data or events, or both.

Communication interfaces provide a mapping between resources and the information exchanged via a communication network. In particular, services provided by communication interfaces may include presentation of communicated information to the resource and additional services to support programming, configuration, diagnostics, etc.

The interfaces are implemented by the libraries of corresponding Service Interface Function Blocks. The libraries of these blocks form the "identity" of a device. A device that contains no resources is considered to be functionally equivalent to a resource.

A resource (Figure 66.14) is considered to be a functional unit, contained in a device, that has independent control of its operation. It may be created, configured, parameterized, started up, deleted, etc., without affecting other resources within a device. The functions of a resource are to accept data and/or

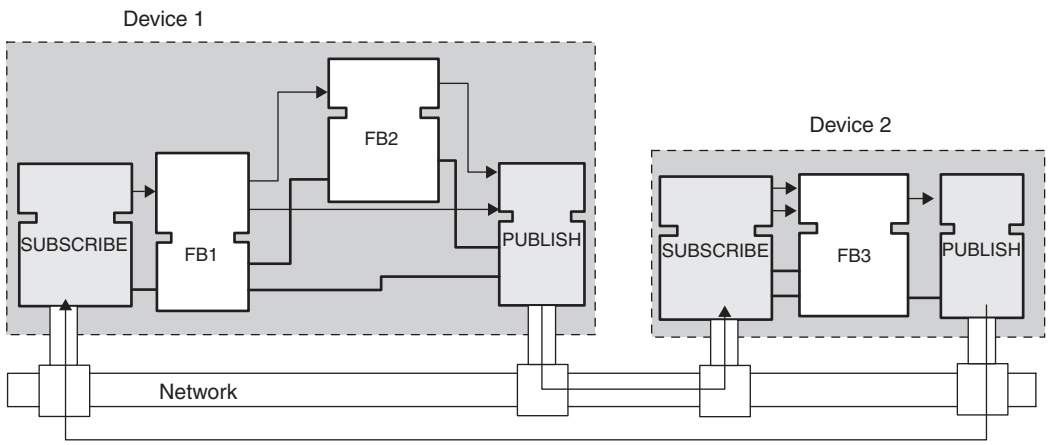

FIGURE 66.12 Communication Function Blocks explicitly connecting parts of the distributed application.

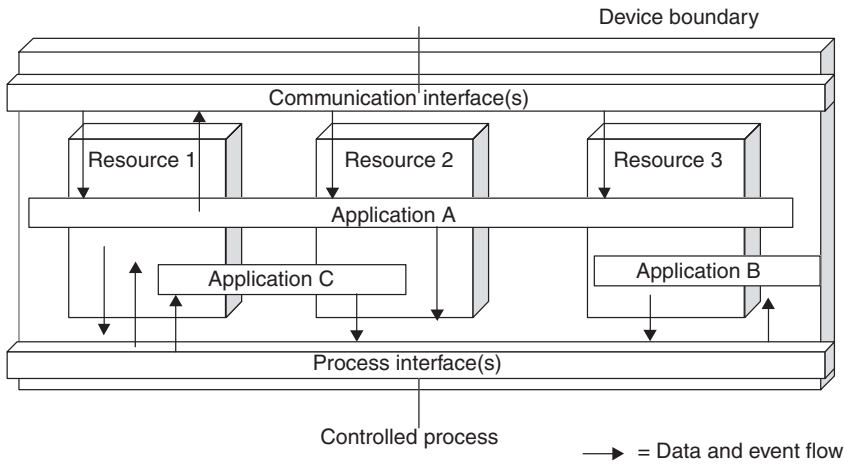

FIGURE 66.13 A device model.

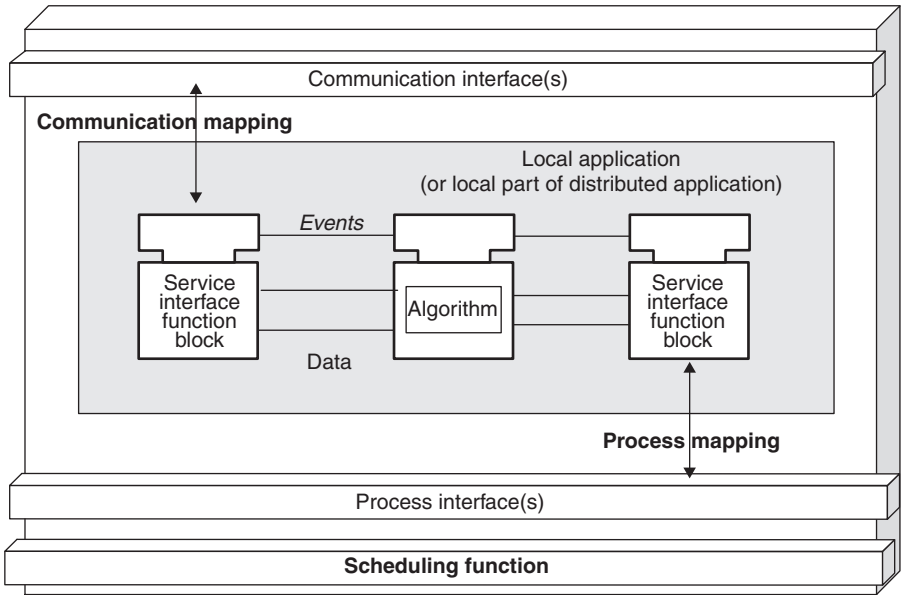

FIGURE 66.14 A model of resource.

events from the process and/or communication interfaces, process the data and/or events, and to return data and/or events to the process and/or communication interfaces, as specified by the applications utilizing the resource.

Furthermore, a resource provides physical means for running algorithms. This means storage for data, algorithms, execution control, events, etc. It also has to provide software capabilities for managing and controlling the function blocks' behavior, scheduling its algorithms (scheduling function), etc.

System Configuration

A system is a collection of one or more devices (Figure 66.15). The devices communicate with each other over communication networks. Also, the devices are linked with the controlled process via sensor and actuator signals.

© 2005 by CRC Press LLC

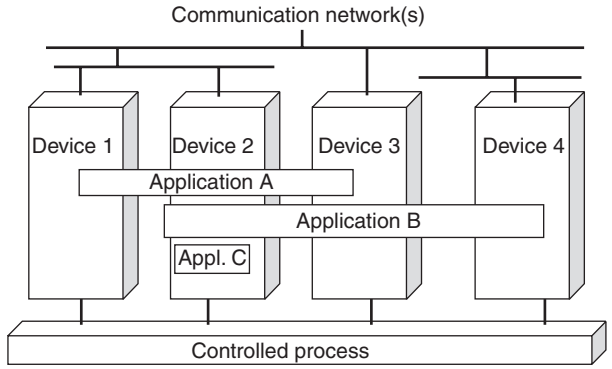

FIGURE 66.15 A system configuration.

Applications are mapped onto the devices. This means that their function blocks are assigned to the resources of the corresponding devices. In this way, a system configuration is formed. A system configuration is feasible if each device in it supports the function block types that are mapped on it. Otherwise, the block would not be instantiated, and the system will not run.

66.3 Illustrative example

Desired Application Functionality

The example "FLASHER" that is used in this section was borrowed from the set of samples provided with the Function Block Development Kit (FBDK). This is the first software tool supporting IEC 61499 system development. It was developed by Rockwell Automation, U.S.A. The toolset can be downloaded from [5]. The example represents an abstraction of an automation system. It is supposed to make four lamps blinking according to a preprogrammed mode of operation.

The system consists of human–machine interface components and of a core functional component. The core component generates the output signals determined by input parameters. The output values are then delivered to the visualization device (lamps). In the form presented here, the system is completely simulated in a computer. All human–machine interface components and lamps exist only on the computer screen. The example visually shows how easily each of the software components that interact with a simulated object can be replaced by components that would interact with the real physical equipment (e.g., buttons, switchers, knobs). After such a reconfiguration, the whole system will then show the same functionality without changing its structure and without redesigning the other components.

Figure 66.16 shows a screenshot of the FBDK containing a system configuration. As a result of its execution, the output frame is produced. The output frame is located in the figure below the FBDK screen. The arrows connect the function blocks with the screen objects created by them.

The system configuration includes one application. It is placed in one device with only one resource. An instance of the device type FRAME_DEVICE is used in this example. This type of device creates a windows frame on the computer screen. The resource of type PANEL_RESOURCE creates a rectangular panel within this frame. If a function block creates an output to the screen, it will be placed in the corresponding panel.

In this particular case, the system configuration implements the application in a centralized manner. The application includes all the blocks shown in Figure 66.16 in the shaded rectangular area. The only block that falls out of the application is the block START of type E_RESTART. It belongs to the resource type PANEL_RESOURCE.

The application creates the following models of human–machine interface primitives. Buttons START and STOP are created by the blocks START_PB and STOP_PB. Both are instances of the type IN_EVENT.

© 2005 by CRC Press LLC

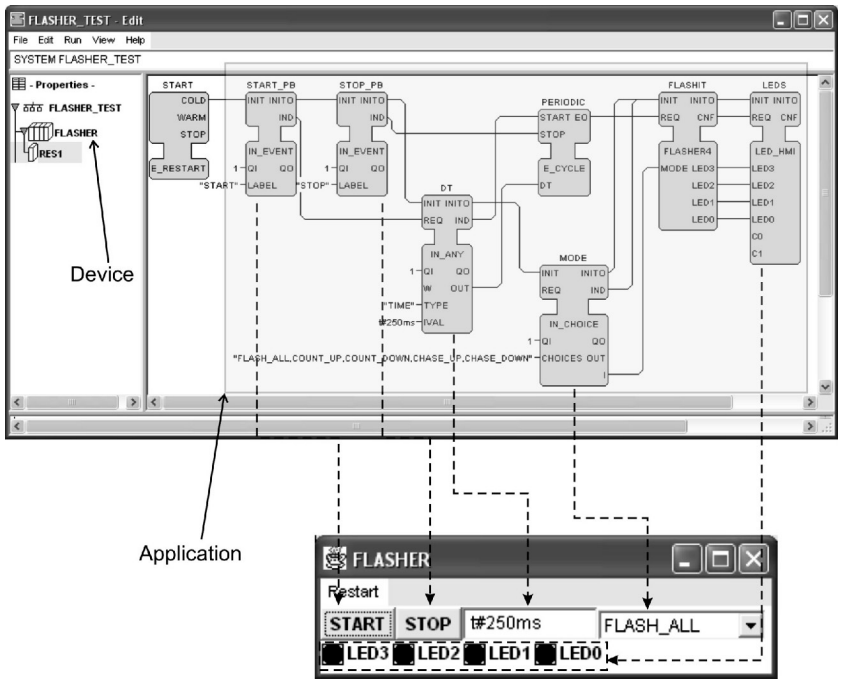

FIGURE 66.16 FLASHER in centralized system configuration.

Block DT creates the input field for the TIME parameter. It is an instance of type IN_ANY. Block MODE creates the pull-down menu to select a desired mode of operation.

The block that produces the output combination is FLASHIT. It is an instance of type FLASHER4. The output values are then visualized by the block LEDS of type LED_HMI. The FLASHER4 generates the output values at every pulse of the event input REQ. The pulses are generated by the block PERIODIC with the frequency determined by the value in the field DT that is received from the block DT.

The operation of the system configuration is started when the resource is initialized, for example, when the device is created (or switched on for more realistic devices). At that moment, the Service Interface Function Block START produces the event COLD (cold restart). It is connected to the input event INIT of the block START_PB. This input event causes the block of type IN_EVENT to place a button image in the resource's panel. The caption of the button is given by the input parameter "LABEL" of the block, that is, "START" in our case. After that, an output event INITO is generated that is connected to the input INIT of the block STOP_PB. It leads to the creation of the button "STOP" and so forth in the chain until the whole picture is created on the resource panel as shown in Figure 66.16.

Once the button START is pressed (e.g., by a mouse click), it ignites the event output IND. This event propagates through the chain of blocks DT and PERIODIC. It enables the latter to generate the output event EO with the desired frequency. Every moment the event comes to the input REQ of the FLASHIT, the output combination of LED0..LED3 is created, and the output event CNF notifies the block LEDS, which updates the picture.

If the operating mode is changed during the operation, the corresponding event IND of the block MODE would notify the FLASHIT. Then, FLASHIT will change the pattern according to which its outputs are generated.

A more detailed description of the function block type FLASHER4 is given now. Figure 66.17 shows the Execution Control Chart of this block. The state machine either switches to the desired algorithm corresponding to the selected MODE of operation (number in the interval 1..5) at input event REQ, or to the initialization algorithm INIT at the input INIT.

© 2005 by CRC Press LLC

Note that one half of the algorithms encapsulated in the FLASHER4 is programmed in Structured Text (ST), while the other half is programmed in Ladder Logic Diagrams (LD). This is shown in Figures 66.18 and 66.19. This illustrates the opportunities the IEC 61499 function blocks provide to reuse the legacy code and even to combine different programming languages in a single software component.

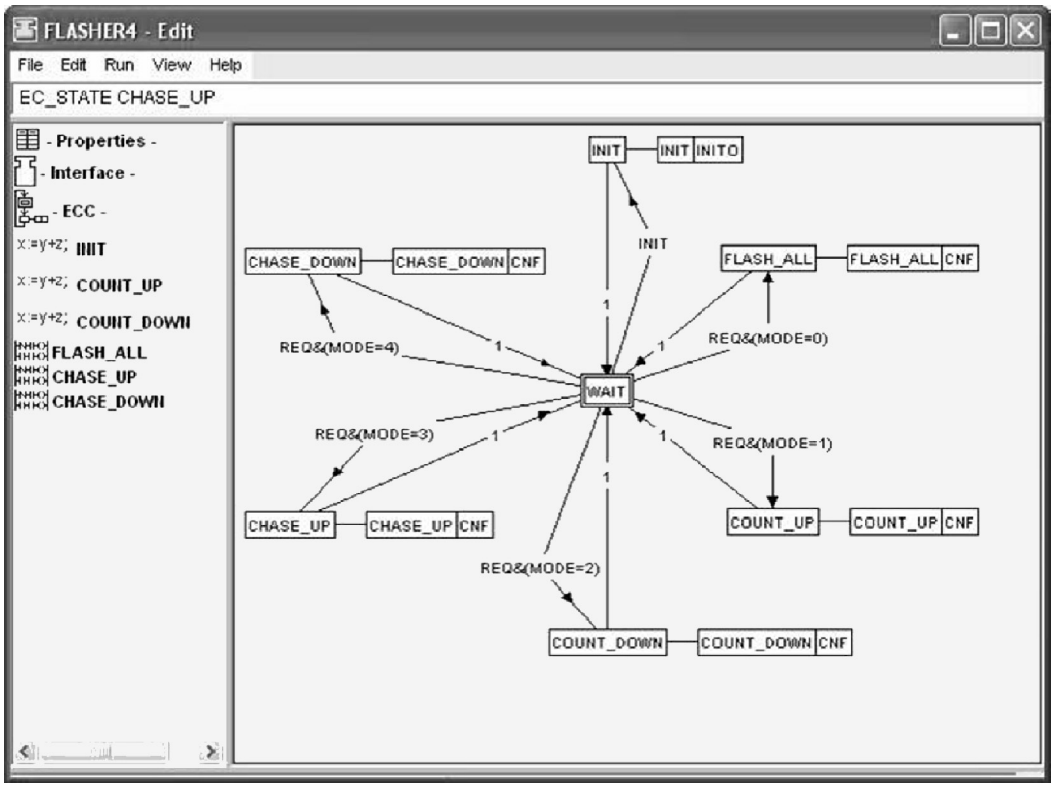

FIGURE 66.17 FLASHER4: Execution Control Chart.

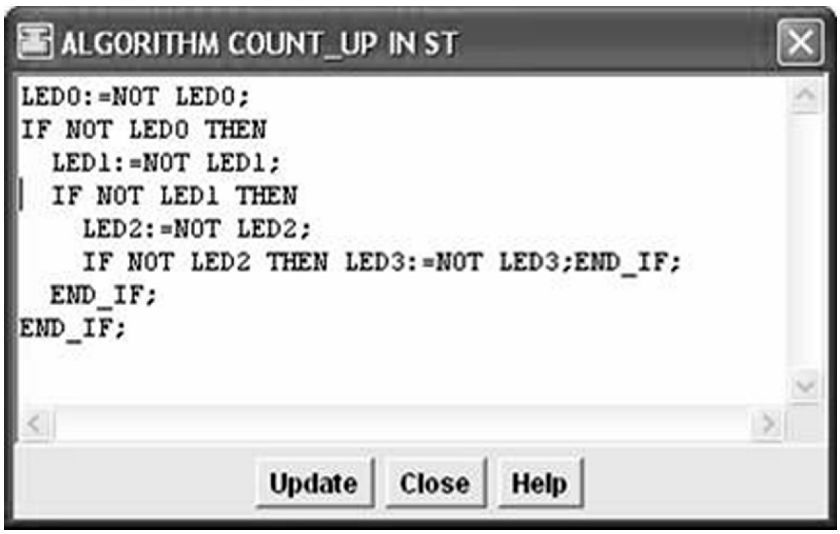

FIGURE 66.18 Algorithm COUNT_UP programmed in structured text.

© 2005 by CRC Press LLC

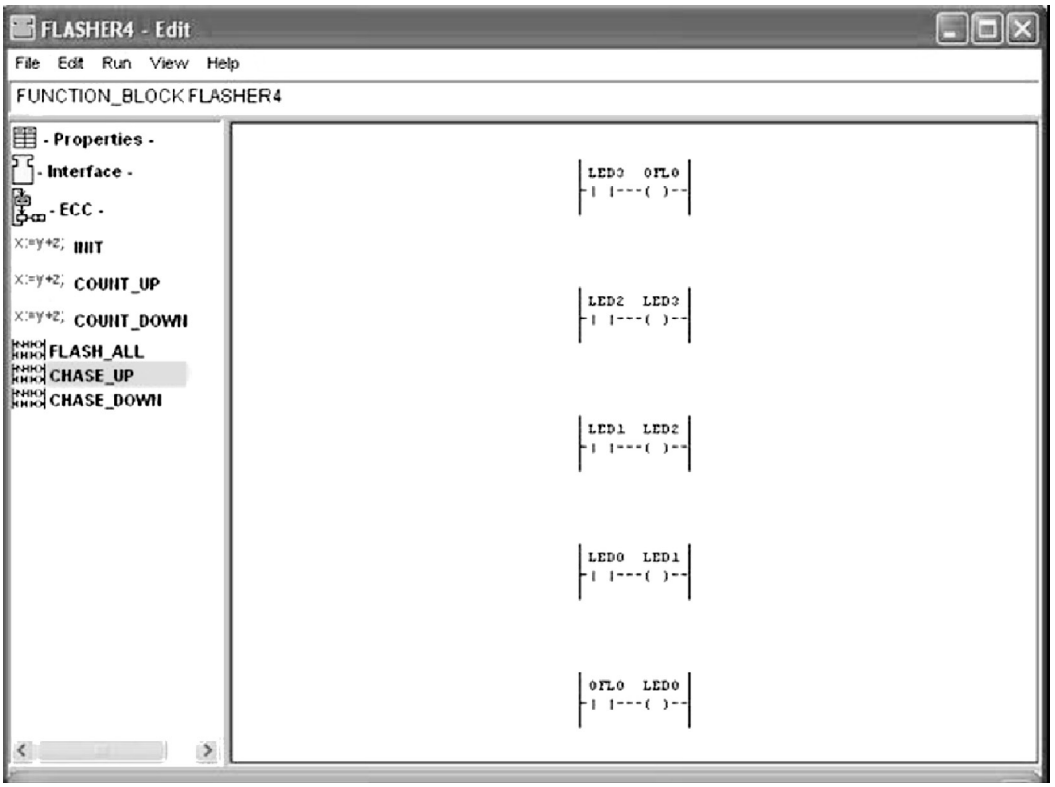

FIGURE 66.19 Algorithm CHASE_UP programmed in ladder logic.

Distribution

The distributed version of the same application is shown in Figure 66.20. The system configuration includes two devices: CTL_PANEL and FLASHER. The function blocks of the application are mapped to either of these devices. In addition, the Communication Function Blocks PUBLISH and SUBSCRIBE are added to connect the parts of the application. The devices may be started or shut down completely independently from each other. As soon as the part located in CTL_PANEL produces any changes in the operation parameters, it will notify the FLASHER's part via the communication channel.

Figure 66.21 shows a distribution of the same application across three devices. Device "FLASHER" (on the right) produces no picture. It produces the output values and sends them to the device DISPLAY given the input parameters received from the CTL_PANEL.

66.4 Engineering Methods and Further Development

In contrast to the present practice of IEC 61131, the specification of a control system following IEC 61499 is a complete change of paradigms. Execution of control code in IEC 61131 is sequential and time-driven. The control engineer who uses the IEC 61499 needs to think in terms of event-driven execution of encapsulated pieces of code. The execution is distributed and concurrent. This requires new methodologies for control system design, verification/validation, and implementation.

A natural way of system engineering using IEC 61499 is a method with the following steps:

1. Identification of the functionality of system components.
2. Encapsulation of basic functionality in these components. This gives the Basic Function Blocks or even Composite Function Blocks.

© 2005 by CRC Press LLC

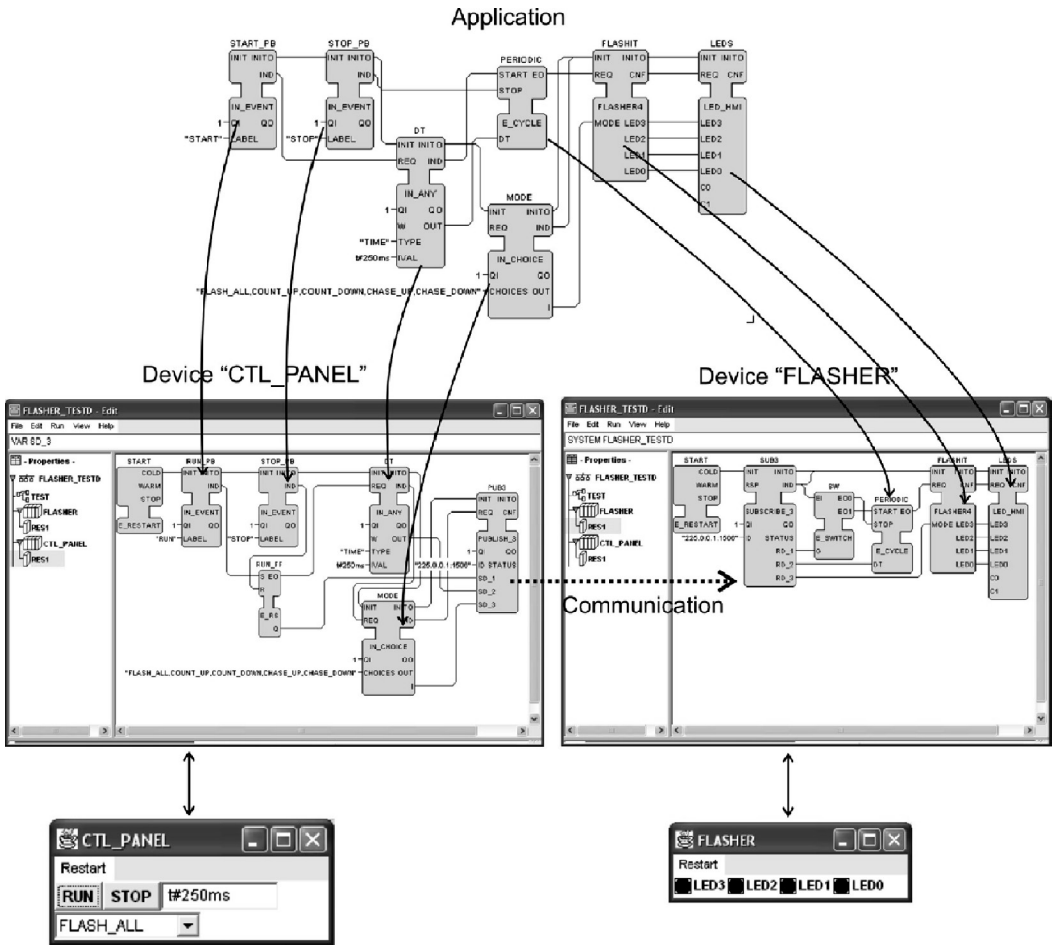

FIGURE 66.20 Application FLASHER distributed across two devices.

3. Interconnection of the function blocks to build an application. External coordination of the network of function blocks may be needed and added.
4. Mapping of the application into a control system architecture.

At least the following questions must be answered to make such a methodology applicable.

- How to encapsulate the existing controllers (sometimes implementing very sophisticated *ad hoc* algorithms) into new event-driven capsules?
- How to specify the component controllers in a way allowing (semi-)automatic integration into distributed systems?
- Conversely, given a desired behavior of the integrated system, how to decompose it to the control actions of the component controllers?

This requires further research and development, in particular, revolving around the concept of Automation Objects [11]. The concept of Automation Objects is understood as a framework for encapsulation and handling of the diverse knowledge relevant to automation systems. This includes operation semantics as well as layouts, CAD data, circuitry, etc. As the scope of IEC 61499 cannot cover all these issues, it probably needs to be combined with ideas arising from other developments, in particular, with IEC 68104 [12] for a more detailed description of device types.

© 2005 by CRC Press LLC

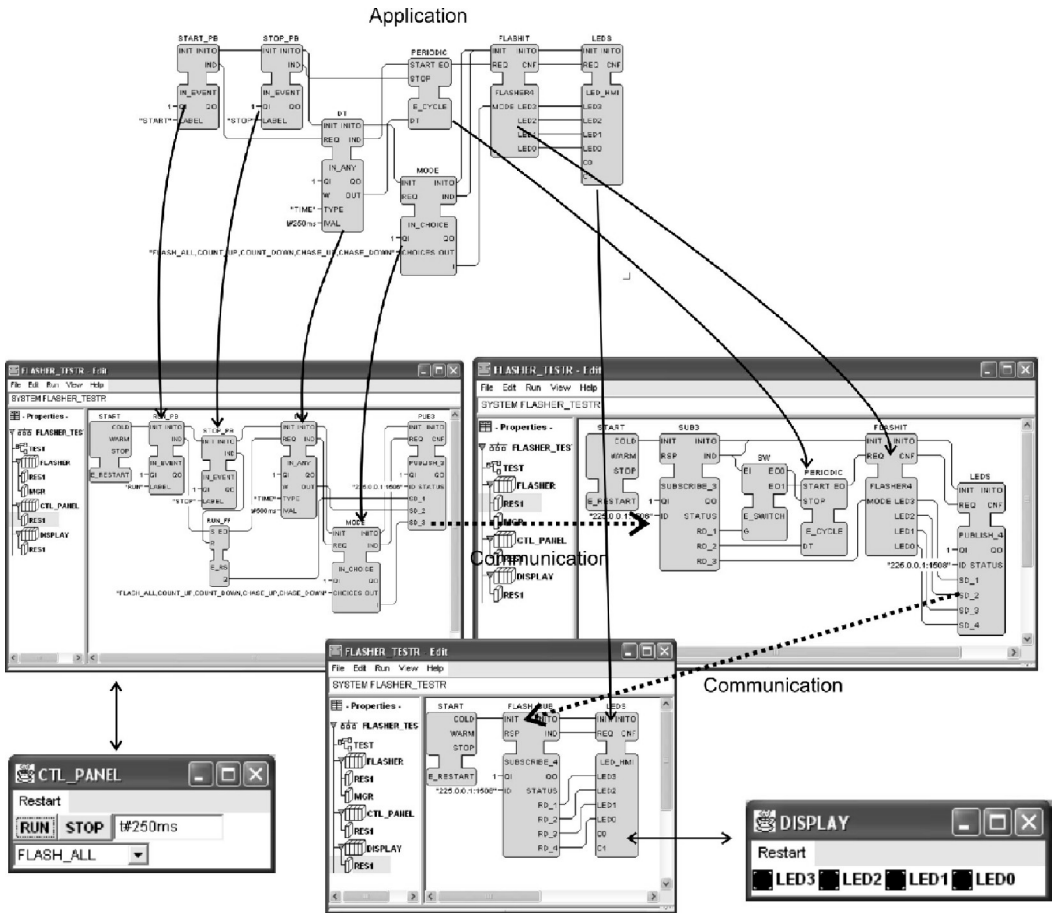

FIGURE 66.21 Distribution of the FLASHER application across three devices.

Conducting such a work requires integration of development activities among leading vendors and users of automation technologies on a global scale. Currently, such an activity is being organized under the support of the Intelligent Manufacturing Systems Research and Development program (www.ims.org) in the form of OOONEIDA project [13].

Currently available engineering methodologies can be found in [6,9]. Also, the idea of combining Unified Modeling Language (UML) with the IEC 61499 promises to provide a consistent engineering methodology for control system engineering. Some details on this can be found in [10].

Another major future issue is how to bring the ideas of reconfiguration to practical applications. The standard itself provides the following means.

1. Basic Function Blocks do not depend on a particular execution platform. They will show equivalent execution semantics on different platforms, regardless of, for example, in which sequence they are listed. This is not the case in the current implementations based on IEC 61131.
2. The functionality of whole applications that are represented as hierarchical networks of function blocks also does not depend on a particular number and topology of computational resources. Thus, system engineering can be done in an implementation-independent way.
3. Models of various devices are represented as device types. This will allow anticipation of the system's behavior after reconfiguration. On the one hand, the way of modeling of devices and resources is very modular. On the other, it uses a very limited number of constituent instruments. It allows modeling of a great variety of system configurations without going into unnecessary details.

© 2005 by CRC Press LLC

4. There are also some other, more technical means provided in IEC61499 to support reconfiguration. One of these is the use of adapter interfaces to minimize interblock connections by means of predefined patterns. Another one includes standard function blocks for manipulations with events.

Another open question for future research and development is how the correctness of the system can be validated. This requires more formal models for simulation or even for formal analysis of the behavior. The concept of encapsulation is extremely useful for embedding such models in the design. In principle, it allows modeling of the whole measurement and control systems with all their diverse components, such as sensors and actuators, networks, computational resources, etc. The models could reproduce the execution semantics of the real system also taking into account such factors as communication delays of particular networks. Moreover, models of the controlled objects can be encapsulated in function blocks as well. This allows to study the behavior of the controller and of the controlled object in the closed loop. The desired properties could be validated by simulation or could even be formally verified. For the first time this approach was applied for formal modeling and verification of IEC 61499-compliant designs in [8]. This approach can also be used for prototyping of the distributed control systems based on their formal models.

It is obvious that all these future developments must be supported by appropriate tools, compliant devices, runtime systems, etc.

Last but not the least, there is a considerable need for training and education of engineering staff to understand and to apply the new concepts of the standard.

Nonetheless, despite the amount of development that still lies ahead, the potential benefits of using IEC 61499 are very clear, and the ideas and concepts define cornerstones of future development and design of distributed control systems.

Acknowledgments

The authors thank Sirko Karras for help in managing the graphic material of this contribution. The authors furthermore express their gratitude to Rockwell Automation and personally to Dr. James Christensen for providing the FLASHER example, for the permission of using Figures 8 and 9, and for the fruitful ideas expressed in the personal communication.

67.1 Introduction

Design problems have increased in complexity over the past few years. The use of Virtual Environments (VE) to simulate and review real-world design problems is being accepted as the norm in most industries today. One factor that impacts the realism of such virtual simulations is the sense of touch and force feedback, which is a very important part of our daily lives [1]. Integration of force and tactile feedback have hence received attention as a new mode of interaction in simulated design and manufacturing environments in recent years. Studies have also been conducted to determine at what point there is a sensory overload, wherein the metric critical to the experiment is being overrepresented, causing confusion and thereby a doubt in the confidence of the person using the system.

© 2005 by CRC Press LLC

67.2 Background on Haptics

Force feedback in virtual reality is often referred to as *haptics*. The word *haptic* is derived from the Greek word *haptikos* or *haptesthai,* which means to grasp or to touch. The principal difference between tactile and haptic feedback is that while sensory input using tactile devices can only be used to impart a superficial sensation of touch, haptic feedback is actively capable of sustaining and returning force inputs to the user. To illustrate this difference, we can consider the example of a simple task of picking up an object in a virtual environment. Using purely tactile feedback, the user will be able to feel this object when he/she comes in contact with it but will not be able to grasp it as his/her hand will pass right through the object due to a lack of resistance, which can only be provided with a haptic "display." Surface textures like surface roughness can be best simulated using a combination of haptic and tactile devices. However, present-day haptic devices that have a fine resolution and sufficient bandwidth are able to simulate surface roughness independently.

A number of haptic devices have been developed in recent years. In the simplest form, haptic devices resemble robotic arms with joints and linkages. With the use of highly accurate encoders, these devices are capable of precisely recording the position and force inputs in three to six degrees of freedom and providing force feedback.

67.3 Computer Interface Technology

The traditional windows and mouse interface that most people are familiar with serves adequately for two-dimensional applications like word processors and spreadsheets. In the realm of the three-dimensional world, these devices have been found to be lacking in a number of ways. Tactile feel of an object in a VE is considered of paramount importance in physical simulations of any kind. The recent appearance of cheap 3-D force feedback joystick for gaming has expanded the use of these devices; but their functionality is still primitive in comparison to more sophisticated haptic hardware.

The sense of touch is a two-way process. Environmental stimuli constantly evoke conscious and subconscious tactile responses. Humans respond naturally in 3-D environments. Computer interface technology has struggled to keep up with the constant demand for information and the explosive growth in program complexity.

Limited capabilities of the computer interface technology severely limit the potential of the user and hamper the potential effectiveness of applications. To demonstrate the importance of physical feedback in a simulation, we can take the case of tool design for aerospace applications that looks at an astronaut training for tool manipulation in outer space. In the absence of a reliable physical simulation, NASA resorts to full-scale mockups of the space shuttle [2]. If this were translated to a virtual environment without force feedback, the user would be able to point to a bolt and it would loosen itself. This does not give the user a good feel for the task as those tasks in the real world; especially in space applications, they are far more complicated.

67.4 Haptic Framework

Haptic applications rely on an accurate representation of force and positions. Most serious simulations have a force model capable of quickly and accurately rendering force and stiffness in correlation with the position of the stylus. Many a time, the virtual object is composed of more than one material having different properties. An example is a simulation involving a dental examination. In order to accurately represent a dental model, one has to account for not only teeth but also surrounding tissue like the gums and tongue. While it may be possible to precompute stiffness and resultant force at every point and interpolate at run-time, using a highly optimized search method or an intelligent data storage algorithm, the application may not lend itself well to changes at runtime. The preferred solution is therefore to create a model map that relies on real-time force calculations for maximum versatility.

Haptic force calculations are very similar to free body calculations based on Newton's third law as represented in Figure 67.1.

67.5 Haptic Hardware

The first haptic devices were derived from the telerobotic arms used in controlling remote robots. This section looks at some of the common variants of such force feedback devices.

Force-Feedback Arms

The simulation of the weight of an object, its inertia, and contact requires force feedback. Robotic arms are common in telerobotics using a master–slave configuration to perform remote manipulation tasks. The master arms employ force-feedback using electric actuators at the joints. Replacing the slave with a computer in the control loop created the earliest force-feedback arms.

Tanie and Kotoku [3] created a force feedback arm specifically for VR applications. Their system consisted of a 4 degree of freedom (DOF) link mechanism with direct drive electrical actuators. A 6-DOF wrist force sensor was placed on the hand grip.

The arm is gravity and inertia compensated, so that the user feels the arm to be weightless when it is not in contact with an object in the virtual environment. However, on contact, the forces felt by the user are computed as:

$$F = [T][B]\Delta r + [K]\Delta r \tag{67.1}$$

where

$[T]$ = Cartesian coordinate transformation matrix
$[B]$ = damping matrix introduced to assure stable contacts
$[K]$ = stiffness matrix which simulates a virtual spring law
Δr = deformation vector of the virtual surface in contact.

The torque vector necessary at the joints in order to replicate the above force is given by:

$$\tau = J(\theta)^{\mathrm{T}} F + \tau_C(\theta) \tag{67.2}$$

where

$J(\theta)^{\mathrm{T}}$ = transpose of the master arm Jacobian matrix
$\tau_C(\theta)$ = compensation torque for arm inertia and weight.

The PHANToM™ Desktop haptic device from Sensable Technologies Inc. is similar in construction but is capable of sensing force in 6-DOF and returning force in 3-DOF. This device is shown in Figure 67.2.

© 2005 by CRC Press LLC

FIGURE 67.2 The PHANToM Desktop (Courtesy Sensable Technologies).

Magnetic Levitation Haptic Devices

The Human–Computer Interaction Institute (HCII) at Carnegie Mellon University developed a 6-DOF haptic device based on the Lorentz force magnetic levitation principle. The magnetic levitation device allows noncontact sensing and feedback, high control bandwidth, and good position resolution. The device is specifically developed for fine haptic motion using the fingertips. It consists of an interactive handle suspended in a "flotor" bowl. Forces are exerted on the interactive handle through six magnets in the flotor bowl. Berkelman and Hollis [4] gave the forces on the flotor to be

$$F = AI \tag{67.3}$$

where

F = vector of length 6, containing the forces and torques at the center of the flotor
I = vector of six coil currents
A = transformation matrix that maps coil currents to forces and is calculated by combining forces and torques.

Utah Hand Master

The Utah Hand Master consists of a master–slave configuration where a four bar link mechanism-based hand master is used to control the slave arm. The pads on each finger rotate in relation to the fixed base and these angular motions are measured via Hall Effect sensors in the pads. Finger movements along the axis of the base pad translate to linear motion and are measured by a separate set of Hall Effect sensors. Similar systems with different actuators are implemented by EXOS Inc. and Bouzit et al. [5] called Rutgers Master II.

67.6 Control of Haptic Hardware

Haptic interfaces have two basic functions. The first is to measure position information from the haptic device and the second is to render the feedback forces so that the user feels them. Typically, haptic applications have force feedback control, which means that given a certain position input from the user, haptic forces are returned. However, some applications use position feedback control wherein force input by the user returns position feedback. Position feedback controllers require the use of force and torque sensors

© 2005 by CRC Press LLC

from which the position is calculated. Position feedback control is not the preferred control method as true position feedback is very hard to achieve and may require the use of extremely stiff actuators. The advantage of using position feedback control is that it reduces the computational load on the model since forces are sensed rather than computed.

Force feedback control systems are open-loop systems. Thus, while a reaction force is returned to the user, there is no force sensing to ensure that the level of force produced in the actuators is accurate. The amount of force actually produced by the actuators depends on physical factors like friction and inertia of the mechanism. To compensate for the above effects and improve control accuracy, the interface needs to incorporate both position and force sensors. This essentially amounts to closed-loop control.

An example of such a system is the one developed by Hannaford and Venema [6]. By expanding network theory, they presented a unified model of the two modes of haptic interaction. Using an analogy of mechanical forces with voltage and position or velocity with current, they reduced haptic interaction to a unified model.

An adaptation of Kirchoff's voltage law to describe force feedback is shown as follows:

$$f_1 - z_1\,(v_p) = f_2 - z_2\,(v_p) = f_p \tag{67.4}$$

where

f_1 = forced sensed
f_2 = force returned
z_1 and z_2 = are mechanical impedances
v_p = velocity of the motion.

67.7 System Performance and Bandwidth Requirements

The performance of haptic devices is influenced by components like the sensors and dampers. Most haptic devices resemble robotic arms and are incapable of being perfectly stiff. The system's overall performance is summarized by its bandwidth. Sensations that require a crisp feeling need higher sampling rates, while soft sensations do not require very high sampling rates. Low sampling rates can therefore have a detrimental effect on the stiffness of the sensation being transmitted. It has been verified experimentally that the PHANToM™ haptic device maintains a uniform bandwidth of 1 KHz during the simulation. Scenegraph or graphics complexity needs to be adjusted to ensure that this minimum bandwidth is maintained. This can be achieved by limiting the number of polygons being rendered. Often, the entire model does not fit in the cone of vision of the user. Culling these polygons from the scenegraph can save valuable computational time.

67.8 Haptic Rendering

Haptic rendering is a computationally intensive process. As described earlier, in order to maintain a continuous sense of touch, it is essential to maintain a minimum update rate of 1000 Hz. Some real-time applications using haptic arms in medical simulations or as tools in surgery may require higher refresh rates. Despite the steady improvement of processing power in the last few years, true real-time rendering of complex haptic models is still difficult to achieve. Many haptic rendering algorithms have been developed over the years to address the problem of displaying complex haptic models within the constraints of available memory and processing power. Some of these techniques have been reviewed in this section.

Most link mechanisms used in robotic arms are inherently compliant systems. Hence, there is a limitation on the maximum stiffness generated by a PHANToM-like haptic device. Most haptic rendering algorithms rely on a vector-based approach to calculate and render a feedback force. It can be assumed that the resultant force vector should be normal to the surface of the object. However, compliance in the mechanism as discussed above can lead to a change in the direction of these vectors and thereby result in

© 2005 by CRC Press LLC

an incorrect force rendering. The problem is compounded when the object in question is thin and there is a merging of the boundaries on either side of the object. Other methods like volume subdivision work well for simple models but produce force discontinuities under certain conditions. Zilles and Salisbury [7] presented the concept of the God-object that addressed the above issues and allows a more realistic force rendering of complex arbitrarily shaped models. In this method, a virtual God-object is superimposed over the point of contact with the object. Unlike the stylus, the virtual God-object does not penetrate the surface and is actually used to compute the resultant forces based on the laws of physics. In their work, they achieved a simulation speed of 1 kHz for an object with 600 triangular polygons on 66 MHz Pentium computer. They claim that significant speedups will be possible by using an improved collision detection scheme as opposed to the simple collision detection used in their test case. Most simulations use a parent–child hierarchical structure to execute geometric and haptic rendering. This makes program execution faster as access to the various nodes is easier. To explain the scenegraph structure, we can consider the example of a simple haptic cube. The parent node would be the transformation node that will have the geometric, lighting, texture, and haptic nodes as its children. Keeping with the top-down hierarchy that governs the scenegraph, any change made to that parent node will affect all the children. The same is true of any of the children who may have children of their own. The real potential of scenegraph representations is apparent in complex VE's where the scenegraph extends several levels deep. Figure 67.3 shows a graphical representation of the scenegraph structure applied to the simulation of a robot.

67.9 Potential Applications of Haptics in Engineering

The information transmitted to the user through touch finds potential use in a variety of engineering applications. A brief review of the applications of haptics indicated its applications in several interesting engineering domains. Complex probabilistic systems are known to contain a factor of risk or uncertainty. Basapur et al. [8] have combined graphic and haptic environment to model uncertainty environment, with the haptic feedback loop accounting for the factor of risk. Hollerbach [9] has employed a haptic interface to probe heterogeneous finite element mesh fitting errors. The amount of error at a particular mesh element was played back as a vibration. This is used as an aide in the preprocessing of finite element meshes. Balijepalli and Kesavadas [10] have explored haptics as a simulation tool in the manufacturing environment (described as case study in this paper), while Joshi and Kesavadas [11] have explored a sympathetic haptic frame work for Product Life Cycle Management (PLM). A more direct force field effect was used by Sharma and Kesavadas [12] to represent vector fields for design problems. An initial point and search vector for exploring design space optimization was implemented in their approach. Costa and Cutkosky [13] have explored perception issues in haptically rendering fractal surfaces. Volkov and Vance [14] studied how a haptic device affects the ability of a person to make design decisions based on virtual prototyping concepts. The specific task involved

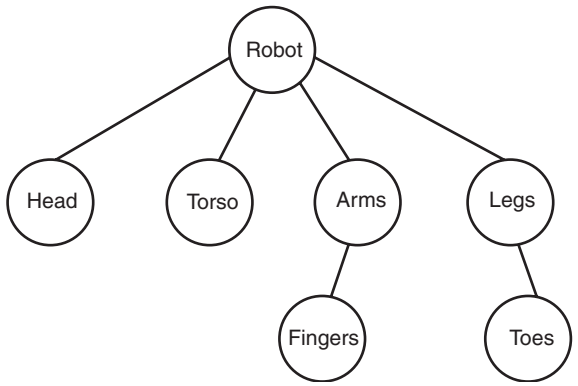

FIGURE 67.3 Scenegraph representation applied to a robot.

© 2005 by CRC Press LLC

evaluation of position and range of motion of a virtual hand brake in a virtual automotive cockpit. This study provides some interesting and informative results regarding preference of haptic treatment. More significantly, it was shown that the users prefer the haptic treatment and this requires lesser time than the nonhaptic treatment for the handbrake design.

In the following sections, two applications of haptics are provided in some detail. The first application involves the use of haptics in simulating complex grinding and polishing task, while the second application explores the use of haptics in design decision-making process.

Operator training of complex grinding tasks

The aim of grinding is to remove asperities on the surface of the workpiece. The theory governing grinding with robots is different from that in conventional machines and needs to be modeled in detail to handle compliance factors of the link mechanism. The force pattern generated during the grinding of scallops depends on the topography of the workpiece.

The contact conditions between the tool and scallops on the surface can be seen in Figure 67.4.

In order to derive the forces at the end effector arm, a model of forces between the grinding wheel and scallops is used. A grinding wheel with a stiffness K_m is assumed and the normal force produced is F_N. However, certain weaknesses were found in this model. They are

1. Low stiffness causes deflection of the end effector arm. As a result, scallops are not removed completely.
2. The high compliance due to the low stiffness can also cause geometrical error.

Prior knowledge of the grinding direction can eliminate the above problems. The normal force F_N is accurately calculated using the Gatlin et al. [15] derivation. If δr is the depth of cut, for complete contact along the width of the grinding tool,

$$F_N = K[C_1]^{\epsilon}[V_w/V_s]^{2\epsilon-1}[D]^{1-\epsilon}[\delta r]^{\epsilon}[D_w] \tag{67.5}$$

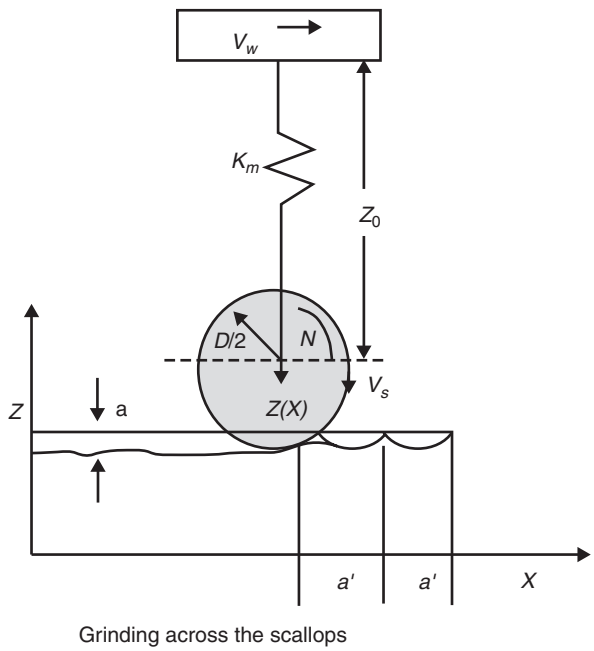

FIGURE 67.4 Contact conditions on a workpiece.

© 2005 by CRC Press LLC

where

D_w = wheel width
C_1 = empirical constant accounting for static cutting edge
D = wheel diameter (mm)
F_N = normal grinding force
K = machine stiffness normal to the part
V_s = wheel surface speed
V_w = relative workpiece velocity
δ_r = wheel depth of cut
ϵ = empirical constant accounting for kinematics of contact
γ = empirical constant accounting for static cutting edge.

The above equation is valid for complete contact of the grinding wheel. However, during a grinding operation, complete contact is not achieved. The length of contact is given as

$$l_k = \sqrt{D_w h} \tag{67.6}$$

The force model is now adapted to account for the contact ratio, which is given as

$$w = (nW/D_w h) \tag{67.7}$$

where

h = contact depth
n = number of scallops in contact
W = width of one scallop from root to root.

Substituting the contact ratio into the normal force equation, we obtain

$$F_N = [\frac{n\,W}{h}]K[C_1]^{\epsilon}[V_w/V_s]^{2\epsilon-1}[D]^{1-\epsilon}[\delta r]^{\epsilon}[D_w] \tag{67.8}$$

where

$$K' = K[C_1]^{\epsilon} \tag{67.9}$$

Image Processing to Obtain Surface Roughness

Traditionally, computer graphics are modeled as a collection of smooth surfaces stitched together to form a composite structure. It is assumed that any or all of the components that make this model can be defined deterministically using mathematical functions. While some complicated structures can be defined by Bezier or B-spline surface patches that use higher-order polynomial functions, this process can be time consuming and very memory intensive. The problem is compounded with complex virtual environments consisting of millions of polygons. With advances in graphics hardware and the ability to texture map digital photographs onto polygons, the load on the graphics engine is reduced. Greater approximations are effectively masked by realistic texture maps. For example, smart billboards consisting of only a single polygon and mapped with an appropriate texture can be made to constantly face the user, thereby eliminating the need to model the environment in multiple views.

These methods are, however, not suitable for modeling terrains from data sources like satellite or aerial photographs. Naturally occurring phenomena do not necessarily conform to well-defined mathematical functions and hence may not be effectively represented using the stochastic methods. The particular method selected for generating a terrain, however, will depend on the end application.

Height Maps

Height maps can hold detailed information about the surface of an object. They represent an effective means of displaying terrain data extracted from photographs. Since the generation of a height map is

© 2005 by CRC Press LLC

dependent on the lighting conditions present at the time, it is not the most accurate method of generating a terrain. However, in computer games like flight simulations where the margin for error in the accuracy of the representation is high, these methods are an effective way of representing background terrain formations. In our application, we are interested in using height maps to represent surface roughness of a workpiece based on the image of that workpiece. For very precise models where accuracy is of paramount importance, precise methods like laser scanning or a roughness meter can be used to extract features of the surface of the workpiece. In our case, by specifying the light conditions in advance, it is possible to reduce the variations in image quality.

Height information can be added to a 2-D image by analyzing the light intensities of its pixels, assuming that the light conditions at the time of taking the picture are constant. Shadows formed on an object are directly related to the height of a particular point, respective to its surroundings. While the lighter areas are elevated, the darker areas of an image are depressed. An example of this principle can be found in photographs of a human face. Incident light causes the elevated areas of the nose and cheekbones to appear lighter than the depressed orbs of the eyes, which usually are darker as shadows tend to form on them. Using this fundamental principle, it is possible to extract some basic height information from a simple image.

Height information is extracted as a function of the light intensity values. The z-coordinate at each pixel location is then calculated choosing a suitable amplification or scale factor. Height is calculated with respect to the minimum intensity value in the image using the relation:

$$height = (intensity - min)/(max - min) \tag{67.10}$$

where

height = calculated height(z-coordinate) from pixel (x,y)
intensity = intensity at pixel (x,y) of image
max, min = maximum/minimum intensity value in image.

Creating the Height Map Surface

3-D height map information can be extracted from a 2-D image source, such as a photograph. An uncompressed grayscale image in Targa (TGA) format is used. An OpenGL TGA loader was developed to load the image header and data into dynamic arrays. The loader is capable of loading uncompressed grayscale and RGB(A) images. In the case of RGB(A) images, the image is converted to grayscale before any further processing is performed. Conversion takes place using the empirical relation:

$$\text{grayscale} = 0.30R + 0.59G + 0.11B \tag{67.11}$$

Intensity values are stored for every pixel of the image. Height information for the image is generated using these intensity values. Grayscale intensity values range from 0 to 255, 0 representing the darkest (black) and 255 representing the brightest (white).

The final height values are obtained by multiplying the height values by the scale factor. Finally, the height map generated is saved into the PNG format.

Figure 67.5 shows an image of a rough surface with a high number of surface asperities. The conversion into height map is shown in Figure 67.6.

The Haptic Model

Two threads are allocated: one for updating the graphics at 60 Hz for mono or 100 Hz for stereo and the second, a haptic servo loop running at 1 kHz. The refresh rate of 1 kHz in the haptic loop has been found to be necessary to maintain a sense of continuity. All developmental work was carried out on a high-end Dual Pentium III computer.

The model was loaded as a VRML file. By reading the field values of the VRML, into the program, a scene graph was constructed giving control over the various parameters of the model. The VRML file

© 2005 by CRC Press LLC

FIGURE 67.5 Image of a patterned rough surface.

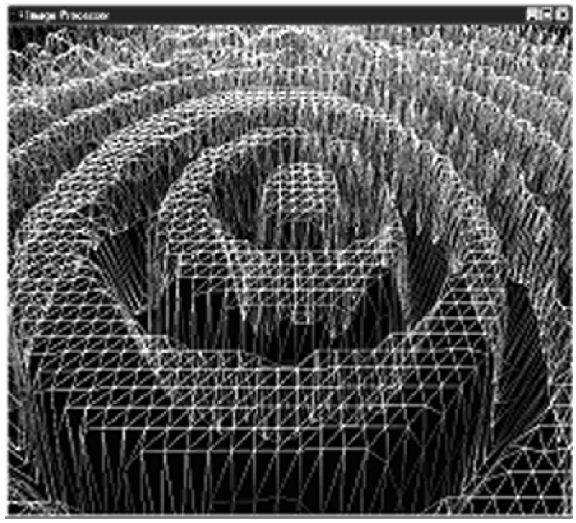

FIGURE 67.6 Surface after extracting height data from image in Figure 67.5.

was used only to load the initial configuration. A simple geometric object, a box in this case, was created. The height map texture was applied on the geometry. All the data extracted from the image (Figure 67.5) were stored in the allocated memory and the necessary lookup functions are precomputed. The rough surface generated by the height maps in Figure 67.6 could then be felt using the PHANToM. Positional information of the stylus was stored sequentially and correlated with the force information at that point. The recorded data are exported for analysis. Using this system, the operator could interactively choose the machining path and the specific surface of the workpiece to be machined. The haptic interface is shown in Figure 67.7.

© 2005 by CRC Press LLC

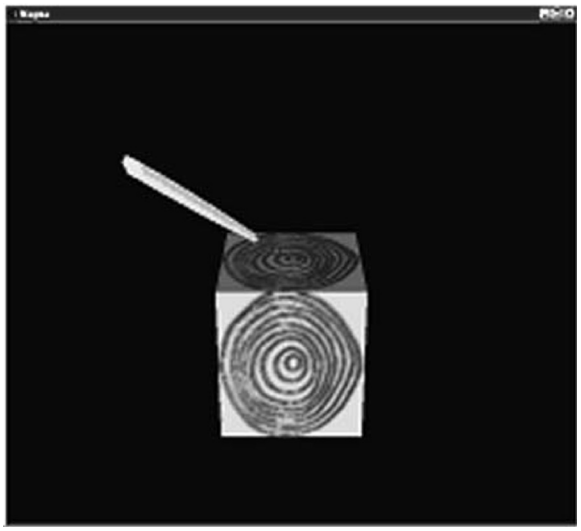

FIGURE 67.7 The haptic interface.

Dynamic Texture Modification for Enhanced Realism

The effectiveness of this simulation is dependent on both the physical characteristics of the height map and the accuracy of the predicted forces. A height map texture that remains unchanged when the applied force is defined as a *static texture*. A static texture greatly limits the practicality of the application. While performing a grinding task, one of the factors that help determine the user's progress is a perceivable change in the feel of the surface being machined. It is extremely difficult for the user to gauge his/her progress without this tactile feedback. In the real world, as the operation progresses, material is continuously removed from the surface. This causes the surface to smoothen out. At the end of the task, if performed correctly, the entire surface should feel and visually appear to be smooth. Hence, a good simulation must take this into account and make suitable adjustments so that the user can perceive changes in the surface texture both haptically and visually.

The variables affecting material removal are speed of the tool, machining velocity, depth of cut, tools stiffness coefficient, and the force applied. Keeping all other factors constant, the amount of material removed is directly a function of the force applied. This information is stored in a table within the program along with the value of the color of the surface texture observed for a particular texture height value. In our case, shades of gray represent different levels of imperfections with white (no z-value) to represent the smoothest surface. The maximum range of height of roughness is small enough to allow a linear approximation. Moreover, the haptic sensors in our hands do not have the resolution to perceive extremely fine changes in roughness and hence the overall error due to the linear approximation is negligible.

A suitable data structure is devised to store this information. At runtime, the haptic device samples the force applied at a particular point and the corresponding color interpolated from the lookup table. The color of the pixel at that point is changed based on the result from the table. The height map is recalculated during the next update, which takes place 1 msec later and the new point is automatically calibrated to reflect the changed height. When the height at a particular point reaches the optimum value, the lookup function is disabled in order to prevent a reverse effect that might signify addition of material.

Another common phenomenon observed in a grinding process arises from the application of excessive force on the workpiece. This leads to an irreversible scarring (gouging of the material from the surface) of the surface. A visual and haptic representation of this phenomenon has been developed, which occurs when the force applied at a particular point exceeds a preset threshold force. Figure 67.8 shows the effects of texture modification as seen by the user.

© 2005 by CRC Press LLC

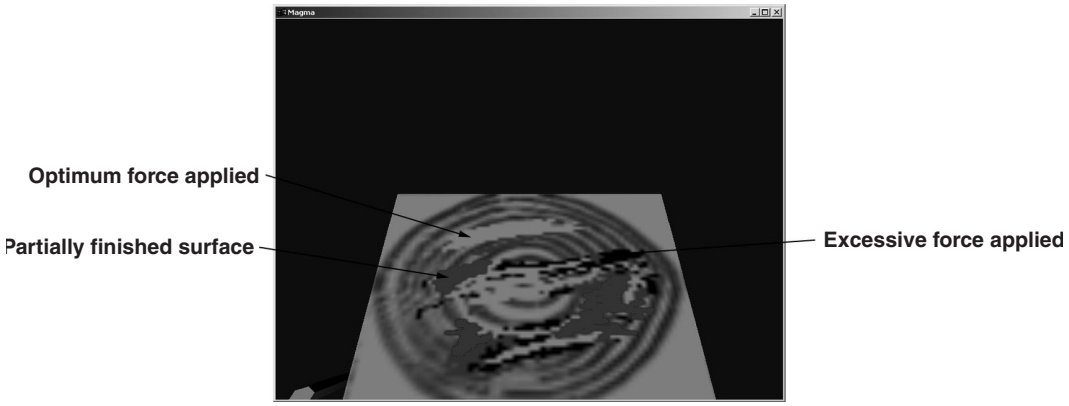

FIGURE 67.8 Dynamic texture modification.

The User Interface

A user interface has been created using OpenGL to display position and force. When training human subjects, in order for them to get a better feel for the force, the new data are displayed once every 5000 cycles of the haptic loop. A 3-D wire frame model of the work piece is displayed in one window (Figure 67.9[a]). The position values of every point, sampled at 1 kHz, are superimposed on this model. The points are color keyed to highlight force distribution on the model, red being the highest force and green being optimum. Shades of orange represent a higher than optimum force. The second window (Figure 67.9[b]) is a plot of the forces at each point, combined with other relevant data like the target force and the moving average. The target force represents the optimum force that the user should apply in order to effectively machine the surface. The moving average is the grouped average of 100 samples of force applied by the user. This plot is also useful in observing the learning curve of the person using the haptic simulator. The third window (Figure 67.9[c]) quantifies the data in the plots and also displays the total time taken. This user interface can read in VRML files containing the indexed face sets, thus allowing virtually any model that is loaded in the haptic framework to be displayed in our GUI.

Experimental Validation

Sets of experiments were performed to bring out the value of using haptics in operator training simulations. Experiments were broadly split into two groups [10]. One group could feel the roughness of the height map texture, while the second could feel only a smooth surface. Both groups were provided with visual updates of the textured surface. The main groups were then subdivided into two subgroups. One was given a specific instruction to follow the direction of the surface pattern and the other was asked to use his/her intuition to select a method in performing the task — that is, to remove the texture and make the surface smooth. Each subject performed the test with two different patterns. The time taken for each subject was recorded. The average force was computed based on samples collected at 1 msec intervals. A questionnaire to assess the user's perception of the haptic sensations fed to him/her was administered. The questions contained a scale from 1 to 5 that gauged the confidence, realism, and security they associated with the force feedback.

Inferences

When an operator performs this task, he/she subconsciously relies on the vibro-tactile feedback communicated through the tool to the hands. The amount of force applied and subsequent force corrections are adjusted automatically because of the perception of this surface roughness. Data clearly show that subjects who could feel the surface roughness could better relate to the actual physical process than subjects who did not.

© 2005 by CRC Press LLC

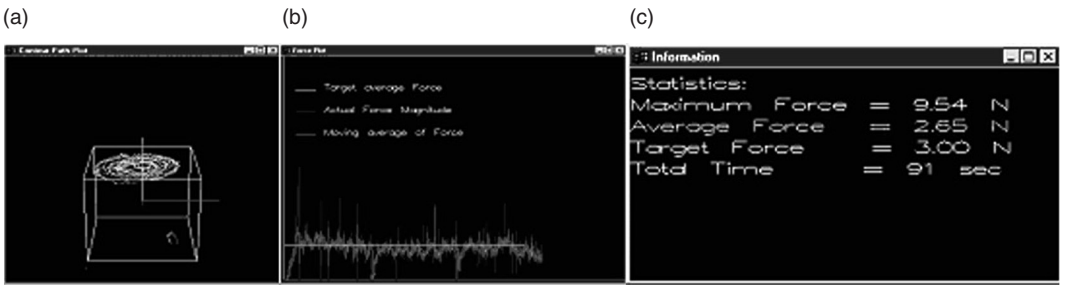

FIGURE 67.9 Graphical user interface.

Without a real-time interface that gives the current force being applied against the desired target, sometimes the only option left to the user is to make an estimate by guessing. This induces a learning effect that in time lets the user predict the force fairly accurately, without referring to any numerical feedback information being displayed. Participant feedback shows that the users with force feedback are in general more confident about their actions than users without force feedback.

67.10 Haptics in Design Optimization

The effect of improved cognition on algorithm performance and evaluation is an exciting area of research. Virtual reality is becoming increasingly popular as a tool for interacting with data and steering the solution, rather than simply displaying results. Constantly evolving haptic technology allows people to directly interact with digital objects and data as they do in the real world using their sense of touch. Haptics is revolutionizing the way engineers interact with computers. Hitherto, designers and artists have used haptics to intuitively sculpt models using digital clay and doctors have trained on haptics-based virtual surgical simulators. Most applications, however, merely seek to make up for the lack of sense of touch and its effects. The current work investigates the application of the haptics loop for decision support activities in core engineering areas like design optimization and shop floor layout. An architecture combining large-scale visualization environment with haptics is proposed. The Simulated Annealing (SA) algorithm, a popular heuristic for solving the Quadratic Assignment facility layout problem, is used as an example to showcase the concept. The use of combined haptics and graphics for sensitivity analysis provides interesting results.

Conceptual Framework for Haptics in Engineering Analysis

In complex design processes, often the user is faced with the task of analyzing very large number of variables. The effect of design decisions on quality, safety, and other important feedback may escape the designer since some of the design or mathematical elements may lack an intuitive feel to it. The ability to present some of these elements in forms of haptic feedback such as force, vibration, resistance, etc., may add a new dimension to the process of design. This work explores a framework for such a system for solving a facilities layout problem using the SA technique. A what-if analysis for shop floor decision making, involving a single choice over several scenarios, can include haptic effects for decision making. Facilities Planning (FP) is the process of locating and laying out of industrial and service facilities to best support the purpose of the facility while respecting constraints on resources such as space and budget. The FP function involves strategic, tactical, and operational decisions depending on the nature of the facility [16].

The multiple FP layout scenarios are visualized using the Virtual Factory (VRFACT) software developed at the University at Buffalo [17]. The PHANToM desktop developed by Sensable Technologies Inc. is used to move the facilities (and machines) around inside the shop floor. The PHANToM desktop produces a buzz effect when the facilities are located at positions corresponding to an optimal configuration. The intensity of this effect is proportional to the solution quality measure. The backbone architecture to provide an integrated GHUI (graphical haptic user interface) is shown in Figure 67.10.

© 2005 by CRC Press LLC

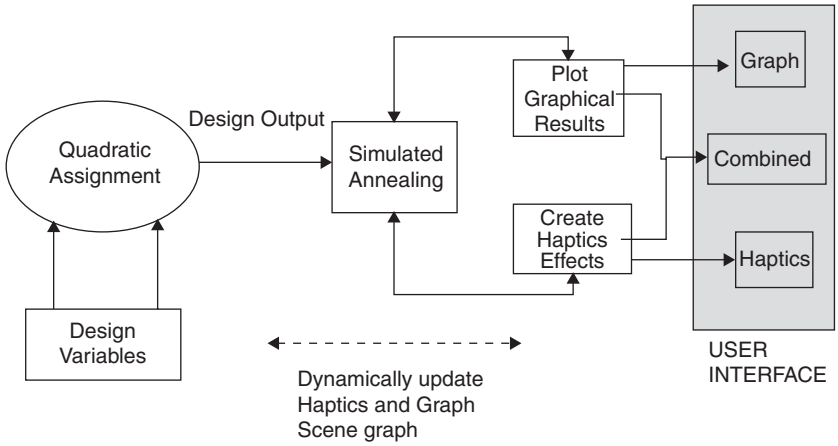

FIGURE 67.10 Haptics-based integrated visualization environment.

The quadratic assignment problem [18] for facility location used to determine the optimum solution is described in the next section. The locations of facilities on the shop floor are obtained and stored using the SA algorithm, described in the following section.

Quadratic Assignment Problem (QAP) Formulation

The layout problem consists of determining the relative positions of the k entities in the set (m_1, m_2, m_k), which may represent either the set of machines, belong to a cell or the set of manufacturing cells within the shop. This analysis seeks to minimize the total distance traveled by the manufactured parts, or pallets of parts, between these entities.

The objective function is defined as

Minimize:

$$E = \sum_{i=1}^{k-1} \sum_{j=i+1}^{k} T_{ij} d_{ij} \tag{67.12}$$

where

Tij = number of pallet transfers between entities m_i and m_j

d_{ij} = distance between entites m_i and m_j

x_{ij} = 1 if the department i is assigned to site k

0 otherwise

where T_{ij} is the number of pallet transfers between machines m_I and m_j, and distance d_{ij} is the corresponding distance. The value of T_{ij} is the number of pallet trips required for transferring all parts, which use the two entities consecutively. Note that the quantity T_{ij} may also be weighted by any combination of parameters to consider special material handling requirements, part weights, actual material handling costs, etc. To quantify the distance d_{ij} between the entities m_i and m_j, the "Manhattan" distance measure is used

$$d_{ij} = |x_i - x_j| + |y_i - y_j| \tag{67.13}$$

where (x_i, y_i) and (x_j, y_j) are the coordinates of the geometric centers of entities mi and mj, respectively. Since the coordinate space is discrete and finite, each point in the space is assigned a unique "position number" in order to simplify the analysis. The problem thus consists in determining the position number corresponding to each of the k entities corresponding to the objective function of Equation (67.13). It is assumed that entities do not overlap when they are assigned to adjacent positions. Furthermore, each position cannot be occupied by more than one entity. The quadratic assignment problem is a difficult

© 2005 by CRC Press LLC

combinatorial optimization problem. An exact solution for problems larger than 14 departments is generally very difficult. Accordingly, the problem is usually solved using heuristic methods.

Proposed Solution Methodology

SA [19] is an approach to solving difficult combinatorial problems that has gained considerable attention in recent years. The approach is based on a Monte Carlo model used to study the relationship between atomic structure, entropy, and temperature during the annealing of a sample of material. In the context of QAP, simulated annealing resembles the pairwise heuristic, with one very important difference: if an interchange increases the total cost, it may still be accepted with some predetermined probability. Thus, there is at least some chance that an unlucky choice for an intermediate solution will not cause the search to be trapped at a suboptimal solution. The sample plot obtained for the SA algorithm is as shown in Figure 67.11 with a snapshot of the layout corresponding to one of the multiple optima.

The SA algorithm produces several optimal layouts making the choice of one particular layout configuration difficult. As shown in Figure 67.11, a minimum material flow may correspond to different combinations of machine locations.

Haptics Process for Design Evaluation

The goal of this research is to develop an interactive analysis tool for helping a designer to try various design options and study its effectiveness using haptic-based multimodal interface. Figure 67.10 shows the sequence of the evaluation process. Thus, the process would require the optimization to be carried out first and then an interactive session would ensue where strategic alternatives would be studied in further detail. An example of such an analysis in the domain of facilities layout would be to study the human factor or ergonomic issue in conjunction with the optimization results. Thus, even though a set of optimization results are in place, the need for two similar machines to be adjacent to each other may override the original goal of the minimizing the distance that a part/pallet moves. However, when altering the machine layout, the effect in terms of the original goal is also ascertained using the proposed interface.

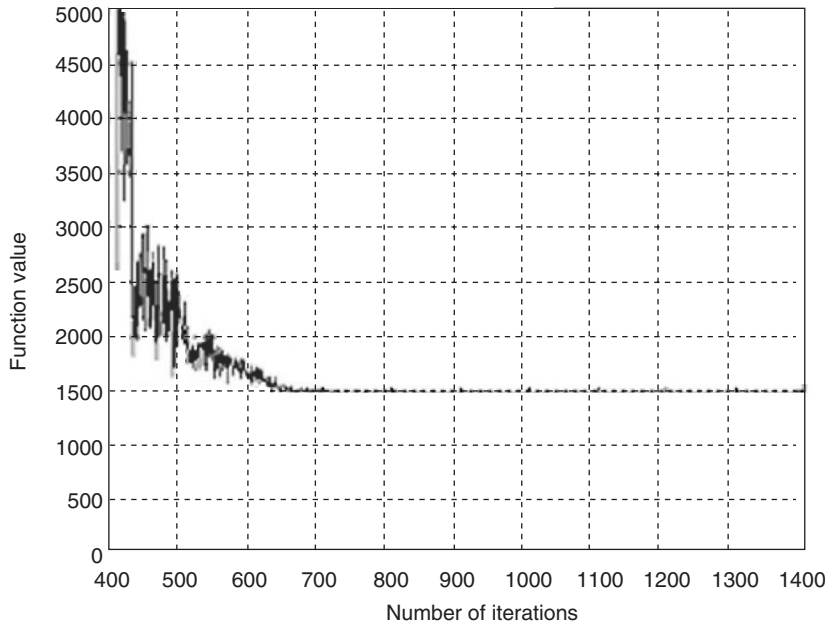

FIGURE 67.11 Sample plot for variation of objective.

© 2005 by CRC Press LLC

The present work provides three modes of this interactive design analysis: (i) using only force effects to represent the optimization results, (ii) graphical plots showing the results, and (iii) a graphical + haptics interface where the user is provided with both graphical and haptic effects simultaneously.

The machines/facilities in the problem are shown as cubes within a shop floor grid as shown in Figure 67.12 (middle). The user can click and drag the machines to different grid locations.

In the haptics interface mode, the cube is moved using the PHANToM haptic device. While a move is being made, based on the efficiency as described in the next section, an appropriate force will resist the movement of the block. The viscose effect creates a feel of moving the block in a resistive environment, such as on a high-friction surface. The resistance to movement of the block is inversely proportional to the efficiency of the solution based on the optimization results already obtained.

In the graphical plot mode, the blocks are moved with the mouse and the results are presented as a 2-D plot. In this case, there is no haptic feedback to the user. In the third mode, both the haptic and graphical results are presented simultaneously to the user. The goal of the above design process is to prompt the user to arrive at the best solution based on the three modes of feedback.

The proposed steps of operations for obtaining a haptics-based integrated decision-making and computational environment is as follows (Figure 67.10):

1. With the proper choice of input parameters, the SA algorithm is run, to obtain layouts corresponding to multiple optima.
2. These objective function values corresponding to these optimal layouts are stored in a file.
3. Choosing a good layout is a combination of the layout corresponding to time as well as a good solution quality measure and are represented as spring stiffness '*k*' and viscosity '*c*' for viscous force effects in a haptic scene graph. These values are normalized to lie between 0 and 1 to represent spring stiffness and 0.002 and 0.009 for viscosity. By moving facilities around to different locations, a viscous effect corresponding to the solution quality measure and CPU time is represented. The resultant force expression is of the form:

$$f = kx + cx \tag{67.14}$$

where "x" is the velocity of the probe at location "x."

The designer makes his/her decision using one of the three modes as described earlier.

Results of a Testing of the Environment

A PHANToM desktop haptic device was used for the experiments. PHANToM is capable of simulation of 3-D force feedback actions such as viscous effects, softness, hardness, vibrations, etc. In order to appropriately

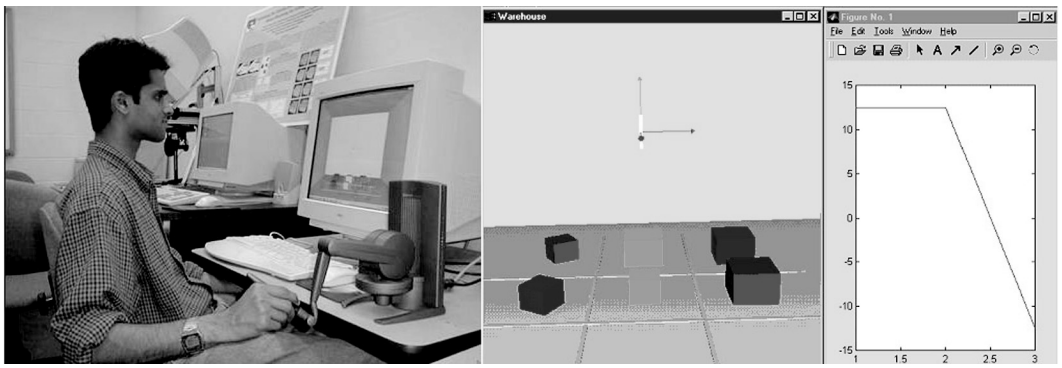

FIGURE 67.12 Experimental setup (left) used in the experiment. The 3-D blocks represent machines (middle) and graph interface shows the efficiency as a plot (right).

© 2005 by CRC Press LLC

represent the machine layout problem, the scene graph consisted of six blocks, in red, green, and blue colors. For each color, two different shapes were created. The placement of the blocks in the grid corresponds to one of three costs: optimal (−12.5), satisfactory (0), or unwanted (12.5). The "goodness" of the layout can be evaluated by plotting the cost corresponding to a particular layout arrangement graphically through a 2-D plot or by getting a resistive force corresponding to the costs associated with the solutions or as a combination of both graphical and haptic effects. Guided by these visual and haptic cues, the layout designer is asked to arrive at a solution. The time taken to arrive at a solution for each set of experiments is recorded and later compared using ANOVA and the "*t*"-test to decide whether there is a significant difference in the results obtained. Twelve subjects carried out the experiments in a completely randomized order. Each subject also answered a questionnaire for a subjective evaluation on using the Phantom desktop and the experiment in general. The designers were encouraged to give their views during the trial run.

Several interesting results were observed in this work. In all, 66% of the subjects preferred a combination of haptics and graphics to pure haptics or pure graphics interface. It was also observed that the time to arrive at a decision was fastest with the haptic interface. Haptics interface took on an average 35–45% less time than the graphics and the graphics+haptics interface, suggesting that haptics is indeed a powerful new way to interact with complex design scenarios.

68.1 Introduction

For interconnection purposes, a factory automation (FA) system can be combined with various sensors, controllers, and heterogeneous machines using a common message specification. In particular, interconnection of heterogenous machines through a common message specification promotes flexibility and interoperability.

For this reason, the *manufacturing message specification (MMS)* standard has been developed. The stan dard specifies a sets of communication primitives and communication protocols for the factory communication environment. In particular, the MMS standard specifies various functionalities of the different FA devices in a compatible way. Thus, users of MMS applications have to use functions from only one unique set of functionalities to operate various kinds of automation machines. Moreover, the different automation machines can communicate among themselves through the standard automation language. This enables transition from the traditional centralized control to the distributed control systems.

© 2005 by CRC Press LLC

The MMS standard is composed of the common standards [1, 2] and the *MMS companion standard (MMS-CS)*. The MMS-CS includes device-dependent specifications for a robot [3], numerical controller (NC) [4], programmable logic controller (PLC) [5], and process control (PC) [6]. In its initial stage, the MMS standard was developed for an application layer of the manufacturing automation protocol (MAP) [7]. Nowadays, MMS has been implemented on top of the TCP/IP protocol suite and is used as a reference model for industrial network or other message protocols, such as the home network protocol [8]. In particular, MMS is implemented in a minimized form as the application layer for Profibus (Process Fieldbus) [9] and field instrumentation protocol (FIP) [10].

A *virtual factory* environment can be used to examine the correctness of an implementation and as a test solution of an FA system prior to installing the system in a real factory communication environment [11, 12]. Furthermore, by using the virtual factory communication system, developing time and costs can be minimized. In addition, it can be used as a training tool of MMS users. In this article, the virtual factory communication system was designed and implemented with the use of the MMS standards and its CS part.

Researches in the MMS technology include application of factory devices, middleware, and multimedia communication. In [13], a real NC machine was implemented using the MMS-enabled application program. In [14], an MMS with common object request broker architecture (CoRBA) was studied. A modified architecture was proposed for multimedia communication in an FA system [15, 16]. The performance evaluation and an analysis methodology of the MMS standard have been studied as well [17–19]. However, to the best of the authors' Knowledge, implementation of a virtual factory communication system using the MMS standard and its CS part has not yet been reported in the technical literature.

In this chapter, we describe the implementation of a virtual factory communication system using the MMS and the MMS-CS standards. In addition, we discuss here the implementation of an MMS Internet monitoring system (MIMS) for on-line monitoring of the developed virtual factory communication system.

This chapter is organized as follows. In Section 68.2, the design of the MMS communication on top of TCP/IP is described. The developed virtual factory communication system is presented in Section 68.3. In Section 68.4, MIMS, the monitoring program of virtual factory, is introduced. Finally, summary and conclusions are presented in Section 68.5.

68.2 MMS on Top of TCP/IP

Two types of protocol structures for the MMS communication on top of TCP/IP, referred to here as "MOTIP," have been studied [3]. One method, which is based on requests on comments (RFC) 1006, uses the open systems interconnection (OSI) 7-layer model [20]. The other method is based on N578 that defines the direct mapping relation between the M-services and the TCP functions [21]. In particular, we chose to use the N578 method in the implemented system because of its simplicity. The differences between the structures of a Full-Map, Mini-Map, and MOTIP are presented in Figure 68.1. In the case of Mini-MAP, IEEE 802.4 token-bus network is used instead of the Ethernet (IEEE 802.3) subnetwork. From

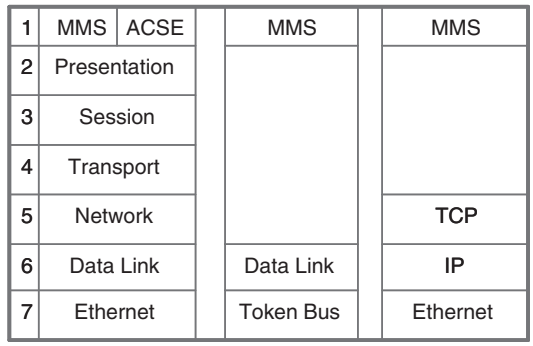

FIGURE 68.1 The various types of the MMS Protocol Structures (Full-Map, Mini-Map, and MOTIP).

© 2005 by CRC Press LLC

Figure 68.1, a Full-Map structure has a scheme similar to MOTIP based on the RFC 1006 method, and the Mini-Map structure is similar to MOTIP based on the N578 method.

The implemented virtual factory communication system is based on the description of a practical test plant shown in Figures 68.2 and 68.3. These figures show an overview (Figure 68.2) and the layout (Figure 68.3) of a practical test plant using the MOTIP-based program. MOTIP-based communication programs have been tested with the Mini-Map and the Full-Map system using a developed gateway, and the developed virtual factory communication system is a miniature of the test plant in Figure 68.3.

M-Services and MMS Interface in MOTIP

As depicted in Figure 68.4, the MMS functions convert a data control block (DCB) to the corresponding parameters of the M services.

Encoding and decoding can be used for converting DCB to PDU directly. The encoding and the decoding rules are based on abstract syntax notation 1 (ASN.l) [25, 26]. The protocol data unit (PDU) is then forwarded to the TCP layer. Table 68.1 presents the mapping relations between M-services and the TCP functions in the MOTIP implementation [14].

The protocol stack of MOTIP using N578 rule is shown in Figure 68.4. Once an MMS function is requested at the MMS client side, the synchronous service or the asynchronous service can be used for communication. Using the synchronous service, the MMS client receives a confirmation through a response from the MMS server. In the asynchronous service, the functions can be executed according to a received event through the response of the MMS server. Most of the implemented MMS services are executed by synchronous mode in the developed system.

68.3 Virtual Factory Communication System

The developed virtual factory communication system was implemented with the Microsoft Visual C++ and OpenGL library [27]. The virtual factory is embodied by integrating each virtual real machine (VRM), the MMS-CS program, and the MOTIP programs. Each VRM can be communicated with through the developed MMS-CS program based on the SNU MMS library [23].

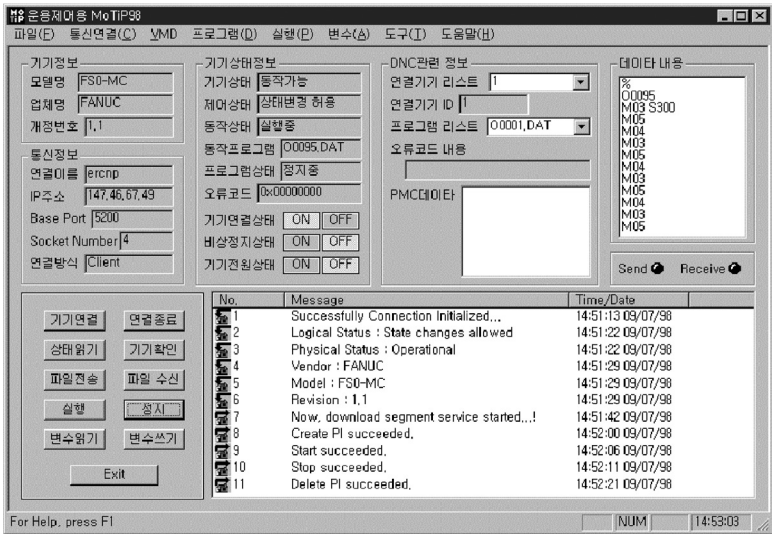

FIGURE 68.5 Screenshot of the MOTIP-based central control program.

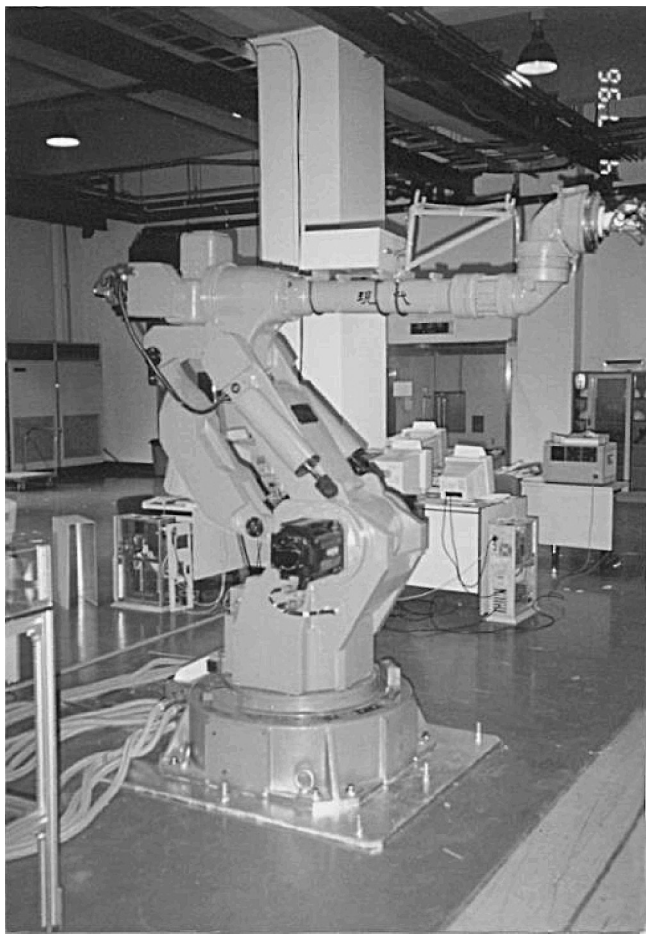

FIGURE 68.6 The practical model of a 6-axis robot VRM.

© 2005 by CRC Press LLC

The MOTIP central server program (see Figure 68.5) can be located in a control room of a factory plant. The MOTIP central server can monitor and command the MMS services to the networked manufacturing machines. The implemented MMS services are as follows: virtual manufacturing device (VMD) service for the status acquisition of a networked machine, domain service for file transfer, program invocation (PI) service for the remote execution of a program, and miscellaneous services for reading and writing services of device status and operations. PI services includes creation, initialization, termination, and deletion of a remotely executed program. PI service can be carried out with other services. For example, the remote execution of a specific program can be performed after downloading the status and segment service using the VMD and Domain service. Figure 68.5 shows the execution of the VMD, the Domain, and the PI services in the MOTIP program.

MMS Companion Standard

The implementations of the MMS-CS VRMs are based on the MMS services specification in [l–6]. Specifically, the services of the implemented MMS-CS VRMS consist of: VMD, Domain, PI, and miscellaneous services.

The implemented services are as follows:

- VMD services (3): *Status*, *Identify*, and *Unsolicited Status*.
- Domain service (5): *Initiate Download*, *Download Segment*, *Terminated Download*, *Initiated Upload Segment*, and *Terminate Upload*.

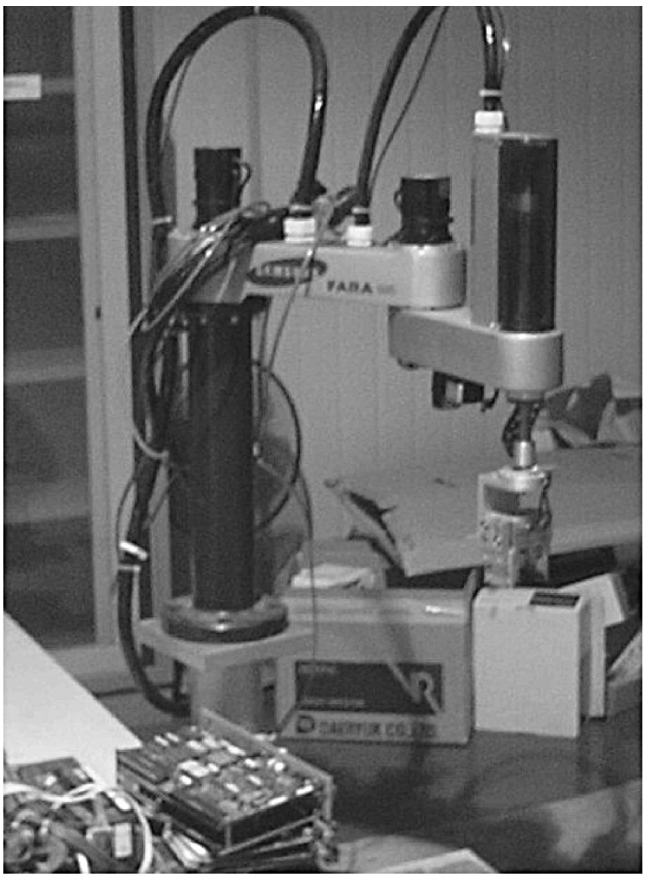

FIGURE 68.7 The practical model of a 4-axis robot VRM.

- PI services (4): *Create*, *Start*, *Stop*, and *Delete*.
- Variable service (2): *Read* and *Write.*

Semaphore, Operator, Event, and *Journal* services have been implemented partially only.

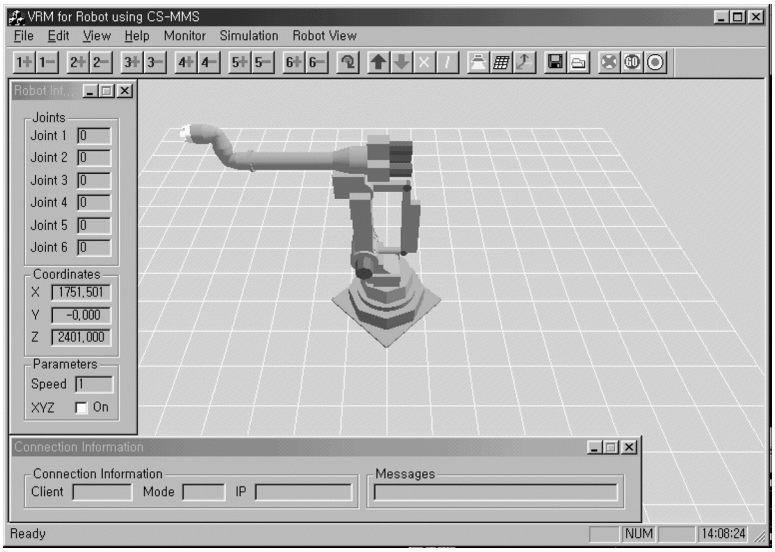

FIGURE 68.10 Screenshot of the 6-axis Robot VRM program.

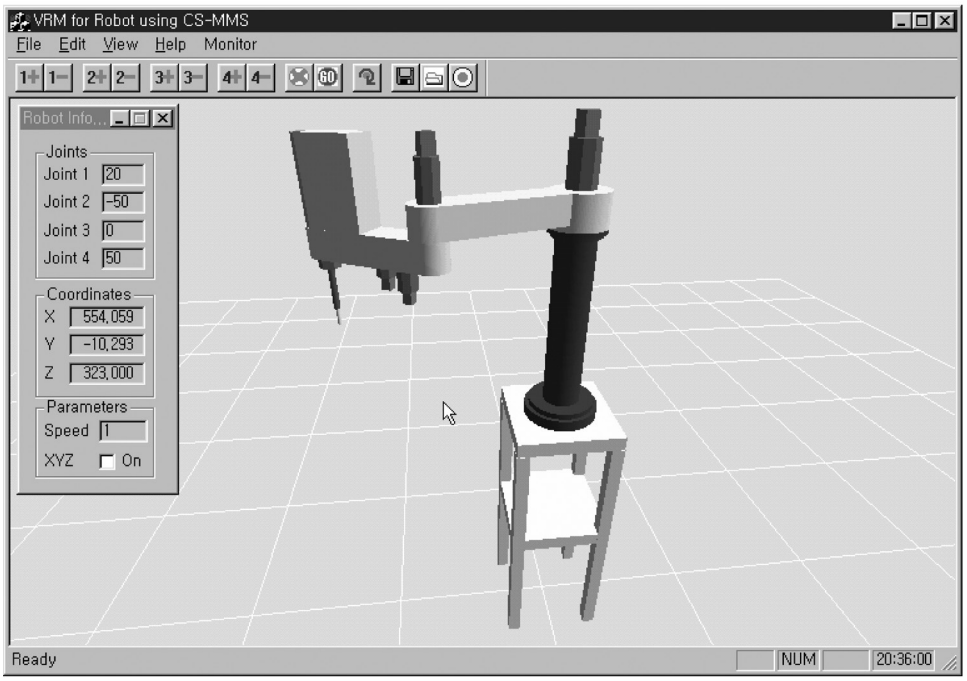

FIGURE 68.11 Screenshot of the 4-axis Robot VRM program.

VRM Using MMS-CS

The virtual factory communication system is operated by controlling each VRM with MOTIP based communication programs. Figures 68.6 – 68.9 show reference models of practical machines. Figures 68.10 – 68.14 show virtual miniatures of the practical machines. The application programs of Robot CS VRMs are modeled after a 6-axis robot made by HYUNDAI Heavy Inc. (Figure 68.6) and the 4-axis scalar robot made by SAMSUNG Heavy Inc. (Figure 68.7). The 6-axis robot is used for conveying the material with

pallet throughout the implemented virtual system. The 4-axis robot takes part in a bolt assembling task of the overall process.

NC-CS VRM is modeled after an NC machine (TNV-40) made by TONGIL HEAVY Inc. (Figure 68.8). NC-CS VRM is responsible for drilling a hole in the sample material.

The application program of PLC-CS VRM is modeled after a cleaning machine with an air compressor and clamps. It is controlled by PLC, which is installed under the cleaning machine. PLC-CS VRM takes part in the cleaning works of assembled parts after the drilling process performed by the NC-CS VRM (Figure 68.12).

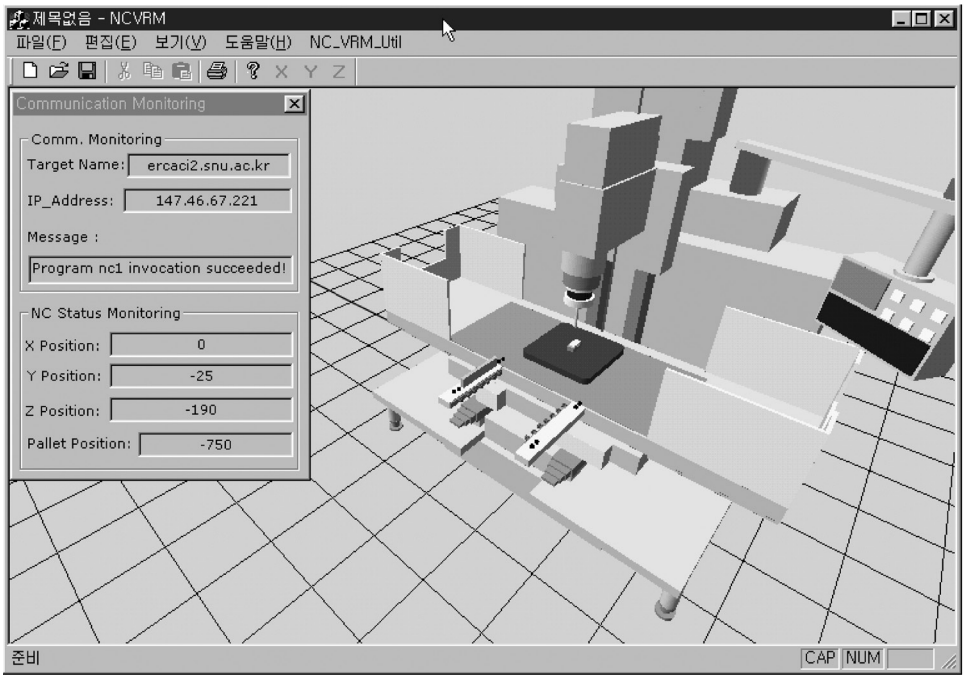

FIGURE 68.12 Screenshot of the NC CS VRM program.

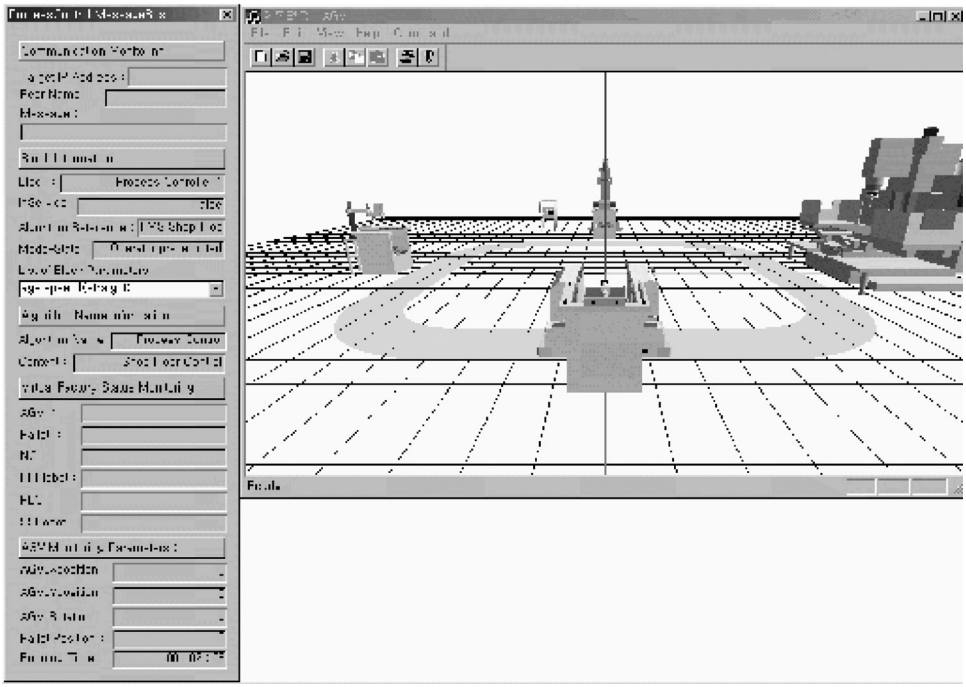

FIGURE 68.14 Screenshot of the PC-CS program.

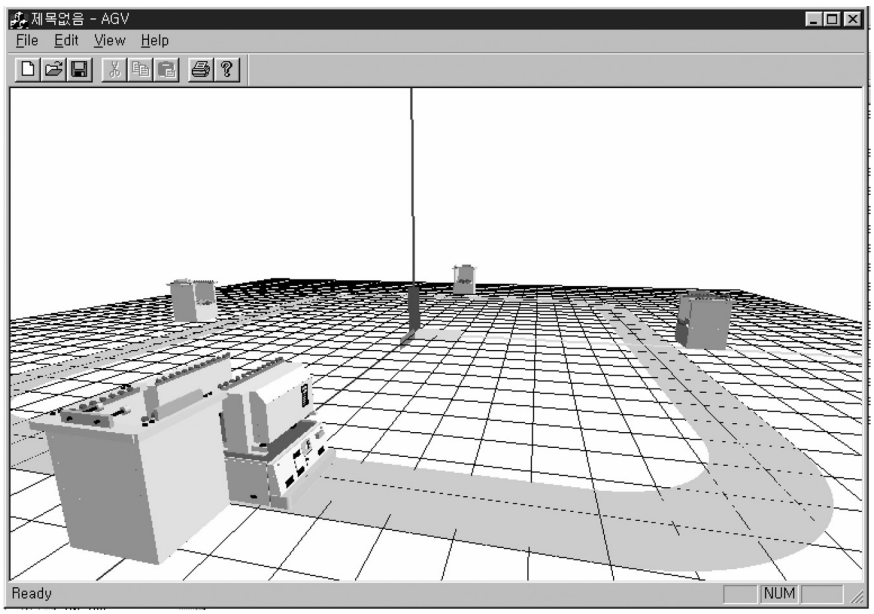

FIGURE 68.15 Screenshot of the AGV movement controlled by the schedule.

The process control VRM program can be scheduled for all the machines with the autonomous guided vehicle (AGV) movement (Figure 68.15). The CS application program includes all the VRMs, the common MMS, and MMS-CS services. The simple test scenario of the application program is presented in

© 2005 by CRC Press LLC

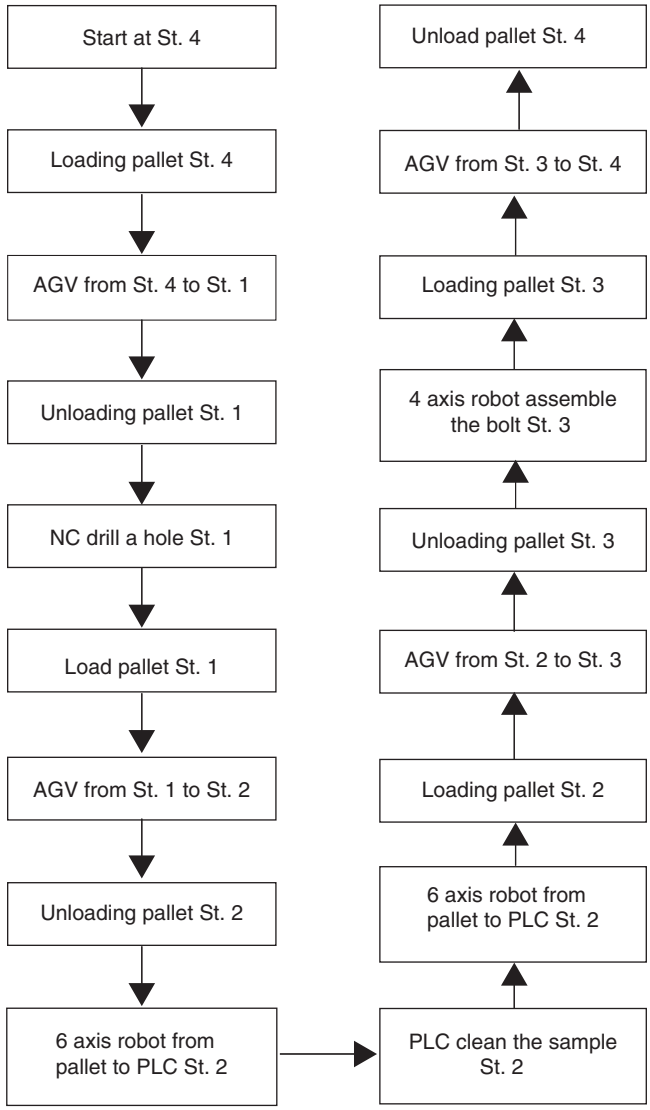

FIGURE 68.16 Block diagram of the demo program.

Figure 68.16. All machines are operated in accordance with their scheduled operation scenarios and they can be modified by the MMS user.

The test scenario begins with the AGV VRM idling status at station 4. The station 4 is the starting and ending station in the developed virtual factory. AGV VRM loads a palette from station 4 (assuming that the AS/RS is aside) and moves to station 1 for unloading the palette. In station 1, the NC VRM executes a hole drilling process in the material. After finishing the drilling process, AGV VRM loads the palette and moves it from station 1 to station 2. In station 2, the 6-axis robot VRM transfers the sample material from the palette to the clamps of the cleaning machine. The PLC CS VRM starts cleaning the sample material using an aircompressor. Then after loading the palette, AGV moves from station 2 to station 3. The 4-axis robot assembles the bolt into a hole of the sample material at station 3. After finishing the assembling process, the AGV moves from station 3 to station 4 and unloads the palette at station 4 (Figure 68.17).

The overall scenario can be scheduled by the MMS user. For reference, the source of the VRMs and the MOTIP program can be downloaded from the site given in [22].

© 2005 by CRC Press LLC

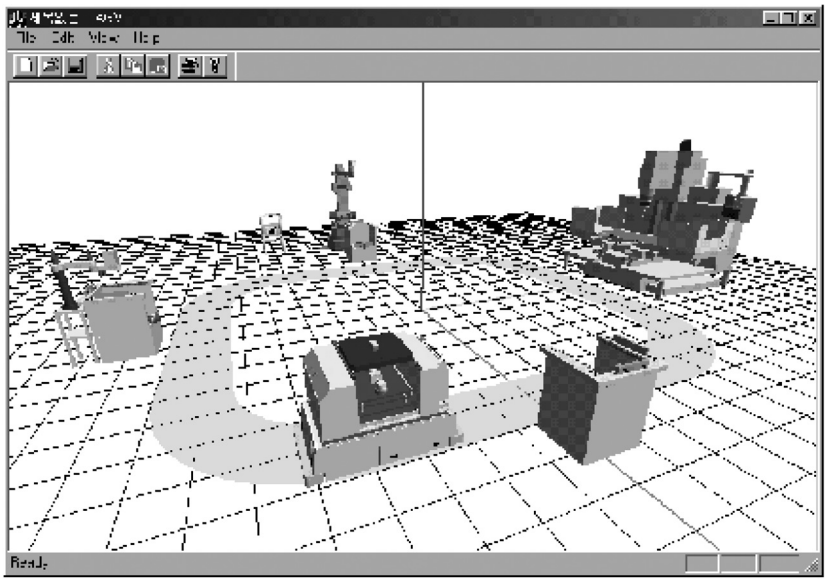

FIGURE 68.17 Screenshot of Process control of the virtual factory: AGV moves from station 1 to station 4 for unloading a processed part on pallete.

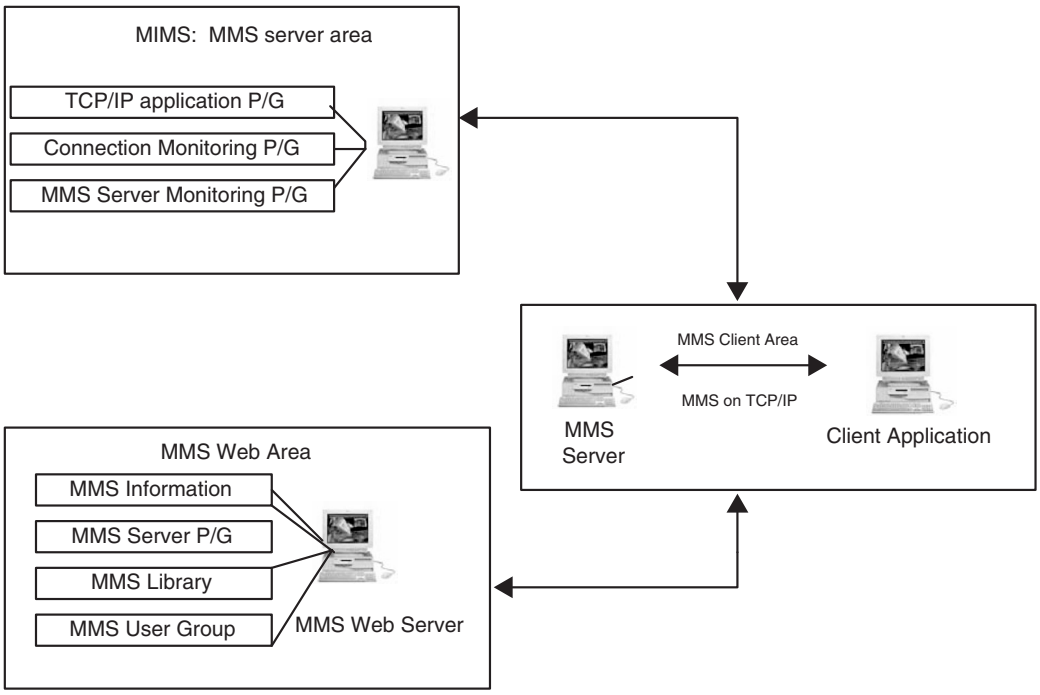

FIGURE 68.18 Structure of the MIMS system.

68.4 MIMS

MIMS is designed for simultaneous monitoring and controlling the status of multiple clients. MIMS transfers the operational information of the virtual factory to an MMS administrator and external MMS

© 2005 by CRC Press LLC

users. Therefore, MIMS can concurrently monitor the status of each networked VRM and several MMS-CS services.

The structure of MIMS is shown in Figure 68.18. The MIMS is composed of an MOTIP application program, the application program using MMS-CS, and each networked VRM.

MIMS is designed for up to 100 multiple users. MMS users can download the MMS-CS and the client-specific program from the site at [22]. Whenever MMS clients use the downloaded program based on the MMS-CS, MIMS can monitor the operation status through the user information and the communication data between the MMS client and server.

The administrator can monitor all the messages from the multiple clients and check the problems in the networked system. The MMS user can then fix their technical problem through the on-line advisories from the MMS server administrator. Therefore, the developed system can serve as a training tool for MMS developers and users.

68.5 Conclusions

A virtual factory communication system using the general MMS, its CS part, and the robot VRMs, NC, PLC, and PC were designed and implemented. The applicability of the virtual factory using the MMS and its CS part described here can be extended to the MMS implementation of a practical plant. In particular, the implemented system can be used as a design guideline of an MMS system for a practical plant. Furthermore, the developed virtual factory communication system and the VRMs can also be used for the verification of the operation of a real factory automation environment.

69.1 Introduction

These days, more and more automation systems, both systems for automating manufacturing processes and for controlling critical infrastructure installations, for example, in power and water utilities, are directly or indirectly connected to public communication networks like the Internet. While this leads to productivity improvements and faster reaction on market demand, it also creates the risk of attacks via the communication network. This chapter surveys how network-connected plants and automation systems can be secured against information system and network-based attacks by state-of-the-art defensive means, and it will provide an outlook on future research.

69.2 Motivation

The influence of automation systems pervades many aspects of everyday life in most parts of the world. In the form of factory and process control systems, they enable high productivity in industrial production, and in the form of electric power, gas, and water utility systems they provide the backbone of technical civilization.

© 2005 by CRC Press LLC

Up to now, most of these systems were isolated, but for the last couple of years, due to market pressures and novel technology capabilities, a new trend has emerged to interconnect automation systems to achieve faster reaction times, to optimize decisions, and to collaborate between plants, enterprises, and industry sectors. Initially, such interconnections were based on obscure, specialized, and proprietary communication means and protocols. Now more and more open and standardized Internet technologies are used for that purpose.

In security terminology, a risk exists if there is a vulnerability, that is, an opportunity to cause damage, together with a threat, that is, the fact that someone will try to find and exploit a vulnerability in order to inflict damage. The importance of automation systems for the functioning of modern society together with market pressure and competition on the one hand and geopolitical tensions on the other make the existence of security threats from terrorism, business competitor sabotage, and other criminal activity appear likely. The pervasiveness of automation systems that are nowadays accessible from anywhere in the world via communications and information technologies for which there are thousands of experts worldwide and that have a large number of well-known security issues creates many IT security vulnerabilities. As a consequence, there are good reasons to investigate and invest regarding how to reduce the IT security vulnerabilities of automation systems, and thus the resulting risks of large financial damage, deteriorated quality of life, and potentially physical harm to humans. This chapter presents an overview of state-of-the-art best practices in that respect, and an outlook on future opportunities.

69.3 Scope

The scope of automation systems considered in this chapter ranges from embedded devices, potentially in isolated locations, via plant control systems to plant- and enterprise-level supervisory control and coordination system, both in the distributed control system (DCS) flavor, more common in factory automation, and the supervisory control and data acquisition (SCADA) flavor, widespread in utility systems [5].

In the associated types of applications, in contrast to commercial and administrative data processing, often not typical data security issues (e.g., confidentiality, integrity) as such are the most important goal; but IT security is one component of the safety and fault-tolerance strategy and architecture for the plant.

69.4 Security Objectives

IT security has a number of different facets that are, to some extent, independent of each other. When defining the security requirements for a system, these facets, on which risk analysis and in turn design of countermeasures are based, can be expressed in terms of the eight security objectives explained in the following.

Confidentiality

The confidentiality objective refers to preventing disclosure of information to unauthorized persons or systems. For automation systems this is relevant both with respect to domain-specific information, such as product recipes or plant performance and planning data, and to the secrets specific to the security mechanisms themselves, such as passwords and encryption keys.

Integrity

The integrity objective refers to preventing modification of information by unauthorized persons or systems. For automation systems, this applies to information coming from and going to the plant, such as product recipes, sensor values, or control commands, and information exchanged inside the plant control network. This objective includes defense against information modification via message injection, message replay, and message delay on the network. Violation of integrity may lead to safety issues, that is, equipment or people may be harmed.

© 2005 by CRC Press LLC

Availability

Availability refers to ensuring that unauthorized persons or systems cannot deny access/use to authorized users. For automation systems this refers to all the IT elements of the plant, like control systems, safety systems, operator workstations, engineering workstations, manufacturing execution systems, as well as the communications systems between these elements and to the outside world. Violation of availability may lead to safety issues, as operators may lose the ability to monitor and control the process.

Authorization

The authorization objective, also known as access control, is concerned with preventing access to or use of the system or parts by persons or systems without permission to do so. In the wider sense, authorization refers to the mechanism that distinguishes between legitimate and illegitimate users for all other security objectives, for example, confidentiality, integrity, etc. In the narrower sense of access control, it refers to restricting the ability to issue commands to the plant control system. Violation of authorization may lead to safety issues.

Authentication

Authentication is concerned with determination of the true identity of a system user (e.g., by means of user-supplied credentials such as username/password combination) and mapping of this identity to a system-internal principle (e.g., a valid user account) under which this user is known to the system. Authentication is the process of determining who the person trying to interact with the system is, and whether he really is who he claims to be. Most other security objectives, most notably authorization, distinguish between authorized and unauthorized users. The base for making this distinction is to associate the interacting user by means of authentication with an internal representation of his permissions used for access control.

Nonrepudiability

The nonrepudiability objective refers to being able to provide irrefutable proof to a third party of who initiated a certain action in the system. This security objective is mostly relevant to establish accountability and liability with respect to fulfillment of contractual obligations or compensation for damages caused. In the context of automation systems, this is most important with regard to regulatory requirements, for example, FDA approval. Violation of this security objective has typically legal/commercial consequences, but no safety implications.

Auditability

Auditability is concerned with being able to reconstruct the complete behavioral history of the system from historical records of all (relevant) actions executed on it. While in this case it might very well be of interest to also record who initiated an action, the difference between the auditability security objective and nonrepudiability is the ability of proving the actor identity to a third party, even if the actor concerned is not cooperating. This security objective is mostly relevant to discover and find reasons for malfunctions in the system after the fact, and to establish the scope of the malfunction or the consequences of a security incident. In the context of automation systems, this is most important in the context of regulatory requirements, for example, FDA approval. Note that auditability without authentication may serve diagnostic purposes but does not provide accountability.

Third-Party Protection

The third-party protection objective refers to averting damage done to third parties directly via the IT system, that is, damage that does not involve safety hazards of the controlled plant. The risk to third parties through possible safety-relevant failures of the plant arising out of attacks against the plant automation

© 2005 by CRC Press LLC

system is covered by other security objectives, most notably the authorization/access control objective. However, there is a different kind of damage only involving IT systems: the successfully attacked and subverted automation system could be used for various attacks on the IT systems or data or users of external third parties, for example, via distributed-denial-of-service (DDOS) or worm attacks. Consequences could range from damaged reputation of the automation system owner up to legal liability for the damages of the third party. There is also a certain probability that the attacked third party may retaliate against the subverted automation system causing access control and availability issues. This type of counter attack may even be legal in certain jurisdictions.

69.5 Differences to Conventional IT Security

As the security objectives in the previous section are generally valid, many security issues are the same for automation systems and conventional, office-type IT systems, and many tools can be used successfully in both domains. However,there are also major differences between these two domains with respect to requirements and operating environment, characteristics, and constraints, which make some security issues easier and others more difficult to address. In the following, some of these differences are explained.

Requirements

While office IT security requirements center around confidentiality and privacy issues, for any automation and process control system the foremost operational requirement is safety, the avoidance of injury to humans. Second after that is availability: the plant and the automation system have to be up and running continuously over extended periods of time, with hard real-time response requirements in the millisecond range. In many cases, this precludes standard IT system administration practices of system rebooting for fixing problems, and makes the installation of up-to-date software (SW) patches, for example, addressing security problems in the running application or the underlying operating system dificult if not impossible.

On the other hand, in contrast to e-commerce applications, connectivity to outside networks including the company intranet is normally not mandatory for the automation system, and although extended periods of disconnection are inconvenient, they will not have severe consequences — after all, many automation systems nowadays still run completely isolated.

Operational Environment

The configuration, both of HW and SW, of the automation system part, which contains the safety critical automation and control devices, is comparatively static. Therefore, all involved devices and their normal, legitimate communication patterns (regarding communication partners, frequency, message size, message interaction patterns, etc.) are known at configuration time, so that protection and detection mechanisms can be tailored to the system. Modifications of the system are rare enough to tolerate a certain additional engineering effort for reconfiguring the security settings and thus being able to trade in the convenience of dynamic, administration-free protocols like DHCP against higher determinism and, as a consequence, security of, for example, statically setting up tables with communication partners/addresses in all devices. Static structure and behavioral patterns also make the process of anomaly discovery for intrusion detection easier.

The hosts and devices in the automation system zone are not used for general-purpose computing, preventing the risks created by mainstream applications like e-mail, instant messaging, office application macroviruses, etc. Often, they are even specialized embedded devices dedicated to the automation functionality, such as power line protection in substation automation. All appropriate technical and administrative means are taken to ensure that only authorized and trustworthy personnel have physical access to the automation equipment. Automation system personnel are accustomed to a higher level of care and inconvenience when operating computer systems, than office staff. This increases the acceptance and likelihood of correct execution of security-relevant operating procedures even if they are not absolutely straightforward and convenient. In many plants, additional nonnetworked (out-of-band) safety and

© 2005 by CRC Press LLC

fault-tolerance mechanisms are available to mitigate the consequences of failure of one or multiple components of the automation system.

One problem with security mechanisms is that they cannot prevent all attacks directly themselves, but produce output, like alerts and log entries, which humans need to review to decide on the criticality of an event and to initiate appropriate responses. This is often neglected as the expert IT staff is not available around the clock to monitor the system. Automated plants, in contrast, are usually continuously monitored by dedicated staff. A defense architecture could make use of this fact, even though these plant operators do not have IT or even IT security expertise.

Challenges

On the other hand, the characteristics of automation systems and devices create some additional security challenges.

Automation devices often have a lower processing performance compared to desktop computers, which limits the applicability of mainstream cryptographic protocols.

The operating systems of such devices in many cases do not provide authentication, access control, fine-granular file system protection, and memory isolation between processes — or these features are optional and are not used due to the above-mentioned limited processing power.

Especially in telemonitoring applications (e.g., SCADA), communication channels with small to very small bandwidth like telephone, mobile phone, or even satellite phone lines are used, which makes it imperative to reduce communication overhead and thus collides with certain security protocols.

Automation systems tend to have very long lifetimes. This has consequences both for the currently operative systems and for newly implemented systems: those currently operative "legacy" automation systems, as far as IT security was given a thought at all, were designed based on a philosophy of "security by obscurity," assuming that the system would be isolated and only operatable by a small, very trustworthy group of people. This kind of thinking persists even today, as can be seen from the 2002 IEEE 1588 standard on precision time synchronization for automation systems for which it is explicitly stated as a design rationale that security functionality is neglected as all relevant systems can be assumed to be secure. Another consequence of longevity is that automation system installations tend to be very heterogeneous with respect to both subsystem vendors and subsystem technology generations.

For newly built automation systems, the long expected lifetime means that the data communication and authentication/access control functionality must be designed so that it will be able to interoperate with reasonable effort with systems and protocols to appear on the market 10 or 20 years later.

Last but not the least, automation systems are operated by plant technicians and process engineers. Due to their training background, they have a very different attitude toward IT system operation and security than corporate IT staff, and frequently a mutual lack of trust has to be overcome to implement an effective security architecture.

69.6 Building Secure Automation Systems

Building secure systems is difficult, as it is necessary to spread effort and budget so that a wide variety of attacks are efficiently and effectively prevented. For automation systems, the challenges mentioned in the section Challenges create additional difficulties. In the following, two common approaches to secure systems are explained and their effectivity is assessed.

Hard Perimeter

A popular doctrine for defense, be it of cities or IT systems, is the notion of the hard perimeter. The idea is to have one impenetrable wall around the system and to neglect all security issues within. In general, however, this approach does not work, for a variety of reasons. The hard perimeter approach does not make use of reaction capabilities: at the time of detection of a successful attack, the attacker has already broken through the single wall and the whole system is open to him. As a consequence, this means that

© 2005 by CRC Press LLC

the wall would need to be infinitely strong, because it needs to resist infinitely long [15]. Also, monoculture is dangerous: the wall is based on one principle or product. If that principle or product fails for some reason to resist the attack, the whole defense is ineffective. The wall must have doors to be usable, which opens it to both technical and nontechnical (social engineering) security risks. Once the attacker has managed to sneak inside, the system is without defense — the risk of the proverbial Trojan horse. A hard perimeter is also, by definition, ineffective against insider attacks. Progressing technology gives the attacker continuously better wall-penetration capabilities. Last but not the least, humans make mistakes: it is illusory to assume that we can design a wall that is without weak spots either in design, implementation, or operation — various border walls in history serve as example.

Defense-In-Depth

The alternative approach is defense-in-depth. Here, several zones/shells are placed around the object that is to be protected. Different types of mechanisms are used concurrently around and inside each zone to defend it. The outer zones contain less valuable targets; the most precious goods, in this case the (safety critical) automation system, are in the innermost zone. In addition to defense mechanisms, there are also detection mechanisms, which allow the automation system operators to detect attacks, and reactive mechanisms and processes to actively defend against them. Each zone also buys time to detect and fend off the attacker. In the spirit of Schwartau's time-based security [15], this allows to live with the fact of imperfect protection mechanisms, as only a security architecture strength of $P \geq D + R$ has to be achieved, where P is the time during which the protection offered by the security system resists the attacker, D is the delay until the ongoing attack is detected, and R is the time until a defensive reaction on the attack has been completed.

Conclusion: There are two basic approaches for securing systems commonly used today, but only one, defense-in-depth, will result in a secure system, provided it is properly implemented.

69.7 Elements of a Security Architecture

In this section, the most important technical elements of a security architecture for automation systems are surveyed. Note, however, that a system cannot be secured purely using technical means. Appropriate user behavior is essential to ensure the effectiveness of any technical means. Acceptable and required user behavior should be clearly documented in a set of policies that are strictly and visibly enforced by plant management. Such policies should address, among other things, user account provisioning, password selection, virus checking, private use, logging and auditing, etc.

The topic of policies and user behavior will not be further discussed here. Example documents are available from various government agencies, IT security organizations, as well as in a number of books.

According to their physical and logical location in the architecture, in the spirit of a defense-in-depth, security mechanisms can be classified as belonging to one or multiple of the following categories. These categories are orthogonal to the security objectives of Section 69.3.

Deterrence. Means of pointing out to the potential attacker that his personal pain in case of getting caught does not make the attack worthwhile. However, in most threat scenarios for safety-critical and infrastructure systems, the deterrence component, especially the threat of legal action, is ineffective.

Connection authorization. Means to decide whether the host trying to initiate a communication is at all permitted to talk to the protected system, and to prevent such connections in case of a negative decision.

User authorization. Means to decide whether and with which level of privileges a user or application is permitted to interact with the protected system and to prevent such interaction in case of a negative decision.

Action authorization. Means to decide whether a user or application is permitted to initiate specific actions and action sequences on the protected system or application, and to prevent such interaction in case of a negative decision. Action authorization is an additional barrier assuming a preceding positive user authorization decision.

Intrusion detection. Means to detect whether an attacker has managed to get past the authorization mechanisms. Most intrusion detection systems are based on monitoring and detecting whether anything "unusual" is going on in the system.

© 2005 by CRC Press LLC

Response. Means to remove an attacker and the damage done by him from the system. Means to lessen the negative impact of the attack on the system and its environment. Means to prevent a future recurrence of the same type of attack.

Mechanism protection. Means to protect the mechanisms for the above-listed categories against subversion. This refers, for example, to not sending passwords in clear text over public networks and hardening operating systems and applications by fixing well-known bugs and vulnerabilities, etc.

Deterrence

The technical mechanisms for deterrence are warning banners at all locations, for example, log in screen, where an attacker — not necessarily an outsider — could access the system. These warning banners should state clearly that unauthorized access is prohibited and legal action may be the consequence. This type of statement could be required to be able to prosecute intruders in certain legislations.

Connection Authorization

The following sections list and explain connection authorization mechanisms for dial-in remote access, WAN, and LAN situations.

Firewall

A firewall or filtering router passes or blocks network connection requests based on parameters such as source/destination IP addresses, source/destination, TCP/UDP ports (services), protocol flags, etc. Depending on the criteria, the specific firewall product uses and how clearly the permitted traffic on the network is defined, a firewall (or, more often, dual-firewall architecture) can be anything from a highly effective filter to a fig leaf.

Intelligent Connection Switch/Monitor

As the information and message flows between the individual devices and applications in an automation system are often deterministic and well defined at system configuration time, this information can be used by a special, intelligent connection monitoring device to determine the legitimacy of a certain message. This goes beyond the parameters that conventional firewalls use, as it also takes into account criteria like message size, frequency, and correctness of complex interaction sequences. Nonconforming messages can be suppressed in collaboration with a switch. In this case, the device is acting as a connection authorization device. On the other hand, an alert can be raised, in which case the device is acting as an automation system-level intrusion detection systems.

Personal Firewall

A personal firewall is an application running on a host as an additional protection for the main functionality of this host, for example, as a firewall, proxy server, or workstation. It monitors and controls as to which applications on the host are allowed to initiate and accept connection requests from the network. In contrast to a (network) firewall, a personal firewall does not control a network segment, but only its own host.

Switched Ethernet

With standard Ethernet, all hosts on a network segment can see all traffic, even that not addressed to them, and multiple hosts sending at the same time can cause nondeterministic delays. The first issue is directly security relevant, and the second one is indirectly security relevant (denial-of-service attacks). Using switches to give each host its own network segment and to directly forward each message only to the intended receiver remedies both issues. Note that there exist attacks on switches to force them to operate in hub mode (broadcast).

Dial-Back

After authentication, a dial-back modem interrupts the telephone connection and dials back to the telephone preconfigured for the authenticated user. This prevents an attacker from masquerading as an

© 2005 by CRC Press LLC

authorized user from anywhere in the world, even if he managed to obtain this user's credentials, because the attacker would also need to obtain physical access the authorized user's phone line. Note that in a number of countries, the technical behavior of the public telephone network is such that dial-back modems can be defeated by an attacker.

Access Time Windows

For automation systems, it is often true that the remote connection is not necessary for operation, but only to upload configuration changes and download measurement values, which are not urgent and irregular in timing. Therefore, if a continuous remote connection is not required, the remote access can be restricted to certain time windows only known to authorized users in order to reduce exposure to attacks. Outside these time windows access is disabled, for example, by electrically switching off the modem or router device.

Mutual Device Authentication

As all communication partners in the automation system (devices and applications) and message flows are known at configuration time, it is possible to require mutual authentication of each communication relationship at run-time, provided the available computing power of the automation devices tolerates the execution of the necessary protocols. This renders the installation of rogue devices ineffective.

User Authorization

Login Mechanisms

Most access control schemes rely on passwords ("something you know") as the underlying authentication principle to establish that the user is who he claims to be. This makes the selection of suitable passwords, as well as their management and storage one of the most important aspects, and potential weaknesses, of each system. Alternatively, instead of a fixed password, a one-time password, generated just-in-time by individualized devices (tokens, smartcards) that are given to all authorized users, is used. It replaces or augments the "something you know" principle by "something you have." The third option for proving identity are biometrics, for example, finger prints. This is the most direct mechanism, but expensive, inconvenient, only applicable to humans (not other applications), and there have been incidents where biometrics products have been fooled by an attacker. In any case, if authentication fails, the user has to initiate a new session to continue communication with the protected system, for example, for another login attempt.

Action Authorization

Role-Based Access Control in Applications

In many situations, not all authorized users are in the same way permitted to execute all types of activities on the system; therefore, the system log-on alone does not offer a sufficient granularity of access control. With role-based access control, each authorized user has one or multiple roles, which correspond to sets of actions he can execute in the application. Role-based access control needs to be designed into each application, as it cannot be normally provided by external add-on devices or applications. Defining the rights in the application in terms of roles instead of actual users improves scalability and makes maintenance of the security configuration easier.

System Architecture for Data Exchange

If the remote access functionality is not necessary for interactive operation and examination of the automation system, but only for upload and download of preconfigured parameters and data, the system can be architected so that direct remote access to the automation device, which is the source or target of the data, is not required. Instead, the remote access occurs only to a less valuable FTP or web server, which acts as a cache and communicates over a series of time-shifted, content-screening data-forwarding operations with the actual data source or target. This strongly restricts the type of interactions that the outside system can have with the automation device.

© 2005 by CRC Press LLC

Managed Application Installation

Through centralized administration and monitoring, it is enforced that only the authorized and necessary applications and services are running on the automation system workstations and servers, and that configurations are not changed by the users. The hosts do not carry user-specific data or configurations and thus can be reinstalled from a known-good source at regular, frequent intervals to remove any unauthorized modification in the system, even if the modification was never detected.

Application-Level Gateway

The process-level network to which the automation equipment is connected interfaces with the higher level LAN, for example, the one to which the operator workstations are connected, only via a small number of gateway servers for application-level communications. Direct interactive access (log-in) to the automation device is disabled in this scenario. As the purpose, the software applications, and the topology/configuration of the automation system are well known, these gateways can be customized for the authorized applications and communications to screen messages passing the interface for validity based on domain-specific criteria, such as predefined interaction sequences. Illegitimate or invalid messages can be suppressed and alerts can be raised.

Dual Authorization

Certain commands issued by a user in an automation system can have drastic consequences. If there are no situations in which these commands need to be entered extremely quickly in an emergency, they can be protected by requiring confirmation from a second authorized user. This mechanism secures the system against intruders, malicious insiders, and serves as a protection against unintentional operator errors.

Code Access Security

Code access security is concerned with restricting what an application is allowed to do on a host (e.g., reading or writing files, creating new user accounts, initiating network connections, etc.), even if it executes in the context of an authorized, highly privileged user. This type of "sandboxing" is available for several computing platforms and can serve as additional protection against applications that are not completely trusted, for example, because they have been developed externally.

Intrusion Detection

Network-Based Intrusion Detection System

A network-based intrusion detection system (NIDS) tries to discover attacks based on known attack profiles and/or unusual system behavior from communication traffic seen on a network segment (type, content, frequency, path of the transmitted messages).

Host-Based Intrusion Detection System

A host-based IDS (HIDS) tries to discover attacks based on known attack profiles and/or unusual system behavior from information seen locally on the host on which it is running. A host-based IDS obtains its information, for example, from file system integrity checkers, which monitor whether important system files change without operational reason, from personal firewall logs, or from application logs, for example, for application-level role-based access control.

Honeypot

A honeypot (single host) or honeynet (subnet) [16] is a subsystem that appears particularly attractive to an attacker, for example, from the naming of the host or files on it, or by simulating certain weaknesses in the installation. It is, however, a dedicated and isolated system without importance for the functioning of the automation system, which is especially instrumented with intrusion detection systems. The idea is that an attacker who breaches the first line of defense successfully will be attracted to the honeypot host first, and thus is at the same time delayed and kept away from the really sensitive areas, as well as detected by the intrusion detection systems.

© 2005 by CRC Press LLC

Authentication/Authorization Failure Alerts

Alerts are sent to the operators or IT staff whenever one of the authentication mechanisms fails, which could indicate an unsuccessful attempt to attack the system. While this would probably not be useful in an office system, due to the high false alarm rate of legitimate users mistyping their passwords, it may be a feasible security mechanism in an automation system with a very small number of concurrent legitimate users and few login actions per time period.

Log Analysis

All actions of the authentications devices are logged, and these logs are manually or automatically screened for unusual occurrences or patterns, for example, that an authorized user is suddenly accessing the system outside his normal work hours.

Malicious Activity Detection/Suppression Protocol

As is shown in [9], network-based electronic attacks originating from malicious devices in an automation system, for example, in a power substation can be categorized as either message injection, message modification, or message suppression. Using a suitable communication protocol for detection of invalid messages, one can reduce these three categories to message suppression, which can in many cases be regarded as a system failure that conventional fault-tolerance and fault-response mechanisms such as redundant devices and emergency shutdown sequences can handle.

Response

System Isolation

The connections between the compromised subsystem, for example, the outer part of the security zone at the interface between automation system and other networks, and other, more important parts of the automation system, are closed to avoid further spreading of the attack. Depending on system/remote access functionality and importance, and on whether delaying the attacker and collection of further evidence, or quick restoration of operation is of higher importance, it is an option to shut down all remote connections, both for the affected and the not-yet affected systems, until the effects of the attack are removed. Like electric power grids, the automation system should already be architected and designed such that it can be partitioned into zones, which can be isolated with minimum disturbance of the whole system.

Collect and Secure Evidence

All logs and media (e.g., hard disks) that contain evidence of the malicious activity are gathered, copied, and stored at a secure location. This evidence can be used to identify the attack and thus the system weaknesses in detail, to locate and assess the amount of damage done by the attack, and also to support legal prosecution of the attacker. In this case, the legally correct handling of evidence is especially important.

Trace Back

This refers to activities that aim at discovering the source of the attack, both as part of the evidence collection process (see above) and to enable stronger defense mechanisms for identified sources of attacks (e.g., blocking). Due to various possibilities of faking packet data, such as the originating address, this is technically not easy. Lee and Shields [6] discuss the various technical options for trace back and their obstacles.

Active Counter-Attack

An active counter-attack has as aim to selectively disable the attacker's computer to prevent further attacks and to "punish" the attacker. Due to the fact that an unambiguous trace back is difficult (see above), that often "innocent" systems are used as intermediary stages for staging an attack, and that the legality of a counterattack is dubious in most situations and localities, a counterattack response is normally not recommended.

Information Sharing

Early sharing of information about on-going attacks, especially novel types of attacks, with the IT community represents good "Internet citizenship" because it gives more defenders a chance to increase alertness and

© 2005 by CRC Press LLC

to remove weaknesses. Many types of attacks, such as distributed denial of service and viruses, rely on the fact that the same weakness can be exploited on a large number of systems, which are then used to launch further attacks. Therefore, reducing the number of systems vulnerable to an attack is in every defender's interest. On the other hand, many companies might be concerned about the effects of making the facts and circumstances of attacks known to competitors and the public. For this purpose, several institutions exist, which receive and distribute information about attacks without disclosing the sources of the information. Examples are the SEI CERT (http://www.cert.org) and various industry branch-specific Information Sharing and Analysis Centers (ISACs).

Selective Blocking

If the origin of the attack and the location of entrance into the system can be identified, blocking rules of firewalls, routers, and access servers, perhaps already at the Internet Service Provider, can be temporarily or permanently modified to close the in-roads of the attack.

Switching to Backup IT Infrastructure

If a system is compromised and its unavailability during evidence collection and restauration is unacceptable, a backup automation system, perhaps with minimum functionality, should be available for immediate switch-over. This backup system consisting of automation system workstations and servers, access servers, firewalls, IDS host, etc., should be preconfigured with different passwords, different network addresses, and, even better, also use software different from the primary system, to avoid that it can be immediately subverted by the attacker with the knowledge gained from the primary system.

Automated, Periodic Reinstallation of Applications, Operational Data, and Configurations

The SW applications of the automation system, as well as static operational data and configurations, especially of the security components, are periodically reinstalled from a known-good read-only storage device (e.g., CD). This removes applications with attacker-installed backdoors (Trojans) or modified system files, for example, password files even if the attack was never detected. Of course, this provides only a weak defense if the security vulnerabilities that allowed the system compromise in the first place are allowed to persist, but it may prevent follow-up exploits by other attackers and frustrate the original attacker sufficiently to turn to easier targets.

New Passwords

When automatically or manually reinstalling system configurations in case of an attack, the passwords should also be changed, in particular those, for the security components, to prevent the attacker from immediately reentering the system with a previously compromised set of credentials.

Activation of Safety Mechanisms

If the attack on the automation system endangers the safety of the plant, standard safety mechanisms such as reverting to manual operation or emergency shut-down are a last resort to protect plant equipment and human life. As a consequence, such safety mechanisms should be decoupled from the networked automation system.

Mechanism Protection

Dedicated Lines

Instead of connecting the dial-in modems to telephone lines, which are accessible to anybody from anywhere in the world, dedicated telephone cables are used, which connect only secure, authorized systems. Among other things, this protects the information between the protected system and the remote user, in particular, his credentials such as passwords during the authentication process, from eavesdropping. However, this scheme offers no protection against the telecommunication company and (government) organizations that can force access to dedicated lines. Also, there have been incidents where attackers were able to subvert the telephone switches of telecommunication providers to access dedicated lines.

© 2005 by CRC Press LLC

Virtual Private Network

A virtual private network (VPN) uses encryption and digital signatures to achieve the effect of a physical dedicated line over a shared medium such as a normal telephone connection or the Internet. A VPN is both cheaper and more secure than a line leased from a telecommunication provider; but the computational overhead for strong cryptography may be unacceptable for certain communicating automation devices.

Disable Remote Reprogramming of Dial-In/Dial-Back Modems

The dial-back mechanism described in the section Dial-Back is only effective if the remote attacker cannot redirect the dial-back call to his own telephone.

Network Address Translation

With network address translation (NAT), the system uses IP addresses internally different from those shown in the externally visible messages. A border device, for example, the firewall, is responsible for on-the-fly translation of addresses in both directions. NAT makes remote probing of the internal network topology for interesting or vulnerable targets much more difficult and prevents certain attacks that bypass the firewall.

Diversity

System diversity, for example, by using different operating systems like Windows and Unix/Linux for the production systems and the intrusion detection systems or other security mechanisms, or by selecting different brands of firewalls for different zones and subzones increases security, as an attacker cannot rely on a single vulnerability in one product to break through all defenses. Thus, it also offers a bit more resilience in the time between publication of an exploit for a vulnerability and the design and installation of corresponding patches in the system.

Role-Based Access Control

Role-based access control is also important for the security functionality itself, to ensure that only security administrators and not all inside users can change security settings and read/edit logs. This is the basis of all security precautions against insider attacks and also creates an additional hurdle for attackers that have broken into the account of one authorized user against taking complete control over the system.

Hardened Host

Mechanisms like role-based access control, logging, and intrusion detection rely on the basic functions of the operating system on the host not having been corrupted by the attacker. Today's applications, operating systems, and system configurations are often so complex and complicated that they have many security vulnerabilities caused by misconfiguration or by applications with security relevant bugs, which are installed as part of the operating system, but that are not really necessary for the automation system functionality. Hardening a system means to remove all unnecessary applications and services, to fix known bugs, to replace critical applications with more trustworthy ones of the same functionality, and to set all system configuration parameters to secure values. Guidelines for the hardening of various common operating systems and applications are available from multiple sources.

69.8 Further Reading

A large number of technical and research publications exist on the issue of IT security for home and office information systems. Schneier [14] gives a good general introduction to the topic, and [13] is the reference on cryptographic algorithms and protocols. Reference [10] is a comprehensive resource on the practical issues of securing a computer network, while [1] and [17] address the issue of engineering secure (software) systems from a larger perspective.

© 2005 by CRC Press LLC

On the other hand, apart from some vendor whitepapers, there is almost no literature on the specific security needs and capabilities of industrial automation systems. Palensky [12] investigates remote access to automation systems, specifically home automation systems, with potentially malicious devices, and proposes the use of smartcards as trusted processors to achieve end-to-end security between each device and its legitimate communication partners. In [8] IT security mechanisms applicable for automation systems are presented, according to which conceptual zone they defend — remote access, operator workstations, or automation devices. Byres [3] investigates networking and network-level security issues for Ethernet networks on the plant floor. Falco [5] motivates and describes efforts to create a protection profile for process control systems according to the Common Criteria security evaluation standard. Moore [7] reports on a survey about IT security conducted among automation system users. Dafelmair [4] promotes the use of a Public key Infrastructure (PKI) for process control systems, and [2] suggests a lightweight PKI for power-utility SCADA systems. Oman [11] applies standard IT security mechanisms to power utility control systems, with special emphasis on password management.

69.9 Research Issues

As can be seen from the scarcity of published work, automation system IT security is a comparatively new field. Much more research will be necessary until both security requirements and opportunities specific for automation systems have been explored to the current level of home and business system IT security. The following are just some of the topics to be addressed in the future:

- Considering that plant control systems have a lifetime of 20 to 30 years, how can effective defense-in-depth security mechanisms cost-efficiently be retrofitted onto them?
- What security mechanisms can and should be required for automation systems? This topic is being urrently addressed by various industry standard organizations, such as the ISA SP99 working group.
- What criteria should be used for assessing and auditing the security mechanisms in automation devices?
- How to cope with the vulnerabilities inherent in networking protocols like SNTP for time synchronization or XML web services/OPC-XML by modifying the protocols or adapting the system architecture?
- How to ensure appropriate levels of access control, data integrity, and data confidentiality for automation devices with low computing power [18]?
- How can the auditability of every interaction and individual accountability of every member of the plant staff who interacts with the automation system be ensured according to regulatory requirements, while at the same time achieving both ease of use in normal operation and fast response times for emergency interventions?
- How can a plant operator, who is not an IT security expert, effectively contribute to plant security?

69.10 Summary

Nowadays, realistic scenarios for network-based attacks on infrastructure/utility automation systems and manufacturing/plant automation systems with respect to both motivation as well as technical feasibility exist. In contrast to business systems, which need to be available for business and protect their confidential data, for automation system IT security, the most important security objective is the integrity of the control system to prevent physical damage and human injury.

This chapter has presented arguments regarding why a defense-in-depths approach with layered mechanisms is a better strategy for securing systems than the often-used approach of placing a security "wall" around the system and leaving the inside unchanged. It has also given an overview of available security mechanisms, pointing out which are specifically applicable to automation systems due to the specific operational characteristics of automation systems.

© 2005 by CRC Press LLC

It remains to recall that, as the saying goes, security is not a destination, but a journey — both the notifications generated every day by an appropriate security system, and the whole architecture of the security system need to be reviewed regularly to detect and adapt to new vulnerabilities and threats.

70.1 Introduction

Sensors are used in many devices and systems to provide information on the parameters being measured or to identify the states of control. They are good candidates for increased built-in intelligence. Microprocessors can make smart sensors or devices a reality. With this added capability, it is possible for a smart sensor to directly communicate measurements to an instrument or a system. In recent years, the concept of computer networking has gradually migrated into the sensor community. Networking of transducers (sensors or actuators) in a system and communicating transducer information via digital means vs. analog cabling facilitates easy distributed measurements and control. In other words, intelligence and control, which were traditionally centralized, are gradually migrating to the sensor level. They can provide flexibility, improve system performance, and ease system installation, upgrade, and maintenance. Thus, the trend in industry is moving toward distributed control with intelligent sensing architecture. These enabling technologies can be applied to aerospace, automotive, industrial automation, military and homeland defenses, manufacturing process control, smart buildings and homes, and smart

© 2005 by CRC Press LLC

toys and appliances for consumers. As examples: (1) in order to reduce the number of personnel to run a naval ship from 400 to less than 100 as required by the reduced-manning program, the U.S. Navy needs tens of thousands of networked sensors per vessel to enhance automation, and (2) Boeing needs to network hundreds of sensors for monitoring and characterizing airplane performance.

Sensors are used across industries and are going global [1]. The sensor market is extremely diverse, and it is expected to grow to $43 billion by 2008. The rapid development and emergence of smart sensor and field network technologies have made the networking of smart transducers a very economical and attractive solution for a broad range of measurement and control applications. However, with the existence of a multitude of incompatible networks and protocols, the number of sensor interfaces and amount of hardware and software development efforts required to support this variety of networks are enormous for both sensor producers and users alike. The reason is that a sensor interface customized for a particular network will not necessarily work with another network. It seems that a variety of networks will coexist to serve their specific industries. The sensor manufacturers are uncertain of which network(s) to support and are restrained from full-scale smart sensor product development. Hence, this condition has impeded the widespread adoption of the smart sensor and networking technologies despite a great desire to build and use them. Clearly, a sensor interface standard is needed to help alleviate this problem [2].

70.2 A Smart Transducer Model

In order to develop a sensor interface standard, a smart transducer model should first be defined. As defined in the IEEE Std 1451.2-1997 [3]

> a smart transducer is a transducer that provides functions beyond those necessary for generating a correct representation of a sensed or controlled quantity. This functionality typically simplifies the integration of the transducer into applications in a networked environment.

Thus, let us consider the functional capability of a smart transducer. A smart transducer should have:

- integrated intelligence closer to the point of measurement and control,
- basic computation capability, and
- capability to communicate data and information in a standardized digital format.

Based on this premise, a smart transducer model is shown in Figure 70.1. It applies to both sensors and actuators. The output of a sensor is conditioned and scaled, then converted to a digital format through an analog-to-digital (A/D) converter. The digitized sensor signal can then be easily processed by a microprocessor using a digital application control algorithm. The output, after being converted to an analog signal via a digital-to-analog (D/A) converter, can then be used to control an actuator. Any of the measured or calculated parameters can be passed on to any device or host in a network by means of network communication protocol.

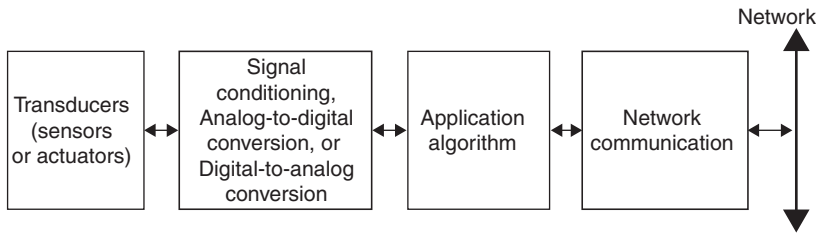

FIGURE 70.1 A smart transducer model.

© 2005 by CRC Press LLC

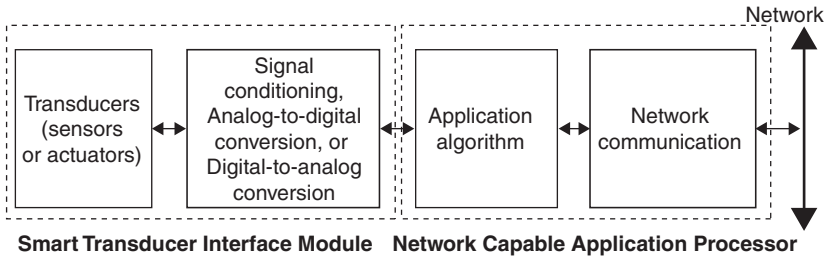

FIGURE 70.2 Functional partitioning.

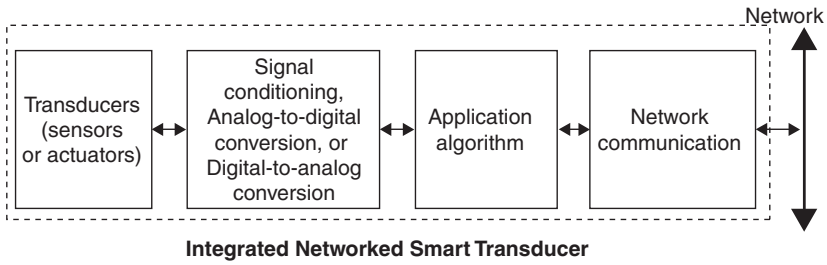

FIGURE 70.3 An integrated networked smart transducer.

The different modules of the smart transducer model can be grouped into functional units as shown in Figure 70.2. The transducers and signal conditioning and conversion modules can be grouped into a building block called a Smart Transducer Interface Module (STIM). Likewise, the application algorithm and network communication modules can be combined into a single entity called a Network-Capable Application Processor (NCAP). With this functional partitioning, transducer to network interoperability can be achieved in the following manner:

1. STIMs from different sensor manufacturers can "plug and play" with NCAPs from a particular sensor network supplier,
2. STIMs from a sensor manufacturer can "plug and play" with NCAPs supplied by different sensor or field network vendors, and
3. STIMs from different manufacturers can be interoperable with NCAPs from different field network suppliers.

Using this partitioning approach, a migration path is provided to those sensor manufacturers who want to build STIMs with their sensors, but do not intend to become field network providers. Similarly, it applies to those sensor network builders who do not want to become sensor manufacturers.

As technology becomes more advanced and microcontrollers become smaller relative to the size of the transducer, integrated networked smart transducers that are economically feasible to implement will emerge in the marketplace. In this case, all the modules are incorporated into a single unit as shown in Figure 70.3. Thus, the interface between the STIM and NCAP is not exposed for external access and separation. The only connection to the integrated transducer is through the network connector. The integrated smart transducer approach simplifies the use of transducers by merely plugging the device into a sensor network.

70.3 Networking Smart Transducers

Not until recently have sensors been connected to instruments or computer systems by means of a point-to-point or multiplexing scheme. These techniques involve a large amount of cabling, which is very bulky

© 2005 by CRC Press LLC

and costly to implement and maintain. With the emergence of computer networking technology, transducer manufacturers and users alike are finding ways to apply this networking technology to their transducers for monitoring, measurement, and control applications [4]. Networking smart sensors provides the following features and benefits:

- enable peer-to-peer communication and distributed sensing and control,
- significantly lower the total system cost by simplified wiring,
- use prefabricated cables instead of custom laying of cables for ease of installation and maintenance,
- facilitate expansion and reconfiguration,
- allow time-stamping of sensor data,
- enable sharing of sensor measurement and control data, and
- provide Internet connectivity, meaning *global* or *anywhere,* access of sensor information.

70.4 Establishment of the IEEE 1451 Standards

As discussed earlier, a smart sensor interface standard is needed in industry. In view of this situation, the Technical Committee on Sensor Technology of the Institute of Electrical and Electronics Engineer (IEEE)'s Instrumentation and Measurement Society sponsored a series of projects for establishing a family of IEEE 1451 Standards [5]. These standards specify a set of common interfaces for connecting transducers to instruments, microprocessors, or field networks. They cover digital, mixed-mode, distributed multidrop, and wireless interfaces to address the needs of different sectors of industry. A key concept in the IEEE 1451 standards is the Transducer Electronic Data Sheets (TEDS), which contain manufacture-related information about the sensor such as manufacturer name, sensor types, serial number, and calibration data and standardized data format for the TEDS. The TEDS has many benefits:

- Enable self-identification of sensors or actuators — A sensor or actuator equipped with the IEEE 1451 TEDS can identify and describe itself to the host or network via the sending of the TEDS.
- Provide long-term self-documentation — the TEDS in the sensor can be updated and stored with information such as location of the sensor, recalibration date, repair record, and many maintenance-related data.
- Reduce human error — automatic transfer of TEDS data to the network or system eliminates the entering of sensor parameters by hands, which could induce errors due to various conditions.
- Ease field installation, upgrade, and maintenance of sensors — this helps to reduce life cycle costs because only a less skilled person is needed to perform the task by simply using "plug and play."

IEEE 1451, designated as Standard for a Smart Transducer Interface for Sensors and Actuators, consists of six document standards. The current status of their development are as follows:

1. IEEE P1451.0, [1]Common Functions, Communication Protocols, and TEDS Formats — *In progress.*
2. IEEE Std 1451.1-1999, NCAP Information Model for Smart Transducers [6] — *Published standard.*
3. IEEE Std 1451.2-1997, Transducer to Microprocessor Communication Protocols and TEDS Formats — *Published standard.*
4. IEEE std 1451.3-2003, Digital Communication and TEDS Formats for Distributed Multidrop Systems — *Published standard.*
5. IEEE std 1451.4-2004, Mixed-mode Communication Protocols and TEDS Formats — *Published standard.*
6. IEEE P1451.5, Wireless Communication and TEDS Formats — *In progress.*

[1]P1451.0 — the "P" designation means that P1451.0 is a draft standard development project. Once the draft document is approved as a standard, "P" will be dropped.

70.5 Goals of IEEE 1451

The goals of the IEEE 1451 standards are to:

- develop network- and vendor-independent transducer interfaces,
- define TEDS and standardized data formats,
- support general transducer data, control, timing, configuration, and calibration models,
- allow transducers to be installed, upgraded, replaced, and moved with minimum effort by simple "plug and play,"
- eliminate error prone, manual entering of data, and system configuration steps, and
- ease the connection of sensors and actuators by wireline or wireless means.

70.6 The IEEE 1451 Standards

The IEEE 1451 Smart Transducer Model

The IEEE 1451 smart transducer model parallels the smart transducer model discussed in Figure 70.2. In addition, the IEEE 1451 model includes the TEDS. The model for each of the IEEE 1451.X standards is discussed in the following.

IEEE P1451.0 Common Functionality

Several standards in the IEEE 1451 family share certain characteristics, but there is no common set of functions, communications protocols, and TEDS formats that facilitate interoperability among these standards. The IEEE P1451.0 standard provides that commonality and simplifies the creation of future standards with different physical layers that will facilitate interoperability in the family.

This project defines a set of common functionalities for the family of IEEE P1451 smart transducer interface standards. This functionality is independent of the physical communications media. It includes the basic functions required to control and manage smart transducers, common communications protocols, and media-independent TEDS formats. The block diagram for IEEE P1451.0 is shown in Figure 70.4. P1451.0 defines functional characteristics, but it does not define any physical interface.

IEEE 1451.1 Smart Transducer Information Model

The IEEE 1451.1 Standard defines a common object model for the components of a networked smart transducer and the software interface specifications to these components [7]. Some of the components are the NCAP block, function block, and transducer block.

The networked smart transducer object model provides two interfaces.

1. The interface to the transducer block, which encapsulates the details of the transducer hardware implementation within a simple programming model. This makes the sensor or actuator hardware interface resemble an input/output (I/O)-driver.
2. The interface to the NCAP block and ports encapsulate the details of the different network protocol implementations behind a small set of communications methods.

Application-specific behavior is modeled by function blocks. To produce the desired behavior, the function blocks communicate with other blocks both on and off the smart transducer. This common network-independent application model has the following two advantages:

1. Establishment of a high degree of interoperability between sensors/actuators and networks, thus enabling "plug-and-play" capability.
2. Simplification of the support of multiple sensor/actuator control network protocols.

© 2005 by CRC Press LLC

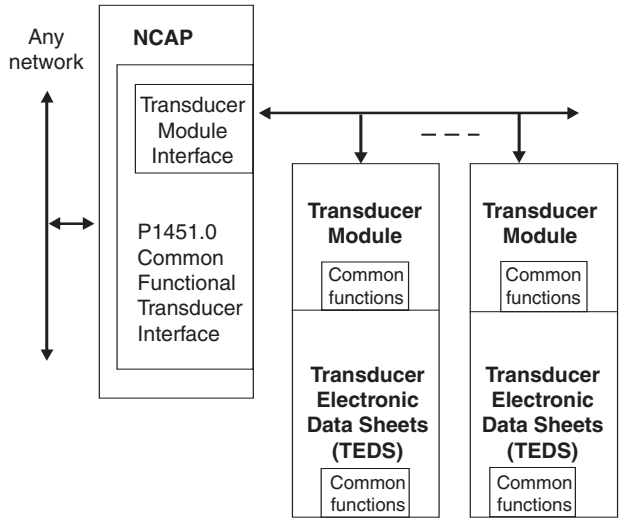

FIGURE 70.4 The block diagram for IEEE P1451.0.

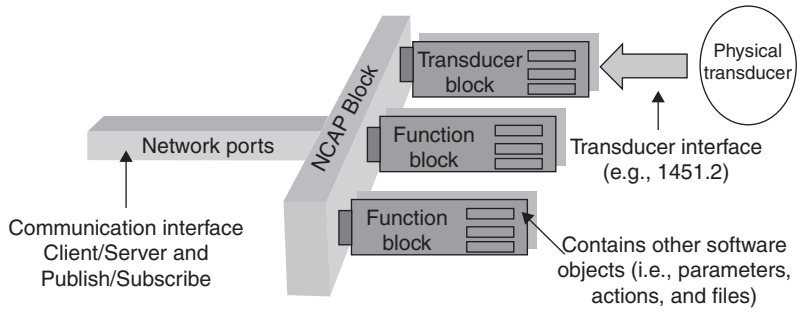

FIGURE 70.5 Conceptual view of IEEE 1451.1.

A conceptual view of IEEE 1451.1 NCAP is shown in Figure 70.5, which uses the idea of a "backplane" or "card cage" to explain the functionality of the NCAP. The NCAP centralizes all system and communications facilities. Network communication can be viewed as a port through the NCAP, and communication interfaces support both client–server and publish–subscribe communication models. Client–server is a tightly coupled, point-to-point communication model, where a specific object, the client, communicates in a one-to-one manner with a specific server object, the server. On the other hand, the publish–subscribe communication model provides a loosely coupled mechanism for network communications between objects, where the sending object, the publisher object, does not need to be aware of the receiving objects, the subscriber objects. The loosely coupled, publish–subscribe model is used for one-to-many and many-to-many communications. A function block containing application code or control algorithm is "plugged" in as needed. Physical transducers are mapped into the NCAP using transducer block objects via the hardware interface, for example, the IEEE 1451.2 interface.

The IEEE 1451 logical interfaces are illustrated in Figure 70.6. The transducer logical interface specification defines how the transducers communicate with the NCAP block object via the transducer block. The network protocol logical interface specification defines how the NCAP block object communicates with any network protocol via the ports.

© 2005 by CRC Press LLC

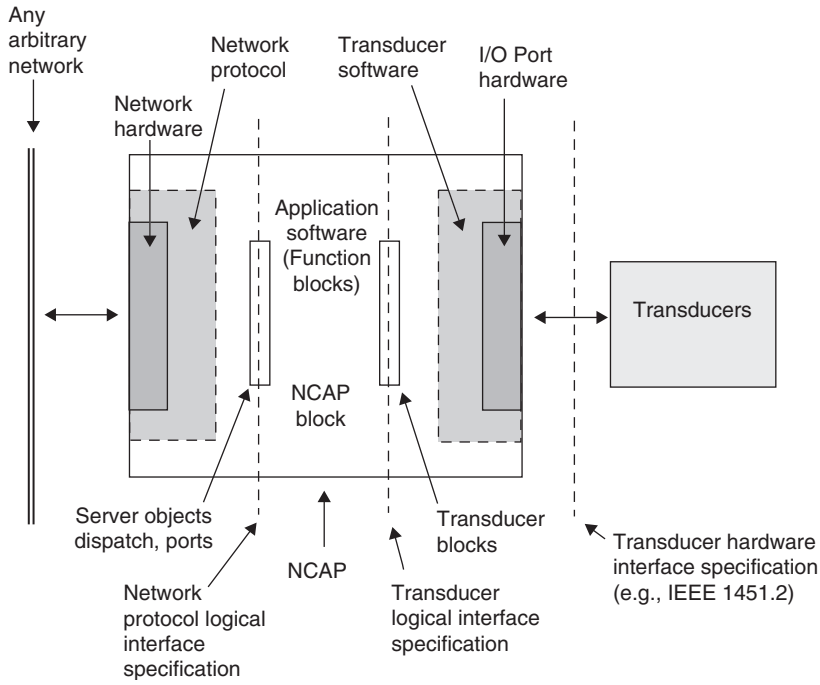

FIGURE 70.6 IEEE 1451 logical interfaces.

IEEE 1451.2 Transducer-to-Microprocessor Interface

The IEEE 1451.2 standard defines a TEDS, its data format, and the digital interface and communication protocols between the STIM and NCAP [8]. A block diagram and detailed system diagram of IEEE 1451 are shown in Figures 70.7 and 70.8, respectively. The STIM contains the transducer(s) and the TEDS, which is stored in a nonvolatile memory attached to a transducer. The TEDS contains fields that describe the type, attributes, operation, and calibration of the transducer. The mandatory requirement for the TEDS is only 179 bytes. The rest of the TEDS specification is optional. A transducer integrated with the TEDS provides a very unique feature that makes possible the self-description of transducers to the system or network. Since the manufacture-related data in the TEDS always go with the transducer, and this information is electronically transferred to an NCAP or host, human errors associated with manual entering of sensor parameters into the host are eliminated. Because of this distinctive feature of the TEDS, upgrading transducers with a higher accuracy and enhanced capability or replacing transducers for maintenance purpose is simply considered "plug and play."

Eight different types of TEDS are defined in the standard. Two of them are mandatory and six are optional. They are listed in Table 70.1. The TEDS are divided into two categories. The first category of TEDS contains data in a machine-readable form, which is intended for use by the NCAP. The second category of TEDS contains data in a human-readable form. The human-readable TEDS may be represented in multiple languages using different encoding for each language.

The Meta TEDS contains the data that describe the whole STIM. It contains the revision of the standard, the version number of the TEDS, the number of channels in the STIM, and the worst-case timing required to access these channels. This information will allow the NCAP to access the channel information. In addition, the Meta TEDS includes the channel groupings that describe the relationships between channels. Each transducer is represented by a channel.

Each channel in the STIM contains a Channel TEDS. The Channel TEDS lists the actual timing parameters for each individual channel. It also lists the type of transducer, the format of the data word being

FIGUR.E 70.7 Block diagram of IEEE 1451.

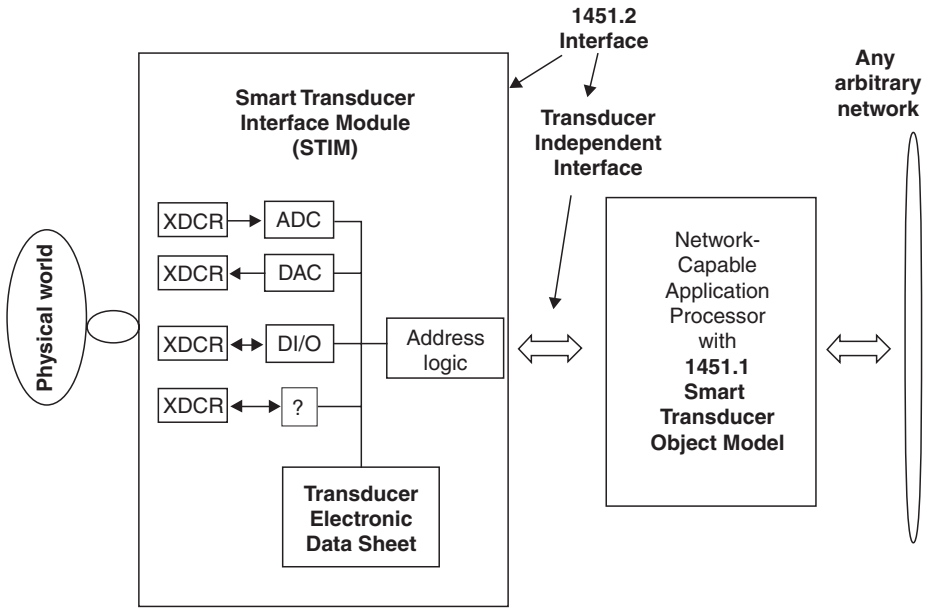

FIGURE 70.8 Detailed system block diagram of an IEEE 1451 smart transducer interface.

TABLE 70.1 Different Types of TEDS

TEDS Name	Type	Optional/Mandatory
Meta TEDS	Machine readable	Mandatory
Channel TEDS	Machine readable	Mandatory
Calibration TEDS	Machine readable	Optional
Generic extension TEDS	Machine readable	Optional
Meta-identification TEDS	Human readable	Optional
Channel identification TEDS	Human readable	Optional
Calibration identification TEDS	Human readable	Optional
End user application-Specific TEDS	Human readable	Optional

© 2005 by CRC Press LLC

output by the channel, the physical units, the upper and lower range limits, the uncertainty or accuracy, whether or not a calibration TEDS is provided, and where the calibration is to be performed.

The Calibration TEDS contains all the necessary information for the sensor data to be converted from the analog-to-digital converter raw output into the physical units specified in the Channel TEDS. If actuators are included in the STIM, it also contains the parameters that convert data in the physical units into the proper output format to drive the actuators. It also contains the calibration interval and last calibration date and time. This allows the system to determine when a calibration is needed. A general calibration algorithm is specified in the standard.

The Generic Extension TEDS is provided to allow industry groups to provide additional TEDS in a machine-readable format.

The Meta Identification TEDS is human-readable data that the system can retrieve from the STIM for display purposes. This TEDS contains fields for the manufacturer's name, the model number and serial number of the STIM, and a date code.

The Channel Identification TEDS is similar to the Meta Identification TEDS. When transducers from different manufacturers are built into an STIM, this information will be very useful for the identification of channels. The Channel Identification TEDS provides information about each channel, whereas the Meta Identification TEDS provides information for the STIM.

The Calibration Identification TEDS provides details of the calibration in the STIM. This information includes who performed the calibration and what standards were used.

The End-User Application-Specific TEDS is not defined in detail by the standard. It allows the user to insert information such as installation location, the time it was installed, or any other desired text.

The STIM module can contain a combination of sensors and actuators of up to 255 channels, signal conditioning/processing, A/D converter, D/A converter, and digital logics to support the transducer-independent interface (TII). Currently, the P1451.2 working group is considering an update to the standard to include a popular serial interface, such as RS232, in addition to the TII for connecting sensors and actuators.

IEEE 1451.3 Distributed Multidrop Systems

The EEE 1451.3 defines a transducer bus for connecting transducer modules to an NCAP in a distributed multidrop manner. A block diagram is shown in Figure 70.9. The physical interface for the transducer bus is based on Home Phoneline Networking Alliance (HomePNA) specification. Both power and data run on a twisted pair of wires. Multiple transducer modules, called Transducer Bus Interface Modules (TBIM), can be connected to an NCAP via the bus. Each TBIM contains transducers, signal conditioning/processing, A/D, D/A, and digital logics to support the bus and can accommodate large

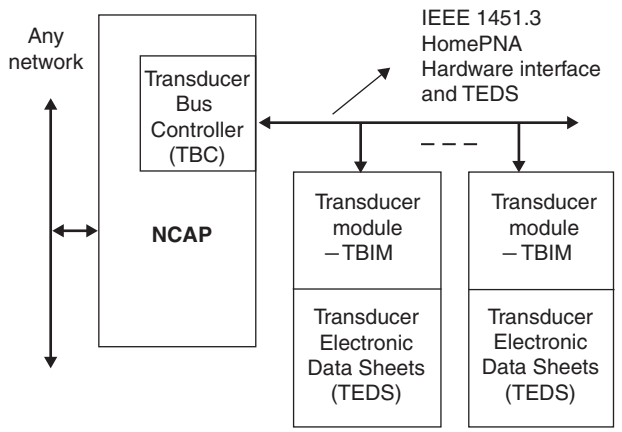

FIGURE 70.9 Block diagram of IEEE 1451.3.

© 2005 by CRC Press LLC

arrays of transducers for synchronized access at up to 128 Mbps with HomePNA 3.0 and up to 240 Mbps with extensions. The TEDS is defined in the eXtensible Markup Language (XML).

IEEE 1451.4 Mixed-Mode Transducer Interface

The IEEE 1451.4 defines a mixed-mode transducer interface (MMI), which is used for connecting transducer modules, Mixed-mode Transducers (MMT), to an instrument, a computer, or an NCAP. The block diagram of the system is shown in Figure 70.10. The physical transducer interface is based on the Maxim/Dallas Semiconductor's one-wire protocol, but it also supports up to 4 wires for bridge-type sensors. It is a simple, low-cost connectivity for analog sensors with a very small TEDS - 64 bits mandatory and 256 bits optional. The mixed-mode interface supports a digital interface for reading and writing the TEDS by the instrument or NCAP. After the TEDS transaction is completed, the interface switches into analog mode, where the analog sensor signal is sent straight to the instrument and NCAP, which is equipped with A/D to read the sensor data.

IEEE P1451.5 Wireless Transducer Interface

Wireless communication is emerging, and low-cost wireless technology is on the horizon. Wireless communication links could replace the costly cabling for sensor connectivity. It could also greatly reduce sensor installation cost. Industry would like to apply the wireless technology for sensors; however, there is a need to solve the interoperability problem among wireless sensors, equipment, and data. In response to this need, the IEEE P1451.5 working group is working to define a wireless sensor communication interface standard that will leverage existing wireless communication technologies and protocols [9]. A block diagram of IEEE P1451.5 is shown in Figure 70.11. The working group seeks to define the wireless message formats, data/control model, security model, and TEDS that are scalable to meet the needs of low cost to sophisticated sensor or device manufacturers. It allows for a minimum of 64 sensors per access point. Intrinsic safety is not required but the standard would allow for it. The physical communication protocol(s) being considered by the working group are: (1) IEEE 802.11 (WiFi), (2) IEEE 802.15.1 (Bluetooth), and (3) IEEE 802.15.4 (ZigBee).

IEEE 1451 Family

Figure 70.12 summarizes the family of IEEE 1451 Standards. Each of the IEEE P1451.X is designed to work with the other. However, they can also stand on their own. For example, IEEE 1451.1 can work without any IEEE 1451.X hardware interface. Likewise, IEEE1451.X can also be used without IEEE 1451.1, but software with similar functionality should provide sensor data/information to each network.

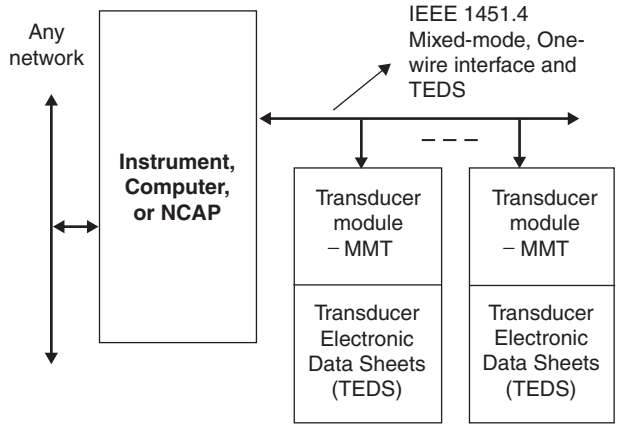

FIGURE 70.10 Block diagram of IEEE 1451.4.

© 2005 by CRC Press LLC

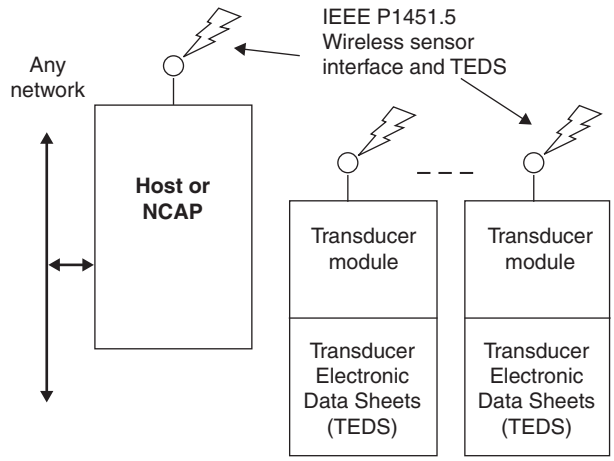

FIGURE 70.11 Block diagram of IEEE P1451.5 wireless transducer.

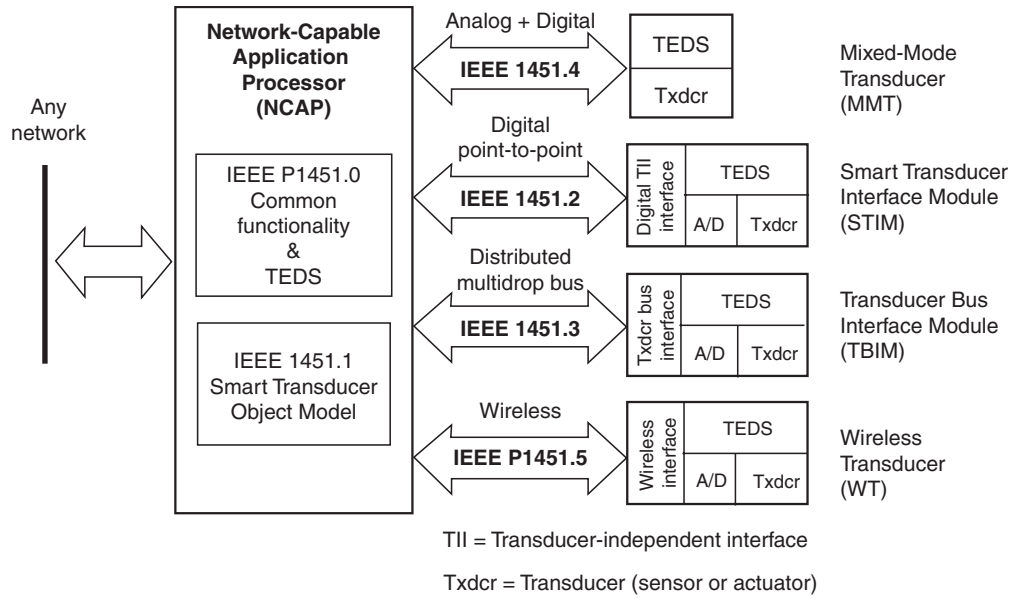

FIGURE 70.12 Family of IEEE 1451 Standards.

Benefits of IEEE 1451

IEEE 1451 defines a set of common transducer interfaces, which will help to lower the cost of designing smart sensors and actuators because designers would only have to design to a single set of standardized digital interfaces. Thus, the overall cost to make networked sensors will decrease.

Incorporating the TEDS with the sensors will enable self-description of sensors and actuators, eliminating error-prone, manual configuration.

Sensor Manufacturers

Sensor manufacturers can benefit from the standard because they only have to design a single standard physical interface. Standard calibration specification and data format can help to design and develop multilevel products based on TEDS with a minimum effort.

© 2005 by CRC Press LLC

Application Software Developers

Applications can benefit from the standard as well because standard transducer models for control and data can support and facilitate distributed measurement and control applications. The standard also provides support for multiple languages — good for international developers.

System Integrators

Sensor system integrators can benefit from IEEE 1451 because sensor systems become easier to install, maintain, modify, and upgrade. Quick and efficient transducer replacement results by simple "plug and play." It can also provide a means to store installation details in the TEDS. Self-documentation of hardware and software is done via the TEDS. Best of all is the ability to choose sensors and networks based on merit.

End Users

End users can benefit from a standard interface because sensors will be easy to use by simple "plug and play." Based on the information provided in the TEDS, software can automatically provide the physical units, readings with significant digits as defined in the TEDS, installation details such as instruction, identification, and location of the sensor.

"Plug and Play" of sensors

IEEE 1451 enables "plug and play" of transducers to a network as illustrated in Figure 70.13. In this example, IEEE 1451.4-compatible transducers from different companies are shown to work with a sensor network. IEEE 1451 also enables "plug and play" of transducers to a data acquisition system/instrumentation system as shown in Figure 70.14. In this example, various IEEE 1451.4-compatible transducers such as an accelerometer, a thermistor, a load cell, and a linear variable differential transformer (LVDT) are shown to work with a LabVIEW-based system.[2]

70.7 Example Application of IEEE 1451.2

IEEE 1451-based sensor network consisting of sensors, STIM, and NCAP are designed and built into a cabinet as shown in Figure 70.15. There were a total of four STIM and NCAP network nodes as shown in Figure 70.15. Thermistor sensors were used for temperature measurements. They were calibrated in the laboratory to generate IEEE 1451.2-compliance calibration TEDS for all four STIMs and NCAPs. The thermistors were mounted on the spindle motor housing, bearing, and axis drive motors of a 3-axis vertical machining center, which is shown in Figure 70.16. Since each NCAP has a

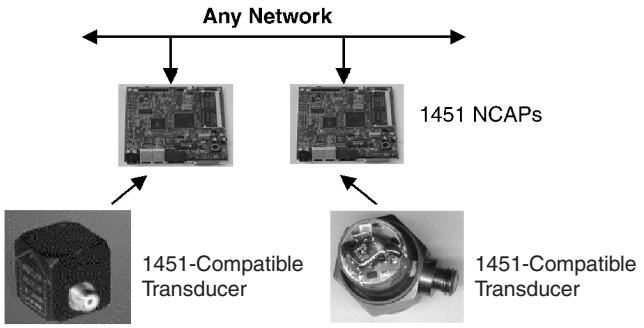

FIGURE 70.13 IEEE 1451 enables "plug and play" of transducers to a network.

[2]Certain commercial products are identified in this paper in order to describe the system. Such an identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the products identified are necessarily the best or the only ones available for the purpose.

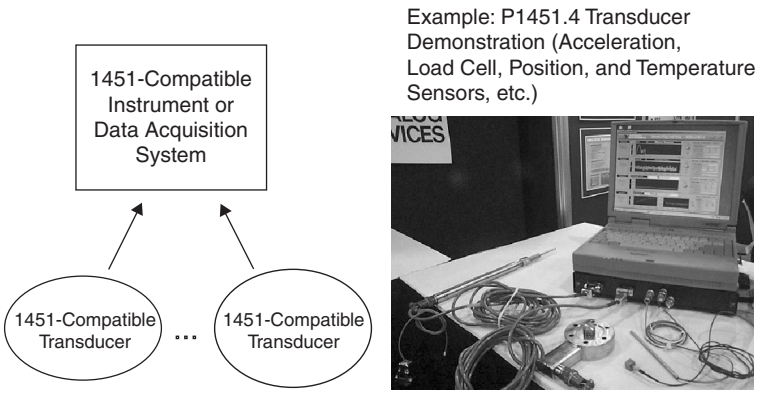

FIGURE 70.14 IEEE 1451 enables "plug and play" of transducers to data acquisition/instrumentation system.

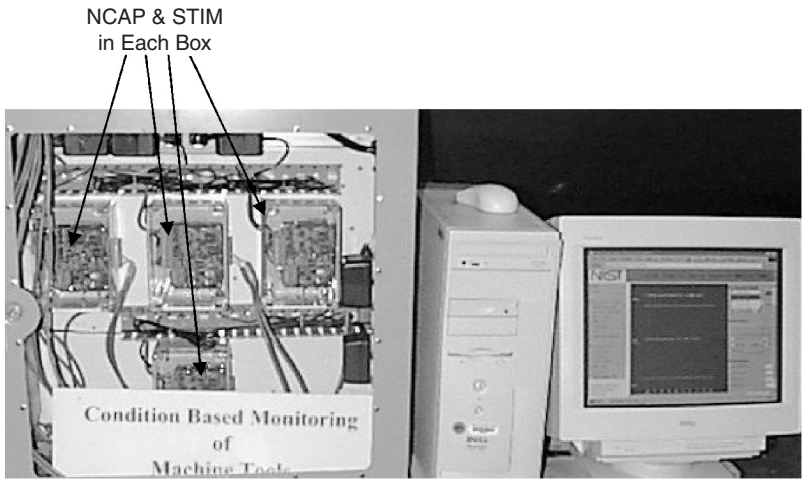

FIGURE 70.15 NCAP-based condition monitoring system.

built-in micro web server, a custom web page was constructed using the web tool provided with the NCAP. Thus, remote monitoring of the machine thermal condition was easily achieved via the Ethernet network and the Internet using a readily available common web browser. The daily trend chart of the temperature of the spindle motor (top trace) and the temperature of the *Z*-axis drive motor (bottom trace) in the machine is shown in Figure 70.17. The temperature rise tracks the working of the machine during the day and the temperature fall indicates that the machine is cooling off after the machine shop is closed.

70.8 Application of IEEE 1451-Based Sensor Network

A distributed measurement and control system can be easily implemented based on the IEEE 1451 standards [10]. An application model of IEEE 1451 is shown in Figure 70.18. Three NCAP/STIMs are used to illustrate the distributed control, remote sensing or monitoring, and remote actuating. In the first scenario, a sensor and actuator are connected to the STIM of NCAP #1, and an application software running in the NCAP can perform a locally distributed control function, such as maintaining a constant temperature for

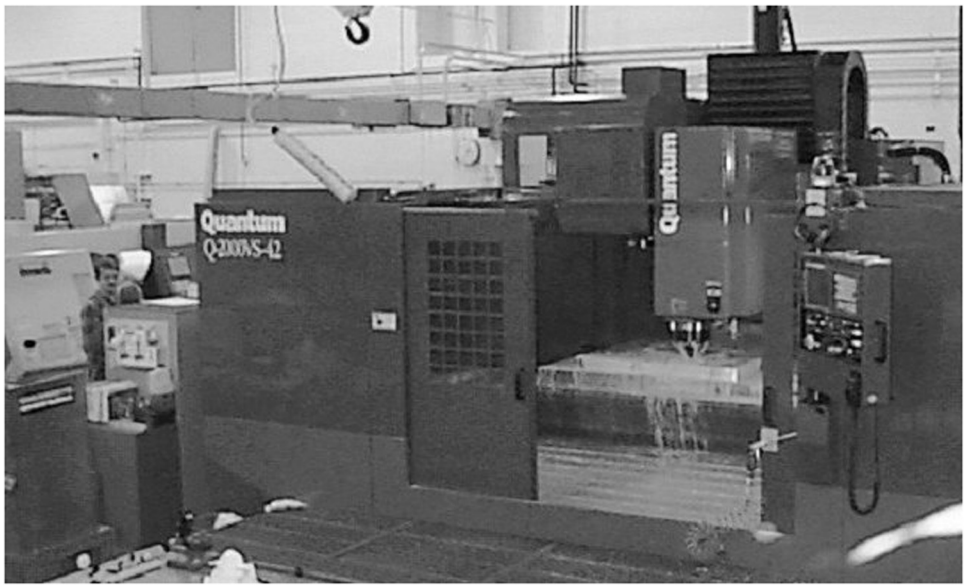

FIGURE 70.16 Three-axis vertical machining center.

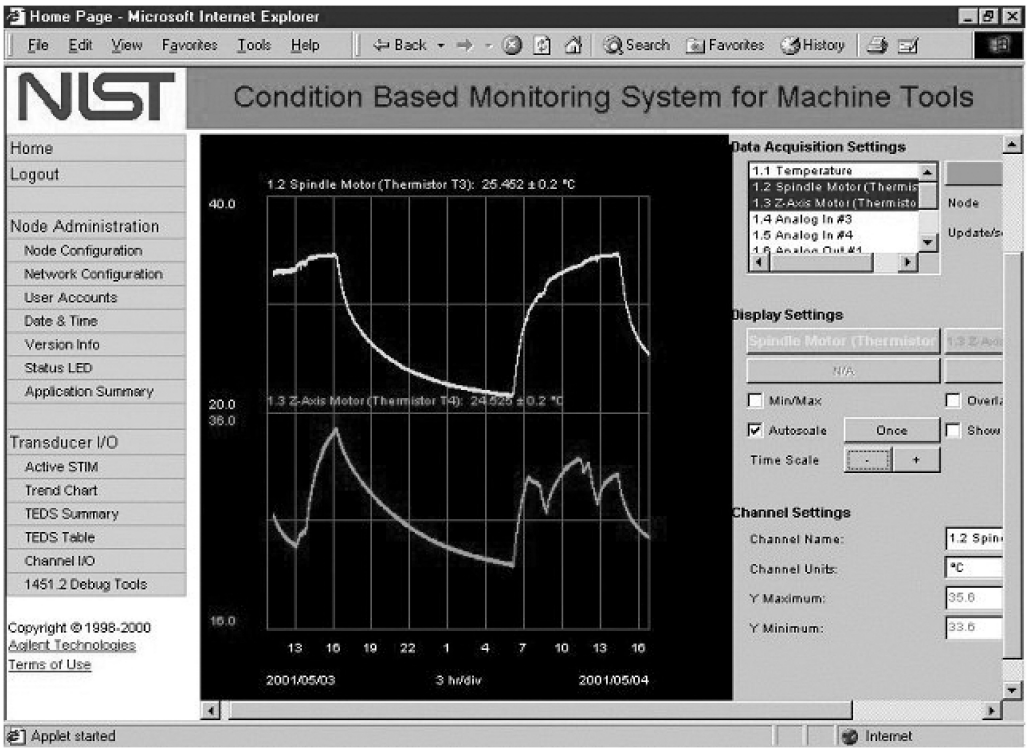

FIGURE 70.17 Temperature trend chart.

a bath. The NCAP reports measurement data, process information, and control status to a remote monitoring station or host. It frees the host from the processor-intensive, closed-loop control operation. In the second scenario, only sensors are connected to NCAP #2, which can perform remote process or condition

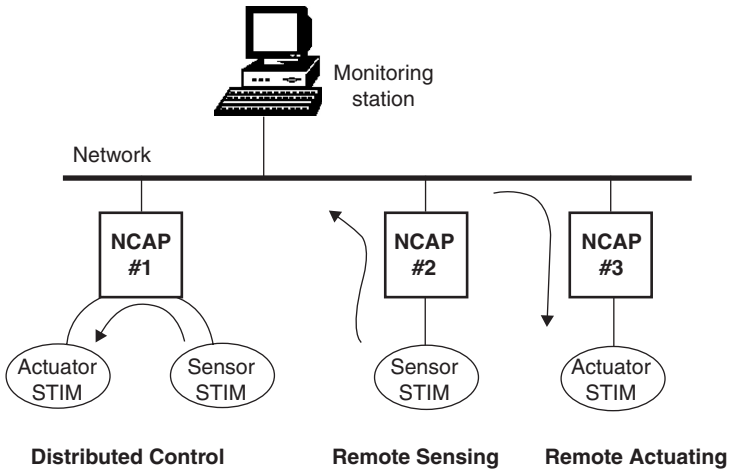

FIGURE 70.18 Application model of IEEE 1451.

monitoring functions, such as monitoring the vibration level of a set of bearings in a turbine. In the third scenario, based on the broadcast data received from NCAP #2, NCAP #3 activates an alarm when the vibration level of the bearings exceeds a critical set point. As illustrated in these examples, an IEEE 1451-based sensor network can easily facilitate peer-to-peer communications and distributed control functions.

70.9 Summary

The IEEE 1451 smart transducer interface standards are defined to allow a transducer manufacturer to build transducers of various performance capabilities that are interoperable within a networking system. The IEEE 1451 family of standards has provided the common interface and enabling technology for the connectivity of transducers to microprocessors, field networks, and instrumentation systems using wired and wireless means. The standardized TEDS allows the self-description of sensors, which turns out to be a very valuable tool for condition-based maintenance. The expanding Internet market has created a good opportunity for sensor and network manufacturers to exploit web-based and smart sensor technologies. As a result, users will greatly benefit from many innovations and new applications.

Acknowledgments

The author sincerely thanks the IEEE 1451 working groups for the use of the materials in this chapter. Through its program in Smart Machine Tools, the Manufacturing Engineering Laboratory of the National Institute of Standards and Technology has contributed to the development of the IEEE 1451 standards.

71.1 Introduction

Control system engineering and the instrumentation of industrial automation belong to a very innovative industrial area with a scope for cost reduction. That is why the costs for equipment and devices are already at a relatively low level. This trend is accompanied by a paradigm shift to digital processing in devices and digital communication among them.

This chapter describes the historical development steps from analog electronic devices connected via 4–20 mA, or 24 V technology, to digital devices with industrial communication connections such as fieldbus and Ethernet/TCP/IP. From these steps, the changes of the commissioning and system integration requirements are derived and the arising technologies to support device manufacturers and system integrators are introduced. All these integration technologies support the instrumentation tasks of field devices. Examples of these technologies are the Device Description Languages (provided, e.g., by

© 2005 by CRC Press LLC

PROFIBUS, Device Net, Fieldbus Foundation), standardized interfaces such as OPC and Field Device Architecture (FDT), control application integration using proxy function blocks written in PLC languages (e.g., in IEC 61131-3 languages), and vertical communication from field devices to SCADA, Decentral Control Systems (DCS), and Manufacturing Execution Systems (MES) by means of XML. The reader will become familiar with up-to-date technologies used in field device engineering and instrumentation tools. The chapter concludes with a formal modeling approach, specifically with a device model. This model provides an abstract view of the described technologies and makes the relations among them visible.

71.2 History of smart devices

Digital information computation in field devices and digital fieldbus communication leads to a change in the handling of automation systems in manufacturing and process control. The field devices now contain much more information than the 4–20 mA signal. In addition, they carry out some functions that are/were originally programmed within the PLC or DCS. These field devices are also known as smart devices.

The consequence is a distributed system. The tools for the design and programming of control applications, commissioning, as well as maintenance need both access to the data of the field device and/or an exact machine-readable product description of the field devices including their data and functions. These device descriptions, from the design of the description to its use, are called device description technology. Using these device product descriptions, it is necessary to integrate standard interface specifications and standardized industrial communication systems.

The following example of a transmitter shows the transformation from an analog 4–20 mA device to a smart fieldbus device. Other types of automation devices were or are moving in a similar direction. Even digital, discrete, and I/O field devices are much simpler, for example, the 24 V technology will also be replaced by fieldbus connected devices.

The transmitter in Figure 71.1 is composed of electronics, which detects the specific measurement value (e.g., mV, mA) and which transforms the detected signal into the standardized 4–20 mA. The adjustment to the specific sensor and wiring is done by trim resistors. Each transmitter is connected to the PLC by its own wires.

Digital signal computation provides a higher accuracy. Therefore, the signal processing is carried out by microprocessors (Figure 71.2). An analog/digital and a digital/analog unit transform the signals two times. The signal processing may be influenced by several parameters, which make the transmitter more flexible. These parameters have to be accessed by the operator. For this purpose, the manufacturer provides a local operator panel at the transmitter, which consists of a display and very few buttons. PC

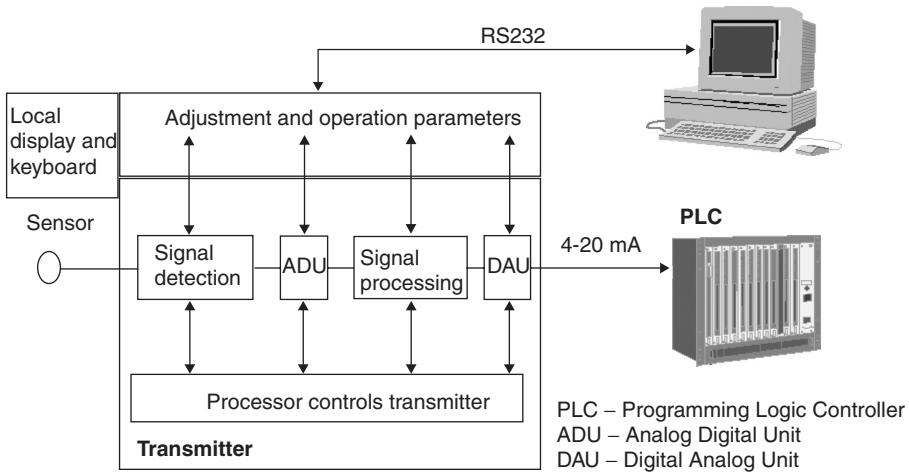

FIGURE 71.2 Structure of smart 4–20 mA transmitters.

tools provide more ergonomic solutions for the commissioning of such smart transmitters, which is necessary if they are more complex.

In principle, in smart fieldbus transmitters, the digital/analog unit at the end of the signal chain in the transmitter is replaced by the fieldbus controller. This increases the accuracy of the devices again. In addition, devices according to Figure 71.3 need specific communication commissioning using additional fieldbus configuration tools.

The smart field device parameterization has moved from manual screwing over local device terminals to PC application software. Additionally, the communication system configuration has to be managed during the commissioning of the instrumentation.

The field device is typically integrated as a component in an industrial automation system. The automation system performs the automation-related part of the complete application. The components of an industrial automation system may be arranged in multiple hierarchical levels connected by communication systems, as illustrated in Figure 71.4.

The field devices are components in the process level connected via inputs and outputs to the process or the physical or logical subnetworks (IEC Guideline, 2002). This also includes programmable devices and router or gateways. A communication system (e.g., a fieldbus) connects the field devices to the upper-level controllers, which are typically programmable controllers or DCS or even MES. Since the engineering tools and the commissioning tools should have access to the field devices and to the controllers, these tools are also located in the controller level. The field devices may directly communicate via the fieldbus or the controller (Programmable Controller). In larger automation systems, another higher level may exist connected via a communication system such as LAN or Ethernet. In these higher-level visualization systems (HMI), DCS, central engineering tools, and SCADA are located. Multiple clusters of field devices with or without a controller as described above may be connected over the LAN with each other or to the higher-level systems. MES, Enterprise Resource Planning (ERP), and other Information Technology (IT) systems can have access indirectly to field devices via the LAN and the controllers or direct via routers.

The result of this development is a large variety of PC-based tools for planning, design, commissioning configuration, and maintenance (Figure 71.4). This problem is also known in the home and consumer electronics. TV, CD player, video recorder, and record player are bought gradually by a family, and may be produced by different manufacturers. Each device is purchased with remote controllers. The user has to deal with different styles, programming approaches, and outlines. This is unacceptable both in consumer electronics and in the industrial environment. Of course, manufacturers desire to be unique regarding functions and features of their products and provide special approaches to interact with the device. The end user gets products very suitable to specific requirements, but he is faced with a broad variety of device interfaces.

© 2005 by CRC Press LLC

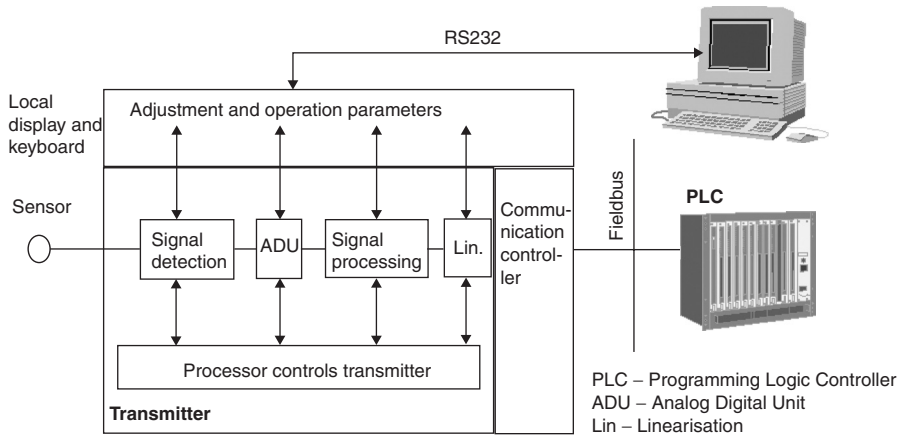

FIGURE 71.3 Structure of a smart fieldbus transmitter.

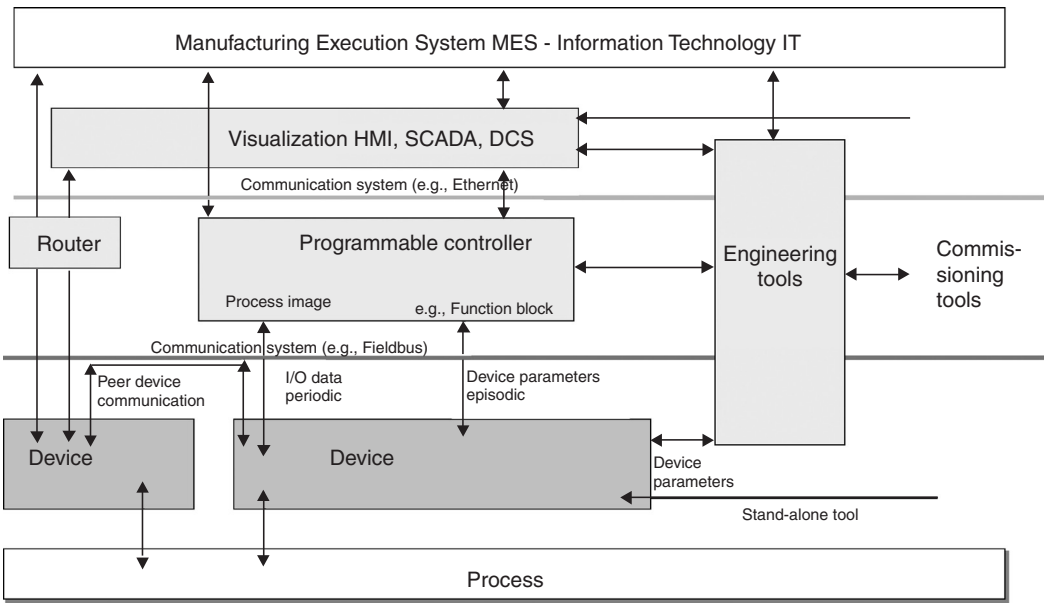

FIGURE 71.4 Typical automation configuration (IEC Guideline, 2002).

The field devices are an integrated part of the entire life cycle of control systems starting with planning/design, over purchase, system integration/commissioning, operation and ending with maintenance. During each phase of the life cycle, specific information represented in different formats is used from the tools. Planning and design define the requirements coming from the process that defines the type and the properties of the field device. The results are the pipe and instrumentation diagram (P&ID) in process control and electrotechnical drawings (E-CAD) in facturing automation combined with device lists. Purchase is made by requests of offers or by web market places directly. Commissioning carries out the parameterization and configuration of field devices in connection with the programming of the programmable controllers. During operation, there are mostly interactions between the controllers and the field devices. The field devices interact with special tools during maintenance. The view to field devices, that is, the used subset of the entire information range, the format of the information (text in manuals, files, data base entries, html pages), and the source of the information (paper, machine readable in the

© 2005 by CRC Press LLC

system, on-line from the device) differ between the lifecycle phases. Therefore, integration technologies deal with multiple technologies. B2B and MES are not within the scope of these collections of technologies. The main reason is that this paper concentrates on the functional aspects of the field device integration. Even planning and design are only mentioned in certain sections because product data management does not yet have tight connections to the functional design of the control system.

71.3 Field Device Instrumentation

Today, the large number of different device types and suppliers within a control system project makes the field device parameterization and configuration task difficult and time-consuming. Different tools must be mastered and data must be exchanged between these tools. The data exchange is not standardized; therefore, data conversions are often necessary, requiring detailed specialist knowledge. In the end, the consistency of data, documentation, and configurations can only be guaranteed by an intensive system test.

The central workplace for service and diagnostic tasks in the control system does not fully cover the functional capabilities of the field devices. Furthermore, the different device-specific tools cannot be integrated into the system's software tools. Typically, device-specific tools can only be connected directly to a fieldbus line or directly to the field device (Figure 71.5).

In order to maintain the continuity and operational reliability of process control technology, it is necessary to fully integrate field devices as a subcomponent of process automation.

Field devices often have to be adjusted to their concrete application purpose; therefore, additional software components are necessary for parameterization reasons. These components are necessary because local operator keyboards, with only a few bottoms and small displays, are not suitable to provide the complex parameterization issues to the operator. In principle, the following cases of application can be found (Diedrich et al., 2001):

- Devices with fixed functionality and without parameterization of its device application. These devices have to provide their communication properties, which is only done according to descriptions such as PROFIBUS GSD and CAN EDS. A communication configuration tool verifies all properties of all devices that are connected at one communication segment and generate the communication configuration in terms of the communication parameters such as baud rate and device addresses.
- Devices with only little parameter data have to be fixed only once during the commissioning phase (e.g., minimum and maximum speed of a drive, calibration for a transmitter). This device should receive the data via fieldbus from the control station. Therefore, many fieldbus systems have added parameterization keywords in their communication-related descriptions, such as PROFIBUS GSD and CAN EDS. Fieldbus configuration tools provide the possibility to edit the parameter values; the controller (e.g., PLC) ensures the persistence of the parameter data, for example, for a restart. This case of application does not need any additional parameterization tools. The replacement of a device after failure can be made easily.
- Devices with many parameters and complex parameterization means (e.g., transmitters, actuators in the process control field) have, for a long time, had local terminals and/or their own commissioning tools. Tools that are able to parameterize many different types of devices from different manufacturers have been established in the market. Well-known languages are HART DDL (Device Description Language [HART, 1995]), Fieldbus Foundation DDL (FF, 1996), and the PROFIBUS EDD (Electronic Device Description [PNO, 2001b]), which belong to the same language family (IEC61804, 2003). These languages are characterized by off-line parameterization, device-specific guidance by the operators, and extensive consistency checks. The management of the persistence data is directly related to parameterization tools; therefore, a replacement of these devices without these tools is not possible.
- Devices with complex parameterization sequences and complex data types (e.g., graphical information representation or video representation) cannot be described by the languages mentioned. Therefore, these devices need device-specific commissioning tools (e.g., Laser scanner).

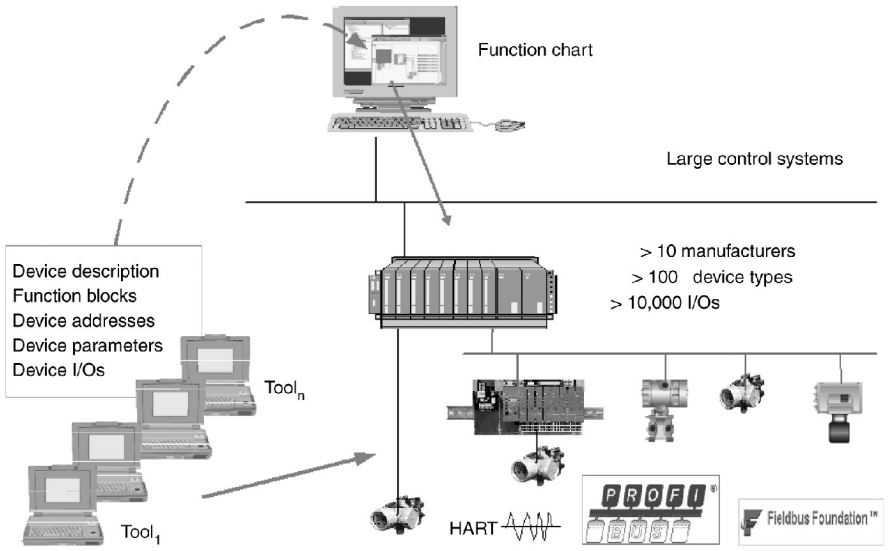

FIGURE 71.5 Different tools and multiple data input have determined field device integration to date (Bruns et al., 1999).

Fieldbus Communication Configuration

GSD Language

A communication segment has to be configured for a certain device configuration. The baud rate, device addresses, and special communication timing parameters have to be adjusted according to the collection of devices and their properties. Therefore, fieldbuses provide communication feature lists in a machine-readable format. Each device is purchased with such a list, which is used by a communication configuration tool to generate the possible or optimal communication configuration.

One example is the PROFIBUS GSD. The abbreviation GSD stands for German Device Data Base (GeräteStammDaten). There is no translation of the abbreviation at all. The GSD describes the communication features and the cyclic data of simple devices such as binary and analog I/O. Communication features are potential baud rates, communication protocol time parameters, and the support of PROFIBUS services and functions (e.g., remote address assignment).

Simple I/O devices (also known as Remote I/O or intelligent clip) are mostly modular. A basic device with power consumption and a central processing unit has several slots, offered to plug in modules with different signal qualities (analog, binary) and quantities (e.g., 2, 4, 8, 16 channels). According to the chosen modules, a different set of data has to be transferred in the cyclic transfer between the PROFIBUS master and slave devices. In other words, every module contributes with a specific set of data to the cyclic telegram. If we consider that the configuration tools of the PROFIBUS master devices (PLC mostly) have to be used device manufacturer-independent, an unambiguous and manufacturer-independent description of the modules is necessary. This is the second main task of the GSD description.

The GSD language is a list of keywords accompanied by their value assignment for each feature of the PROFIBUS DP protocol, which is configurable, and the module specification. This list is accomplished by a device and GSD file identification. The following example shows what a GSD file looks like (Figure 71.6).

Modules are represented in the GSD by the keyword "Module." Between the Module and the End_Module keyword, the declaration of the contribution of the module to the cyclic data telegram is specified in terms of binary codes, the so-called Identifier Bytes. Each module has a name that is printed at the configuration tool screen. If the module is chosen, the specified Identifier Bytes will be

© 2005 by CRC Press LLC

concatenated to the configuration string, which is transferred from the master to the slave during the startup of the cyclic data transfer (CFG service of PROFIBUS-DP [2]). In addition, the range and the default value of variables can be configured, which is supported by the variable declaration possibility of GSD. These data specified in the module GSD construct are transferred with the so-called PRM service (PRM from parameterization) of PROFIBUS DP ([2]).

GSD Tool Set

All PROFIBUS DP manufacturers are obliged to sell these devices with a GSD file, which is checked by the PROFIBUS User Organisation (PNO). The PNO offers a special GSD editor, which guides the engineer during the GSD development (Figure 71.7). The engineer chooses the features of the device with a mouse click from the superset of all existing PROFIBUS-DP features. The editor generates the syntactic right GSD ASCII file. This file is not compiled.

The configuration tools read these GSD files and present the specified device features for communication configuration and adjustment of some application parameters. The result of this configuration process are the configuration and parameterization strings for the PROFIBUS DP services (Figure 71.8).

The handling of GSD is very simple and needs no specific training. It matches exactly the needs of simple I/O with no or less application parameterization.

Field Device Application Parameterization — Device Description Languages

Two kinds of users can be distinguished for the task of parameterization:

- the end user or operator of a plant or machine and
- the system integrator.

For the end user of a distributed control system, the most important thing concerning device description is its transparency. The end user wishes to see only the graphical user interface of a device represented in the SCADA-software or other Human Machine Interfaces (HMI). Therefore, the electronic device description has to be constructed following the plug and play concept. Furthermore, exchanging a device in an application is required not to lead to a big engineering task, but is required to be done simply and securely by a technician. The device description has to support this.

In contrast to the end user, the system integrator, who carries out the engineering, instrumentation, and documenting, has different targets to meet. His goal is to reduce the engineering time for solving

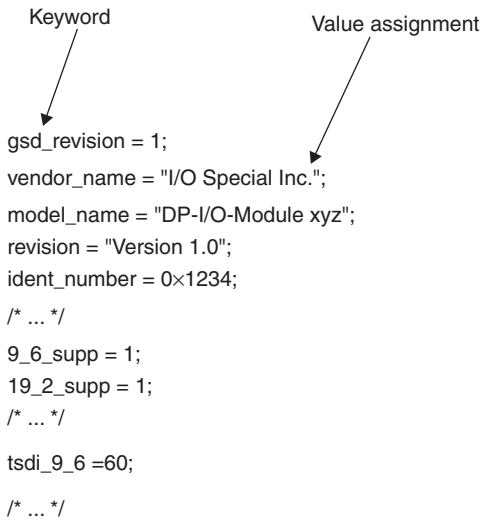

FIGURE 71.6 Example GSD file subset.

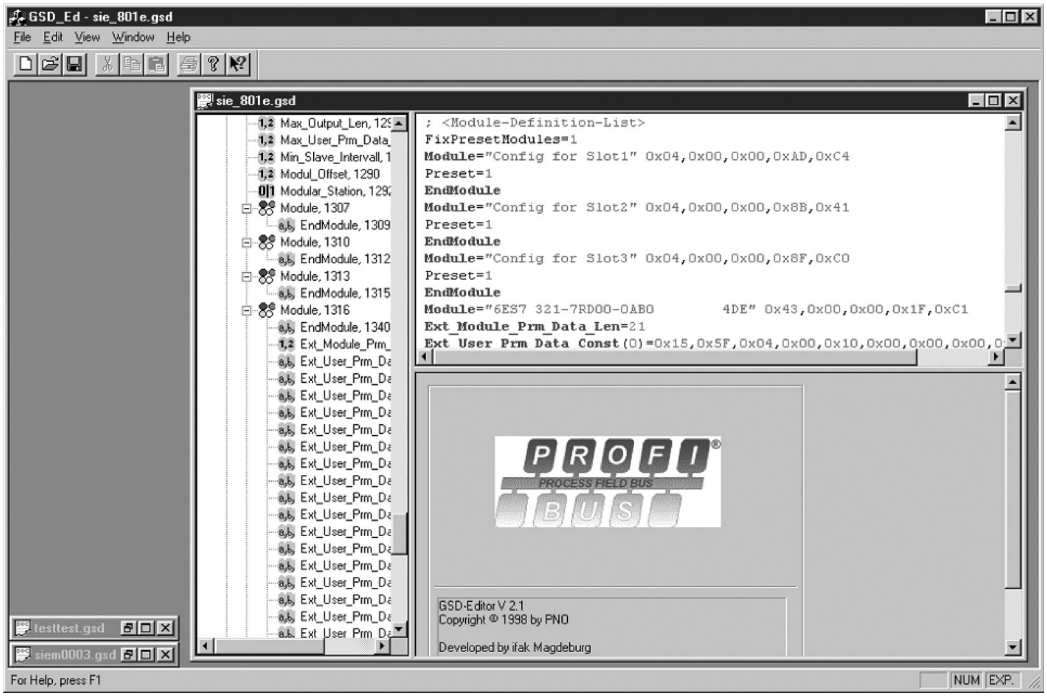

FIGURE 71.7 GSD editor snapshot.

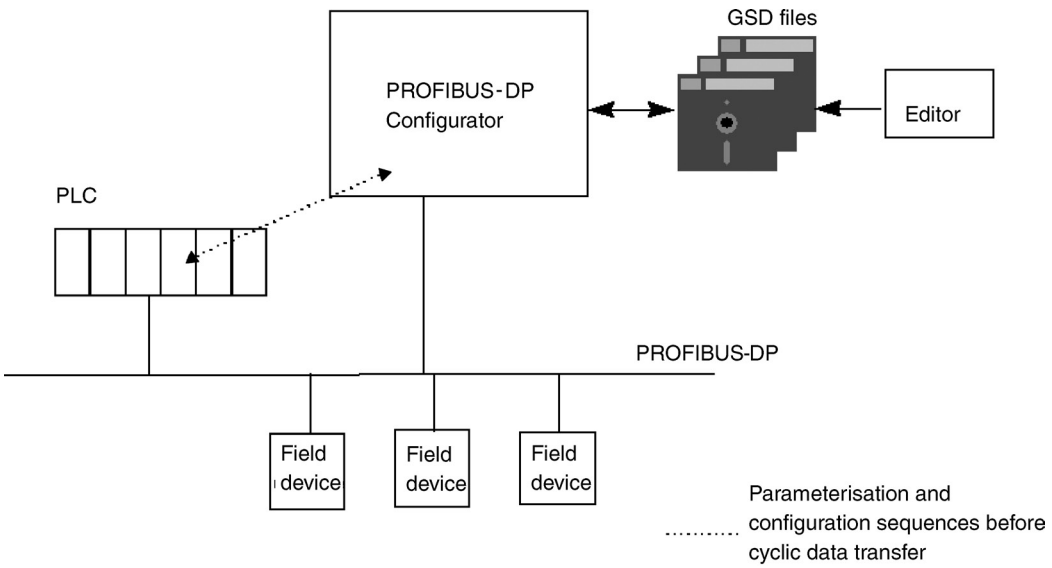

FIGURE 71.8 Tools and handling of GSD.

interoperability problems but to enhance the engineering effort to design the optimal application with regard to the quality of the product to be produced with the process control system. The effectiveness of his work, comprising all preproducing phases of the plant/machine life cycle, depends directly on the support of a well-defined, standardized and a complete machine-readable description of the devices he has to deal with.

© 2005 by CRC Press LLC

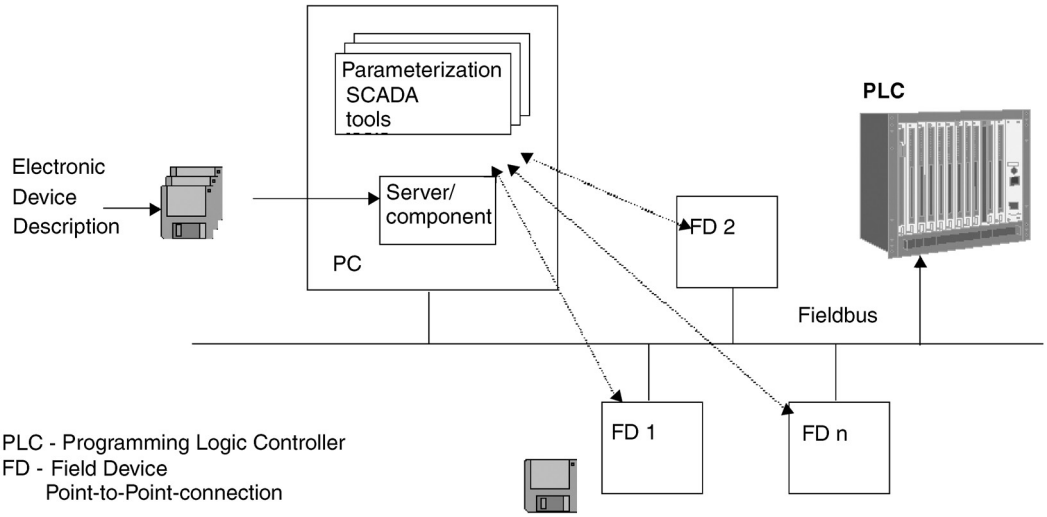

FIGURE 71.9 Using EDD in parameterization tools.

The conclusions from this analysis are that the Device Description Language has to be designed mainly from the system integrator's point of view, because he has to deal directly with the electronic device description. The fieldbus community developed some approaches to exchange data by electronic means. This includes DDL (e.g., for HART, FF, and Electronic Device Description for PROFIBUS).

The main features of this description technology, including the according language, can be summarized as follows:

- An EDD (in terms of a file) is delivered by the device vendor together with the device.
- EDD is used in the engineering process of the distributed control system, supporting planning, commissioning, operation, diagnostics, and maintenance.
- There are different EDD presentations possible, source in a human-readable way and binary format.
- The EDD is mostly stored on disk and can additionally be stored within the device (transport via fieldbus).
- The EDD is nearly independent from the underlying fieldbus system.
- The EDD is used to describe information identifying each item and defining relationships between them (hierarchical, relational).
- The EDD offers language elements for presentation within an HMI and for communication access.
- An EDD-file represents a static description, that is, the declarative part of the device; therefore, only the external interface/behavior of the device is described (no interest in internal code).

A parameterization tool needs special adaption to functions and parameters of each device, which should be commissioned or visualized (Figure 71.9). The EDD contains all device functions and parameters. The functions and parameters differ between the devices, but they are described with a defined language. The tools understand this language and adapt themselves to the described functionality. Adaptation means modification of the screen outline (e.g., content of the menus and bars), and the interactions with the devices. Generally speaking, the devices will be purchased with disks containing their own device description, and the tools get their specific configuration by reading and interpreting this device description. The main parts of the EDD are as follows:

- Description of variables and parameters including their attributes (Process Variable — PV with label for screen prints, e.g., Level hydrostatic, data type floating point, access right read/only, default value = 0).
- Presentation of variables in HMI tools (e.g., PV with label "Temperature").

© 2005 by CRC Press LLC

- Guidance of the operator during commissioning (e.g., order of menu entries at hand-held terminals or PC tools).
- Table of content of all visible elements of the device.
- Device configuration parameter (e.g., identifier for plug-in modules of modular devices).
- Communication configuration parameters (e.g., baud rate = 500 kBaud).

The following example gives a short look-and-feel of the language:

EDD is a formal language used to describe completely and unambiguously what a field instrument looks like when it is seen through the "window" of its digital communication link. EDD includes descriptions of accessible variables, the instrument's command set, and operating procedures such as calibration. It also includes a description of a menu structure that a host device can use for a human operator. The EDD, written in a readable text format, consists of a list of items ("objects") with a description of the features ("attributes" or "properties") of each. Some example fragments from an (imaginary) flowmeter EDD are shown in Figure 71.10.

The major benefit of DDL for suppliers is that it decouples the development of host and field devices. Each designer can complete product development with the assurance that the new product will interoperate correctly with current and older devices, as well as with future devices not yet invented. In addition, a simulation program can be used to "test" the user interface of the EDD, allowing iterative evaluation and improvement, even before the device is built.

For the user, the major benefit is the ability to mix products from different suppliers, with the confidence that each can be used to its full capacity. Easy field upgrades allow host devices to accept new field devices. Innovation in new field devices is encouraged. The EDD is restricted for the description of a single device and use in a mostly stand-alone tool.

Software tools for automation are very complex and implements a lot of know-how. The number of sold products is relatively small in comparison with office packets. The definition of standardized DDL increases the potential users of the tools and speeds up the use of fieldbus-based automation.

Programming of the Control Applications with Integrated Field Device Functions

The Proxy-Concept organizes the functional and data relations between field devices and programmable controllers (e.g., PLCs; Figure 71.11). Field devices implement some signal processing, such as scaling or limit check, which was a part of the programmable controller libraries using the 4–20 mA technology. The consequence of this change is an interruption of the sequence of functions, which have already been carried out in one compact PLC program. This program has been developed with one software tool. Now different devices with different resources, which are scheduled in an asynchroneus manner, carry out the functions and it is unclear if the sequence order works in the necessary way. Additionally, PLC and field devices are programmed with different tools. The IEC 61499 (IEC 61499, 2001), PROFInet (PROFInet, 2002), and IDA (IDA, 2001) standards provide means to address the problems; however, these standards are not yet available on the market.

It would be favorable if the PLC programmer can use the decentralized functions in its normal programming environment with all the characteristic features. This would be possible if there is a device function block in the PLC library. This device function block represents the field device as its data input and output interface. The internals of this device function block are manufacturer specific. This concept of device function blocks of remote functions is known as the proxy concept. The communication between the proxy and the field device is carried out by cyclic (for process variables) and acyclic (for device parameterization, e.g., batch) means, that is, communication function blocks of the PLC. If these communication function blocks are standardized and the PLC IEC 61131-3 [11] compliant, the device function blocks are portable in an easy manner. Portable device function blocks mean that the communication function blocks are PLC manufacturer independent at its interface and main behavior. The specification of IEC 61131-5 that specifies such communication function blocks does not fulfill the requirements for an interoperable data transfer and is not well accepted in the market. Therefore, PROFIBUS has built its own specification, which is based on the IEC [xx].

FIGURE 71.10 Device Description example.

Proxies, that is, device function blocks, are additional components that have to be provided by a field device manufacturer. This is a consequence of the increase of device functionality, the decentralization of the system and its engineering, and of the resulting distributed system. Proxies are a very good basis for manufacturer- and user-specific functionalities, which can be implemented as PLC programs

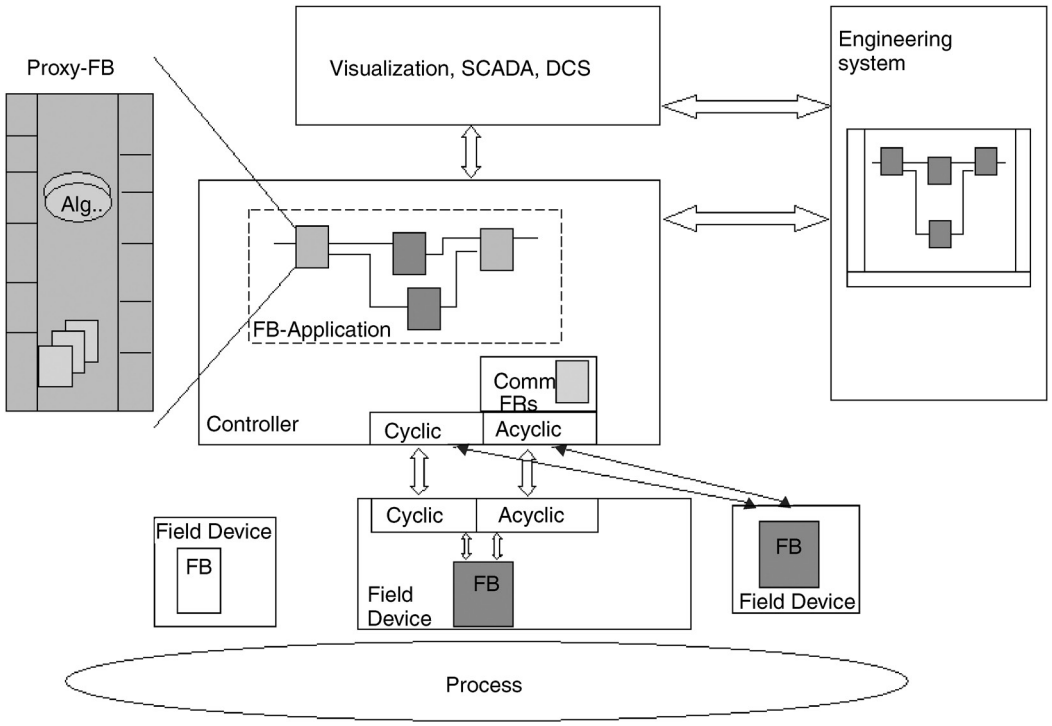

FIGURE 71.11 Proxy-concept based on a function block.

instead of embedded software in the field device. Therefore, more flexibility of the manufacturer satisfying user requests is possible. This flexibility can be implemented using different platforms of different PLC manufacturers.

Field Device System Integration

Common for the technologies described in the previous subsections is the limited scope of data in so-called "stand-alone" tools. The engineering and supervisory system (Figure 71.4) needs data from all devices and components in order to provide a noninterrupted information flow between the tools.

In order to maintain the continuity and operational reliability of process control technology, it is therefore necessary to fully integrate field devices as a subcomponent of process automation [2]. To resolve the situation, the German Electrical and Electronic Manufacturers' Association (ZVEI) initiated a working group in 1998 to define a vendor-independent FDT architecture. This FDT concept defines interfaces between device-specific software components (DTM, Device Type Manager) supplied by device manufacturers, and engineering systems supplied by control system manufacturers. The device manufacturers are responsible for the functionality and quality of the DTMs, which are integrated into engineering systems via the FDT interface. With DTMs integrated into engineering systems in a unified way, the connection between engineering systems (e.g., PLC applications) and inconsistent field devices becomes available. The FDT specification specifies what the interfaces are, not the implementation of these interfaces [2]. Figure 71.12 shows the FDT architecture. From the figure, we can see that DTMs act as bridges between the frame-application and field devices.

FDT Frame-Application

As one component of the FDT structure, the frame-application is supposed to manage data and communication with the device and embedded DTMs. According to the environment a DTM is running in,

© 2005 by CRC Press LLC

the frame-application can be an engineering tool, or even a web page. But here, we consider frame-application as an engineering environment that integrates field devices and their configuration tools and controls DTMs within a project. The project is a logical object to describe the management and controls, at least in the lifetime of device instances in terms of the DTM within a frame-application (PNO 2001a). In view of a DTM, interfaces such as IPersistPropertyBag (Connection Storage in Figure 71.12), IfdtCommunication (Connection Communication in Figure 71.12) specified in PNO (2001a), determine what the frame-application can do.

DTM

The DTM is the key concept of field device integration, with each DTM representing one field device. In addition, more than one device of a common type can also be represented by a single DTM object. Moreover, a device can be subdivided into modules and submodules, for example., a device with its remote I/O modules. If a device supports remote I/O channels (in the FDT concept, the I/O of a device is called a channel), it also acts as a gateway. For example, a gateway from Profibus to HART is logically represented by a gateway DTM that implements the operations for channel access. Each time a user wants to communicate with a certain device connected via an interface card between the communication section of the frame-application and the device, an instance of the corresponding DTM is asked to be built. During the user's operation on the device, the whole lifetime of this DTM object is controlled by the frame-application. This is the concept of COM technology. In fact, DTM is implemented as a Microsoft COM object, which will be dynamically loaded when the user intends to obtain information of the device or set parameters to the corresponding field device, and then released after the operations. All these interactions are carried out via interfaces specified in the FDT specification (Figure 71.13).

The interfaces IDtm and IDtmInformation specified in PNO (2001a) provide basic functions used by the frame-application to obtain information for the DTMs and execute certain operations on the corresponding devices. If the device represented by a DTM has its process values, another interface specified in PNO (2001a), IFdtChannel, acts as the gateway to deal with the connection to substructure, such as remote devices connected via Remote I/O channel to the master device. For some special tasks, such as documentation and communication, a DTM must implement the task-related interfaces if it supports the tasks.

The device manufacturer has multiple choices for the development of these DTMs. The DTM can be written manually in a high-level language, for example, in C++ or VB. It is also possible to generate DTMs out of

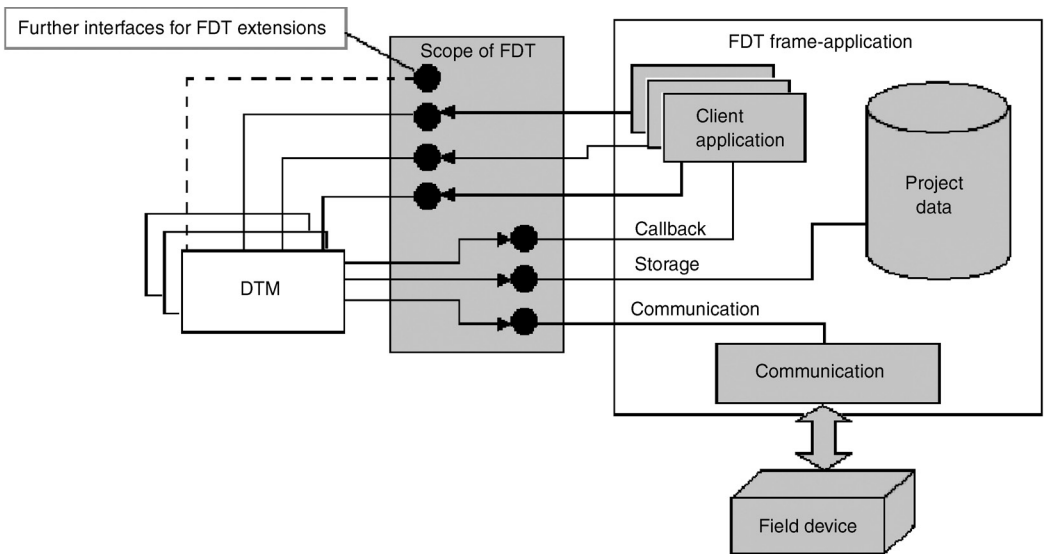

FIGURE 71.12 The architecture of Field Device Tools /PNO 2001a/.

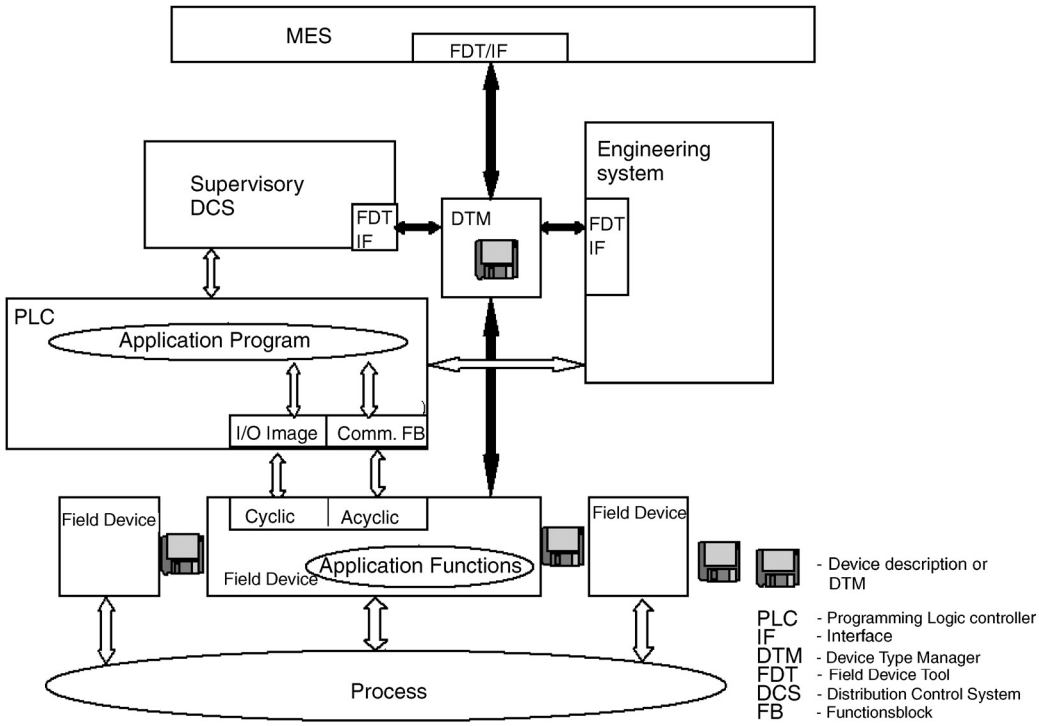

FIGURE 71.13 Integration of DTMs in the automation architecture using FDT interfaces.

existing device descriptions or provide DTM interpreting existing DTMs. Parameterization tools can be transformed to DTMs developing a wrapper around the tools that are conformed with the FDT interfaces.

FDT Interfaces

From the above parts, interfaces of frame-application and DTMs are mentioned and shown as the bridges between frame-application and DTMs. From the outside of an object, we can see only these interfaces that are specified according to their special functionalities but their implementation remains invisible and encapsulated.

With the help of FDT specifications and the corresponding interface technology, the user (engineering system manufacturer) will be able to handle devices and their integration into engineering tools and other frameworks in a consistent manner.

71.4 Fieldbus Profiles

Profiles are functional agreements between field device manufacturers to provide interoperable device functions of a certain device class to other field devices, controllers or DCS, SCADA, and engineering systems. Device classes have common functional kernels accompanied by the variables and parameters. These common set of variables, parameters, and functions are called profiles. Profiles reduce the degrees of freedom using the variety of the communication system and the choice of application functions of the device classes (Figure 71.14).

There are certain degrees of compatibility and accordingly degrees of cooperation between profile-based devices (compatibility levels). Compatibility levels are applicable for various roles of a device, for example, control, diagnosis, parameterization/configuration, and even applicable to subsets of its functionality. This means that one device can have different compatibility levels regarding different interfaces to the system. The levels are dependent on well-defined communication and application device features (Figure 71.15).

© 2005 by CRC Press LLC

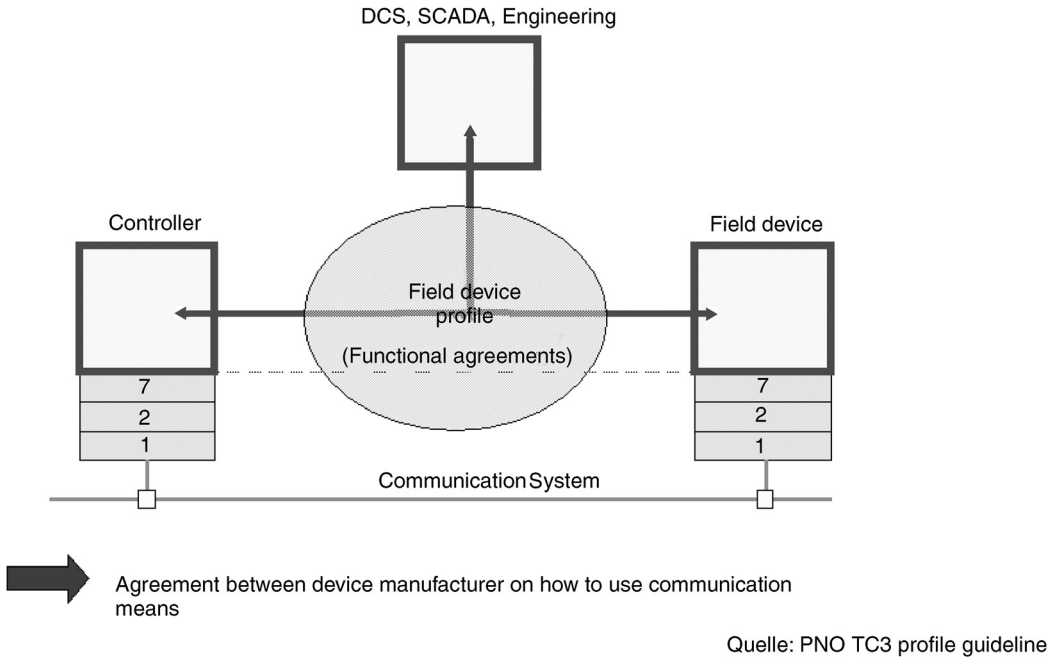

FIGURE 71.14 Profile in the automation architecture.

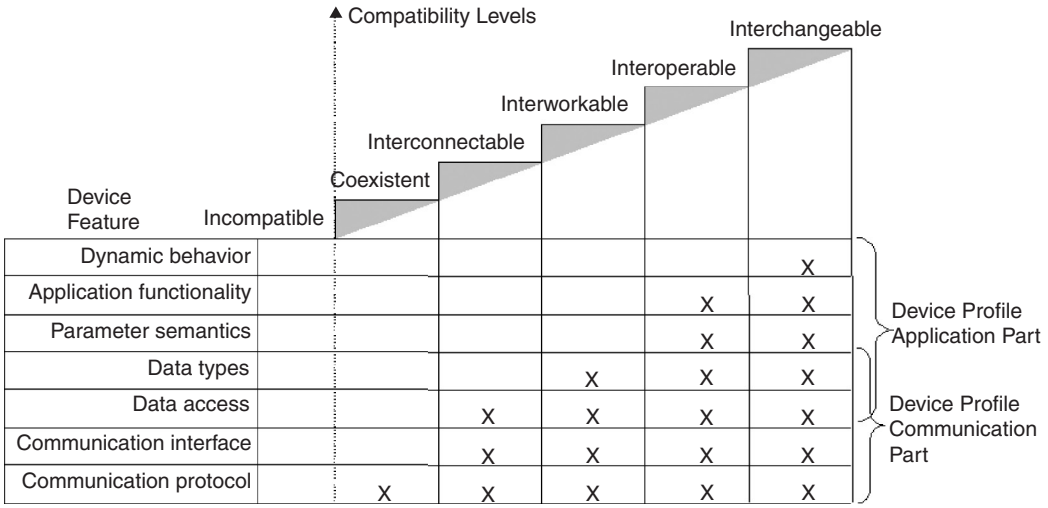

FIGURE 71.15 Levels of functional compatibility (IEC 61804, 2003).

The device features are either related to the communication system as it is specified in the standard (e.g., protocols, service interfaces, data access, data types specified in IEC 61185, and IEC 61784) or related to the device application such as data types and semantic of the parameters, application functions, and dynamic behavior of the application. Profiles usually provide a mixture of compatibility levels regarding parts of the profile and their different users. For example, the main measurement value of a device is defined very precisely regarding data type, semantic including dynamic behavior; hence, devices are interchangeable for this measurement value. The same profile may skip to specify parameters that are

© 2005 by CRC Press LLC

used in the function chain from the electrical signal at the process attachment to the measurement value. Then, devices are not fully interoperable regarding their parameterization.

The main benefit of profiles are:

- The state-of-the-art functionality of device classes are specified including their parameter semantic. This makes it possible that human device users as well as tools find the same functions and parameters with the same names and behavior in devices from different manufacturers.
- It is possible to provide communication feature lists (eg., GSD), EDDs, DTMs, and proxies for device classes with profiles.

71.5 Model for Engineering and Instrumentation

The handling of the life cycle of DCS is a complex process that can only be done using sophisticated tools (hardware, software). Here, it is very important to design a noninterrupted life cycle, that is, to achieve a information transfer from one step to another step without losing information, and to ensure a single-source principle while putting information into the system. This information is used in each step to create a special view for the user. This cannot be done using paper documents for storing and transporting information. However, the usage of database management systems is not sufficient as long as open technologies are not applied. It is necessary to use databases and communication systems that follow a commonly agreed transfer syntax and standardized information models that ensure the meaning of the information (semantics). Basically, a connection between all tools in a DCS must be created (Diedrich, Ch. and Neumann, P., 1998a).

There are several possibilities to classify the life cycle/the engineering of DCS (Alznauer, 1998). Such classification can be made using:

- the hierarchy of the control functions,
- their timing sequence, and
- their logical dependencies.

All life cycle phases that are connected to field devices should be united under the rubric "instrumentation" and described as use cases. Instrumentation is defined as follows:

> Instrumentation comprises of all activities within the life cycle of the distributed control system where handling of the field devices (logically or physically) is necessary.

Therefore, instrumentation can be considered as the intersection of the life cycle of the distributed control system and the field device. Figure 71.16 shows the instrumentation steps as a UML use case diagram. There is only one actor, who is not described in detail.

Device Model

Field devices are linked both with process, via I/O hardware/software, and with other devices via communication controllers/transmission media. The center of our attention is on the field device as the computational power is increasing rapidly as mentioned above. Thus, the applications are run more and more on these devices, and the application processes are becoming more and more distributed. We have to solve the problem of configuring and parameterization of these field devices during the operation for real-time data processing purposes, diagnosis, parameter tuning, etc. Therefore, there is a need to model such field devices (Diedrich and Neumann, 1998a). A field device can be characterized by

- internal data management (process I/O image, communication parameters, application parameters),
- process interface,
- information processing (e.g., Function Blocks),
- communication interface (Fieldbus, Ethernet-TCP/IP, etc.),
- (optional) man/machine interface (local display, buttons, switches, LEDs), and
- (optional) persistent memory and others.

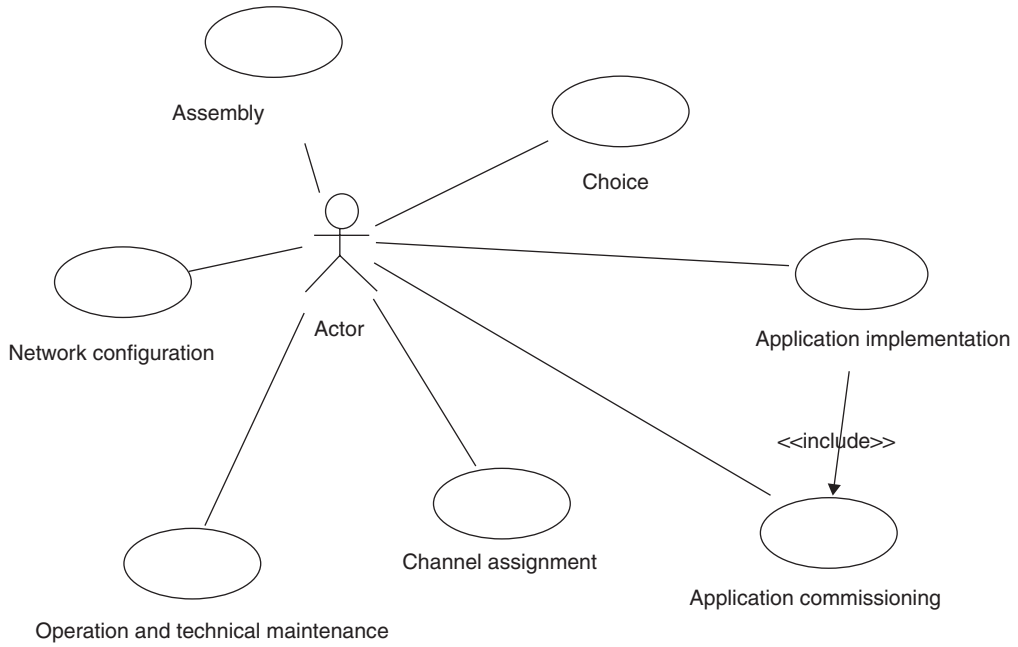

FIGURE 71.16 Use case Diagram Instrumentation (Simon, 2001).

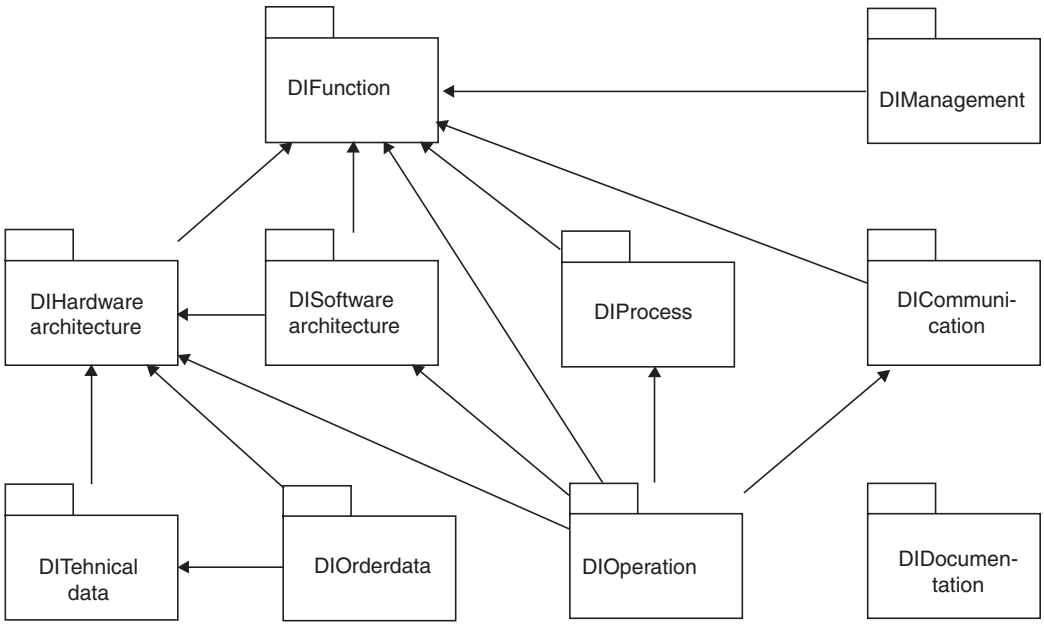

FIGURE 71.17 Device model related to the instrumentation (Simon, 2001).

We can define a device model as shown in Figure 71.17 (represented by UML packages), which supports the data exchange between instrumentation steps. This is a very abstract presentation of a device model.

The packages DIFunction, DIHardwareArchitecture, DISoftwareArchitecture, DIProcess, DICommunication, DIManagement, and DIOperation (DI stands for Device Instrumentation) are important. The packages depicted in Figure 71.17 contain the detailed model represented by UML class

© 2005 by CRC Press LLC

diagrams modeling the different views on a device. The details of the packages are beyond the scope of this chapter. However, the figures show the internal structure of elements (i.e, classes), for example., variable, function, and function block are described in detail in terms of its attributes and methods. The described relations between the classes and the attributes and methods are the basis for the development of the tools for the noninterrupted engineering and instrumentation. Figure 71.18 depicts the class diagram of the package DIFunction.

Figure 71.19 depicts the class diagram of the package DICommunication.

Figure 71.20 depicts the class diagram of the package DIOperation.

Simon, (2001) contains all other class diagrams needed for modeling the semantics of field devices as well as further explanations. This model has to be described by description languages to generate the basic information for an uninterrupted tool chain.

Description and Realization Opportunities

The device model can be implemented (realized) in several ways. It is possible to derive the FDT/DTM structure and interfaces, EDD, field device proxies, function blocks, and other technologies from this device model. For this paper, we chose EDD and an Extended Markup Language (XML)-based language. For the computable description of device parameters for automation systems components, the so-called Electronic Device Description Language (EDDL) has been specified (NOAH, 1999); (PNO, 2001b; Simon and Demartini, 1999). EDD is used to describe the configuration and operational behavior of a device and covers the following aspects (Neumann et al., 2001):

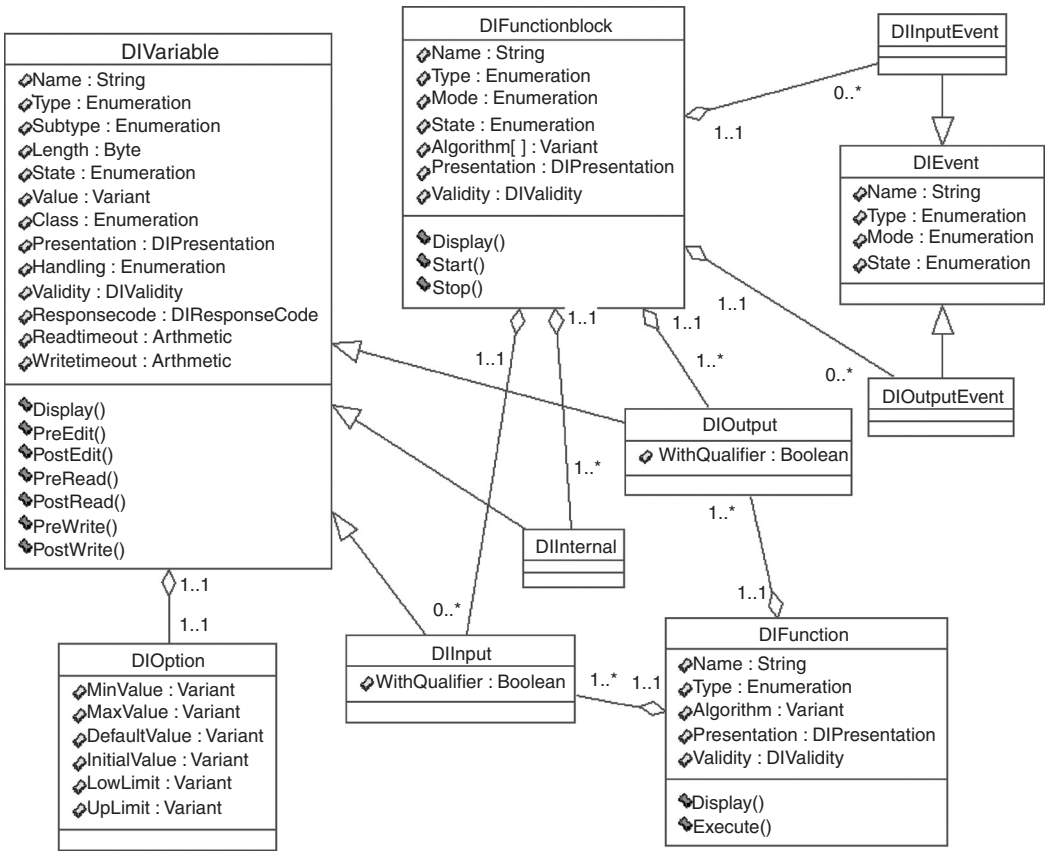

FIGURE 71.18 Package DIFunction (Simon, 2001).

© 2005 by CRC Press LLC

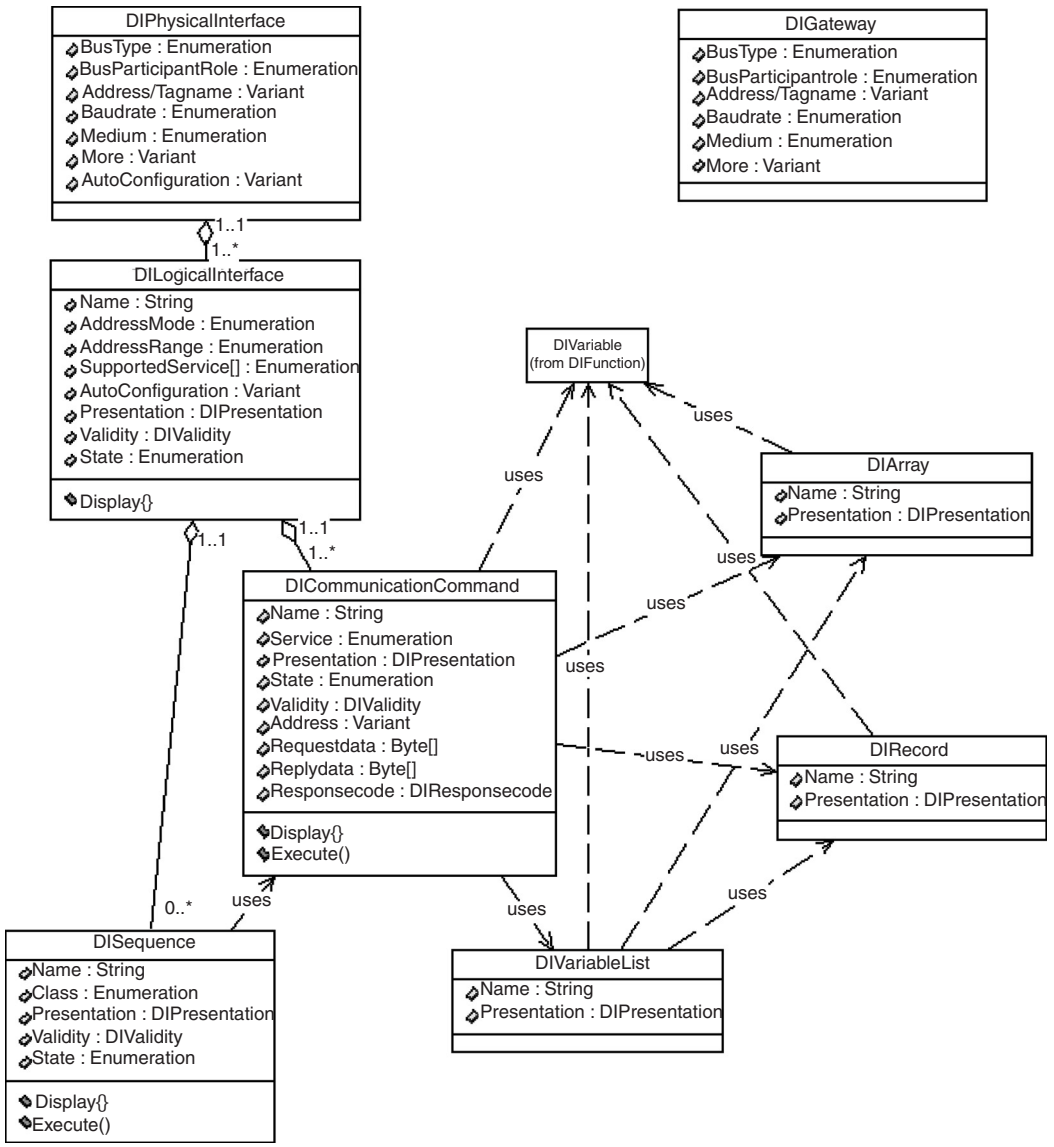

FIGURE 71.19 Package DICommunication (Simon, 2001).

- description of the device parameters, semantically defined by the field device model mentioned above,
- support of parameter dependencies,
- logical grouping of the device parameters,
- selection and execution of supported device functions, and
- description of the device parameter access method.

Overall Example Using EDDL

EDD is based on the ASCII standard. XML could be a promising approach for the future, especially because of its use in other areas. Both approaches contain definitions for the exchange of device descriptions using files. These definitions are not given here; however, a small example is used to show that different realizations can and must be based on the same solid foundation — the device model.

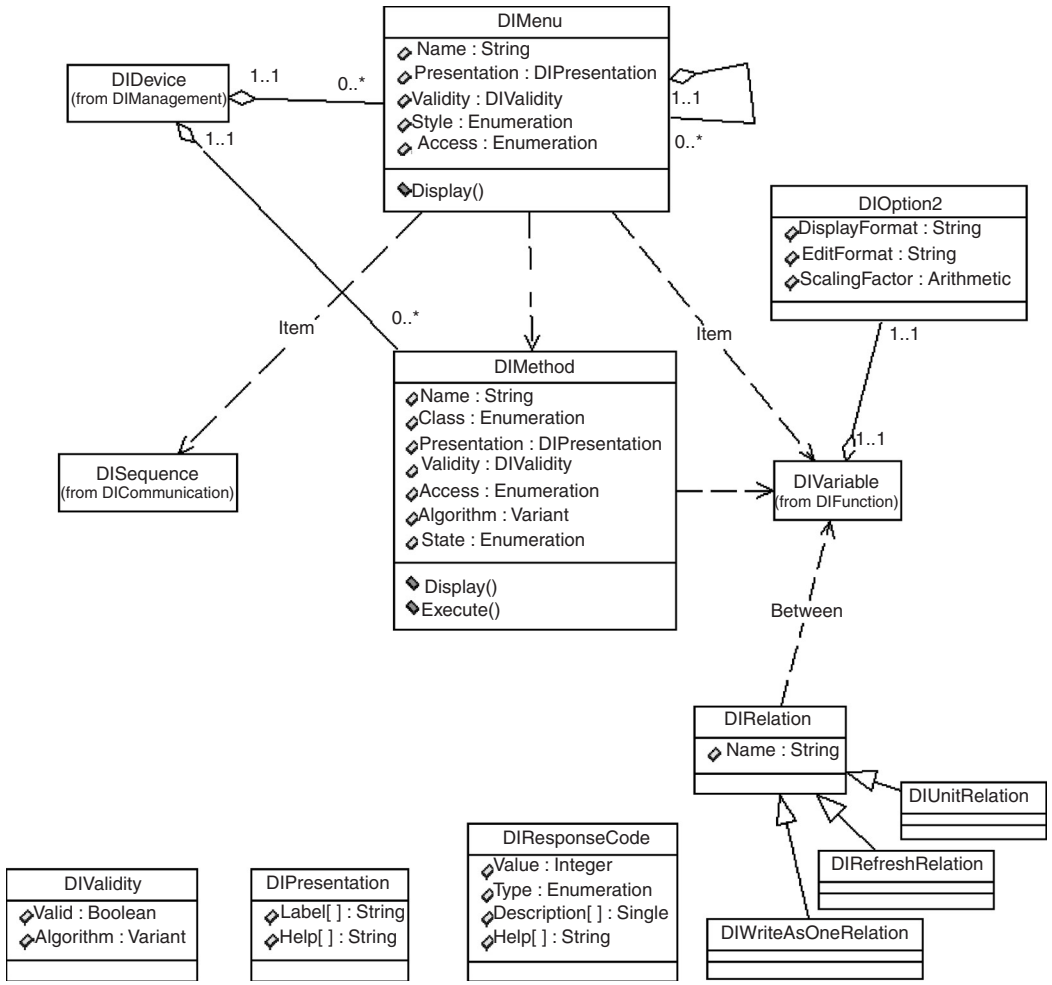

FIGURE 71.20 Package DIOperation (Simon, 2001).

The example comprises of a variable (package DIFunction), which is described by name, data type, label, and help.

The class DIVariableExample as shown in Figure 71.21 is the starting point.

The realization as an EDDL is described using language production rules shown in Figure 71.22.

A sentence created according to these rules may resemble Figure 71.23.

Using this definition of a variable, a commissioning tool provides the human–machine interface (Figure 71.24):

The XML Approach

The XML (Bray et al., 1998) expands the description language HTML with user-defined tags, data types, and structures. In addition, a clear separation between the data descriptions, the data, and their representation in a browser have been introduced. Furthermore, declaring syntactical and semantical information in a separate file (Document Type Definition, DTD) allows reusing the description structure in different contexts. This provides a number of benefits when using the same XML description file for different tasks. Different views can be implemented on top of the same data. The description can be hierarchically organized. Depending on the functions to be performed, the XML data can be filtered and

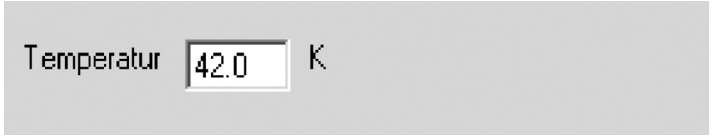

FIGURE 71.24 Human–machine interface showing a variable.

associated to software components (controls, Java beans, etc.). The selection of the necessary information and the definition of their presentation details can be performed by means of scripts and style sheets. The style sheets are a part of the development of XML (Boumphrey, 1998). In most cases, they are implemented using the extensible Style Language (XSL). The XML file, the scripts, and the different style sheets can be used to generate HTML pages, special text files, and binary files (components, applets) necessary to build the certain functions of the software tools. The distribution of the generated HTML pages and associated software components is done following the concepts used in an Internet environment. The major benefit of this solution is a unique, reusable description with an excellent consistency and reduced efforts of the description process.

© 2005 by CRC Press LLC

For the realization using the XML approach, the specification of a schema is necessary. Figure 71.25 shows part of it describing the element variable.

An instance of this schema may look as shown in Figure 71.26.

A standard web browser creates interface as in Figure 71.27.

The unit (Kelvin) is not supported by the example model. The help text is not visible, and the name of the variable is not used. Based on the data type, the value provided by the device is shown.

The presentation of the small example underlines the objectives targeted by the modeling approach. If the internal structures of different realizations are similar, that is, they follow the same field device model, then it is possible to build translators from one realization to another and to secure investments already done. Similar presentations with the same contents provide the opportunity to simplify training and education through previous recognition.

Device Descriptions are necessary for the integration of intelligent field devices in commissioning tools, maintenance tools, engineering systems, or MES/ERP systems. Device Descriptions comprise device models and presentations based on the models (e.g., ASCII files). The XML concept may help to extend the application scope of Device Description because it is becoming one of the basic technologies of the fast-growing Internet and various e-engineering activities. At present, we can observe a transition to XML-based Device Descriptions, which is characterized by the following issues:

- XML- and ASCII-based Device Description have to use the same device model to retain the semantics already developed by automation industry,
- new application functions supporting different phases of the life cycle of an automation system have to be defined using different views on the Device Description, and

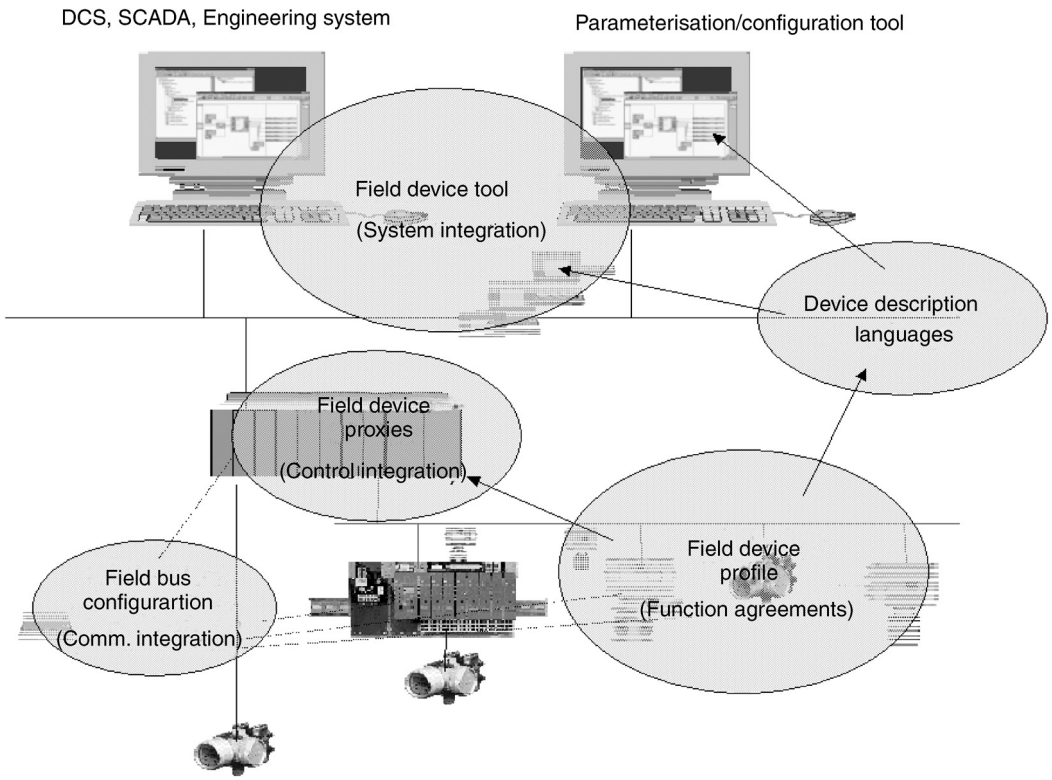

FIGURE 71.28 Integration technologies in automation systems.

- consequently, a new chain of tools for creating and using Device Descriptions has to be developed.

A necessary precondition is the international standardization in this area, which is currently done in the European standardization CENELEC and the IEC.

71.6 Summary

Field devices are integrated parts of the entire automation system. Therefore, new technologies arise to provide means for the device manufacturer, system integrators, and system suppliers to design, commissioning, operate, and maintain systems with a large variety of field device classes (Figure 71.28). These technologies are named integration/instrumentation technologies.

Field device profiles define common sets of functionality that are provided by devices of different manufacturers in an interoperable way. This is the semantic basis for the other technologies. The Bases for all integration are configured communication systems, which use feature list languages. The EDDL the field device proxies, and FDT/DTMs provide means to integrate device-specific and innovative features in the system. All these are integration/instrumentation technologies of field devices in distributed control and engineering systems.

Intelligent Sensors: Analysis and Design

72.1 Introduction

72.2 Designing an Intelligent Sensor
Analysis • The External Model • Functional Decomposition of a Service • Sensor Architectural Design

72.3 The CAP Language
Description • Illustration • Implementation

72.5 Conclusion

E. Dekneuvel
University of Nice Sophia Antipolis

72.1 Introduction

Today, thanks to the advances in numerical processing and communications, more and more functionalities are embedded into distributed components with the charge for them of providing the right access to these services. Complex systems are then seen like a collection of interacting subsystems embedding control and estimation algorithms. The inherent "modularity" concept underlying this approach is the key answer to the increasing complexity of the systems and this has led to the definition of new models and languages for the formal specification of the components [Medvodovic-00]. In this chapter, we are more particularly interested in "intelligent sensors," components associating computing and communication devices with sensing functions [Staroswiecki-96]. In order to reduce the complexity, the design of an intelligent sensor requires the necessity to provide a model of the sensor at a high level of abstraction of the implementation. The disparity of the knowledge encapsulated within the instrument renders the modeling process very sensitive to the modeling strategy adopted and to the models used. A real-life component like the intelligent instrument usually involves the cooperation of three kinds of programs [Halbwachs-93]:

- A level of data management to perform transformational tasks.
- One or more reactive kernels to compute the outputs from the logical inputs, selecting the suitable reaction (computations and output emissions) to incoming inputs.
- Some interfaces with the environment to acquire the inputs and process the outputs. This level includes interrupt management, input reading from sensors, and conversion between logical, and physical inputs/outputs. Communication with the other components of the system will also be managed at this level.

Data management covers research fields like the probability theory, the possibility theory, the measurement theory, and uncertainty management. Unlike a numeric sensor that provides an objective quantitative description of objects, a symbolic sensor provides a subjective qualitative description of objects [Benoit-2001]. This qualitative description, adapted to the sensor measurement, can be used in

© 2005 by CRC Press LLC

Knowledge-Based Systems (KBS), verifying the validity of a measurement or improving the relevance of a result [Dekneuvel-92]. The reactive part is probably the most difficult part of the design of the intelligent sensor. Like all reactive systems, the intelligent sensor must continuously react to its environment at a speed determined by this environment. This often involves the ability of exhibiting a deterministic behavior, allowing concurrency, and satisfying strict real-time requirements.

A generic intelligent sensor model has been developed to help during the specification step of the sensor functionalities [Riviere-96]. The purpose of the intelligent sensor generic model is to provide a high level of abstraction of the implementation of the sensor, focusing on the fundamental characteristics that the sensor must exhibit. For this, the generic model uses the point of view of the user to describe the services and the operating modes in which the services are available [Staroswiecki-96]. Then, by using a language to compute the formal description, we are in a position to evaluate the component, from a static and/or dynamic point of view. The availability of a language to compute the formal model allows the evaluation of the component. Once the component is validated, a prototyping step can be launched in order to obtain an operational system prototype. This prototyping step being usually expensive in time and resources, the final implementation should be made as much as possible using automatic synthesis from the high-level description to ensure implementation that are "correct by construction" [Edwards-97].

In this chapter, after reviewing the main characteristics of the generic intelligent sensor formal model, we discuss an implementation of the model provided by the CAP language, a language specifically developed for the design of intelligent sensors.

72.2 Designing an Intelligent Sensor

Analysis

As stated earlier, the diversity of the embedded functions, the flexibility, and the reuse argue for a distribution of the functionalities inside a complex system into areas of responsibility [Harel-90]. From an external point of view, an intelligent sensor will be considered as a modular unit behaving as a server. As such, it will be designed to offer its customers (the operator, others instruments, or other modules) an access to the various functionalities encapsulated inside the sensor.

Let us consider the following simple example. A navigation system has to be designed using a closed loop on a surface like a wall to control the locomotion. As can be seen in Figure 72.1, the environment of the system to be designed exhibits various entities or *actors*, such as the axes, the operator, and the obstacles. Every occurrence of a *start_moving* request, a closed loop is activated until a new request like *stop_moving* is emitted by the operator. Once the links between the system and the environment are defined, the functional specifications can be established. For this, a dataflow diagram (see Figure 72.2) can be easily defined by identifying data necessary for the navigation goals: a position measurement value useful for the closed loop to compute the values of the speed to be applied on the various axes.

Suppose we now decide to include another activity that will enable the system to follow a predefined trajectory. In this way, the operator (or a high-level decisional system) is provided with a possibility to

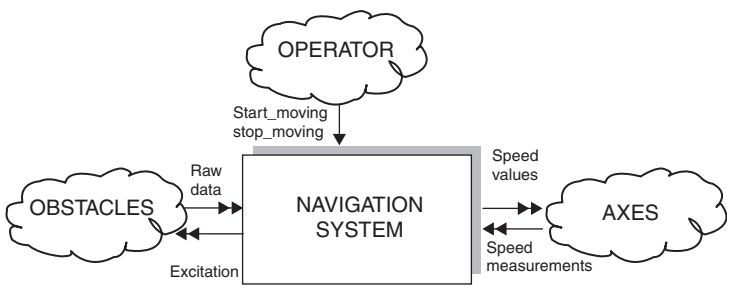

FIGURE 72.1 Context diagram of the application.

© 2005 by CRC Press LLC

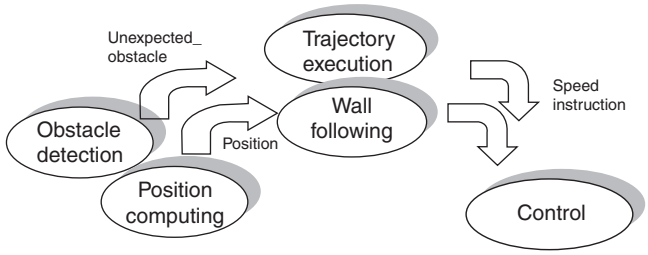

FIGURE 72.2 A global dataflow diagram.

choose between two methods according to the current context of the execution. This trajectory execution activity can be an interesting way of knowing if unexpected obstacles are encountered along this trajectory in order to stop the system before striking one of the obstacles. If both functionalities, the obstacle detection and the computing of the position, use the same physical resource (a set of ultrasonic sensors, e.g.), it is better to encapsulate them for homogeneity inside a subsystem in charge of the physical resource. The intelligent sensor module interacts with the environment through several messages. This is the interface of the module. The structure of a message (its *signature*) is generally limited at this level to a list of parameters such as the sender identity, the communication medium used, and the contents. We usually differentiate between messages for data communication and messages for control. Control messages enable the customers to communicate with the sensor in a bidirectional way, using a client–server protocol (see Figure 72.3). The customer requests the launching of an activity through the request link. The customer receives an identification number for its demand and can be informed about the status of the request (activity launched, terminated, etc.), thanks to another message of control (reply).

To be effective, the intelligent sensor interface description must be complemented by the *behavioral* description of the module. While the structural viewpoint describes the internal organization of a complex system, the behavioral viewpoint will express all the information that characterizes the module to be designed from an external viewpoint [Calvez-93]. A generic model of an intelligent instrument has been developed for this purpose, using the concept of *external services* to qualify the set of operations offered to the outer entities. Bouras [Bouras-98] gives the following definition:

Definition I: From an external point of view, a service is the result of the execution of a treatment, or a set of treatments, for which one can provide a functional interpretation.

In other words, the execution of a service typically results in the production of output values according to input values and consumed by the execution of a processing. The services are not limited to measurement aspects. The set of the services covers a large spectrum of functionalities that we can expect from intelligent sensors. Intelligent sensors must be configured, calibrated, and enabled, so that they can provide their measurements to the rest of the system. Selection of a particular sensor, an alimentation, a reference voltage and a sampling frequency are common examples of configuration services that can be used to set the value of these parameters. Processing embedded inside services can be as simple as the acquisition of a value but usually, it involves more complex treatments like signal processing (to improve, e.g., the resolution of a given value), the data processing, the validation of the measurement, and so on.

In the generic model of an intelligent sensor, a service will consequently be modeled by two sets of parameters:

External: that is, how the service communicates with other services. The services are gathered into User Operating Modes.

Internal: that is, how the external service is decomposed into internal basic processing units.

Let us examine in details both aspects successively.

© 2005 by CRC Press LLC

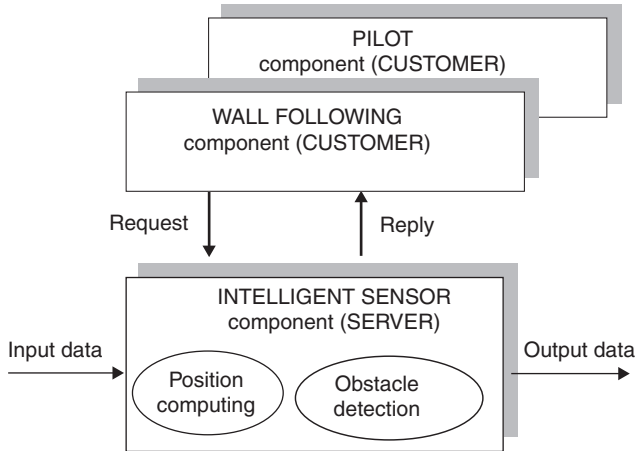

FIGURE 72.3 The intelligent sensor interface.

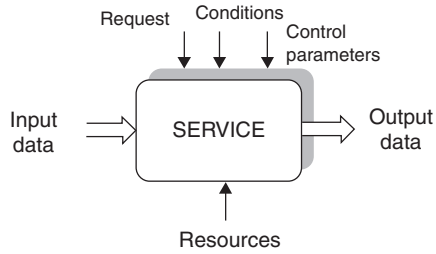

FIGURE 72.4 Graphic model for representing a service.

The External Model

Figure 72.4 depicts the external model of a service in use. A service is mainly described by the *input/output data* and is triggered by an external event. The used data and events can be organized into classes, with the description of a set of characteristics such as the format, the accuracy, the refresh period, etc., for each data class. The description of the input and output behaviors exhibits the possible interconnection between the service and those that precede or follow this particular service. This is then a data-driven representation of the service relationships equivalent to an explicit representation with the advantage of being more efficient and general (new services can be added without being obliged to physically interconnect the entire system).

Control parameters are received from the "parent" activity that requests the service. The control parameters affect the modalities of processing and the modalities of the underlying sensor that the service might encapsulate. The control parameters are usually passed in conjunction with the service activation request. For example, one can easily imagine the obstacle detection service running in a cyclic shooting modality or in a single shooting modality, depending on the nature of the activity that requests the service.

The launching of a service can be conditioned by the verification of its *activation conditions*. The distinction between a request and a condition is that the request for a service is emitted by the user, while the condition is processed by the system. These conditions are often related to the access rights or the security aspects and induce the verification of the origin of the request, the mode of transmission used, etc.

Resources include both hardware (sensor, CPU, memory, etc.) as well as software (extended Kalman filter, etc.) Input and output data can also be considered as resources with the problem of the data obsolescence.

Other properties can be added like *time and complexity measures,* which can help to select between different methods.

© 2005 by CRC Press LLC

The set of services can be easily assimilated to a set of instructions we find in a regular computer. To cope with various states of the sensor that can occur during its life (out of order, in configuration, in manual exploitation, in automatic exploitation, etc.), the different external services are organized into coherent subsets of user operating modes (USOMs). In the model, a sensor service can be requested, and thus accepted, only if the current active USOM includes this service. This prevents the request of services when they cannot be available. According to Bouras [Bouras98]:

Definition II: An external mode is a subset of the set of external services included in the intelligent instrument. An external mode includes at least one external service and each service is included in an external mode at least.

The operating modes can be easily described thanks to a labeled transition system where the label is the external event matching the request of commuting the current mode (see Figure 72.5). Moreover, in each USOM, a notion of context may exist. The context is the subset of the services that are implicitly requested as long as the system remains in the given USOM. The external services included inside an USOM are supposed to behave independently. We say that they belong to orthogonal regions of a state, sometimes termed as *constellations*. As an example, the external services inside the intelligent sensor of the navigation system could be structured into a *wall following* or an *execution trajectory* mode. The *position computation* and *the obstacle detection* services would be implicitly executed when entering the corresponding mode. If the sensor reveals a complex state space, it can be decomposed into nonoverlapping substates to reduce the complexity. For example, the *wall following* and *execution trajectory* states can belong to a more general *measuring* state, often called a macrostate or a superstate, itself belonging to an *active* macrostate, etc. Some properties that the design must satisfy and that can be checked against the functional specifications have been elaborated. They complement the formal model. For example, properties may express some axioms such as:

1. An external mode is a nonempty set of external modes.
2. Each external service belongs to one external mode, at least.
3. In an intelligent instrument, the set of disconnected vertexes in the state-transition diagram is empty, that is, there is no external disconnected mode.
4. A transition between two modes is unique in the graph.
5. Each external mode must be reachable and each external mode can be left, etc.

These properties must be verified to guarantee a safety production of the intelligent instrument. For example, the verification of the property 4 can be easily done by checking if the fan-in and fan-out degrees of every vertex of the graph are not equal to zero. An incidence matrix can help in doing this.

The external point of view of the intelligent instrument will be usually complemented with a second level of description, to capture the algorithmic flow. This level must exhibit the treatments that concur to the global functionality, which is usually called *internal services.*

Functional Decomposition of a Service

Complex operations often need to be decomposed into multiple primitive operations in order to produce the overall behavior. For example, an external measurement service can induce a very complex treatment,

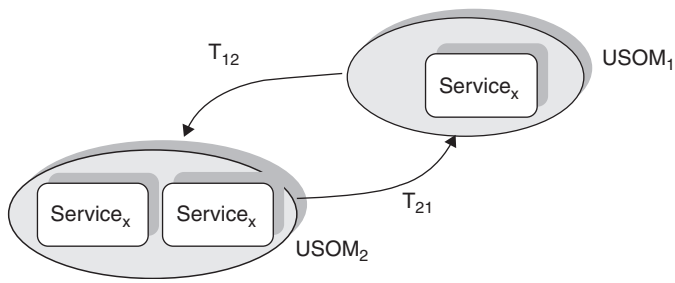

FIGURE 72.5 The Concept of USOMs.

following probably a step of initialization and, for self-terminated services, followed by a step of termination. Thus, Definition I is usually complemented with the following definition [Tailland-00]:

Definition III: An external service is the result of the execution of internal services.

From the point of view of the designer, an internal service is an elementary operation, possibly extracted from a library of components, for which no further decomposition is needed. Its I/O behavior can be easily described through an algorithm. Depending on the area of applications, such a conceptual unit can be known under various appellations such as a module, a codel [Fleury-94], etc.

The functional decomposition of a complex external service into internal services clearly has the following advantages:

- A structured programming helps the designer to describe the different steps of the treatment, without using internal state variables.
- Transitions from one step to an other explicitly define the possible interruption points of the service. Between these points, the operation is considered to be an atomic transaction. This preserves the functionality of coherency problems (loss of data and so on).
- Reuse of common units of programming: they are common to different services or are a result of previous developments. For example, an obstacle detection service and a position computing service can share several common portions of code: the signal emission, the signal acquisition, and so on. These units can be part of a library of IP modules.

As the reader can see, there is no mention at this level of the nature of the realization. Design units can be implemented on customized or software processors. The hardware units can also be freely implemented in the discrete domain using FPGA or DSP components, or by using analog components in the continuous domain. In order to reduce the complexity of the design, the definition of the executive architecture (a problem known as the *partitioning* problem) must be postponed during a detailed design step, taking into account various design constraints like economic and real-time constraints. The internal description of a complex service can be expressed using an activity diagram. The activity diagrams are well suited to show algorithmic details or procedural flow inside the service. They are often compared to flowcharts but they are more expressive. Such a diagram describes the internal operations to be achieved on the incoming flow and their temporal dependencies. Depending on the complexity of the service, the detailed refinement of an activity can be performed using several hierarchical successive levels. The processing step in the Figure 72.6 can, for example, be refined into a feature extraction step followed by a data classification step and a final decision step in sequential ordering. Elementary operations, those for which no refinement is needed, will be described by their internal behavior, usually through an algorithm. The activation of the internal services is controlled by *internal events*.

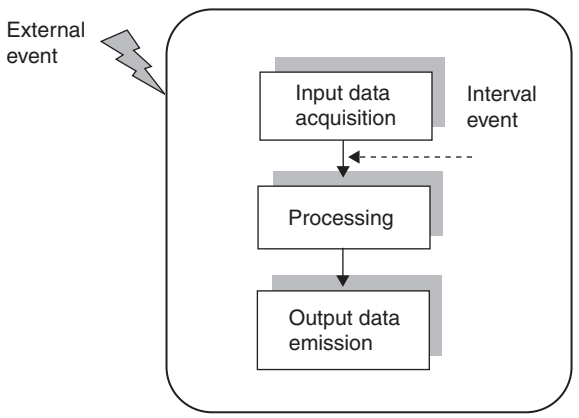

FIGURE 72.6 Example of a functional decomposition.

© 2005 by CRC Press LLC

Definition IV: An internal event in an intelligent instrument is an event that is produced and consumed by the instrument itself.

The producer gives rise to the event. Consumers can react to this event in order to start their processing. The activation of an operation will often depend on the completion of the previous operation; but more complex temporal dependencies will also frequently occur like the activation of a signal processing operation conditioned to the end of an external conversion operation. In this way, an external service can itself be in the position of a client of another component, dynamically starting an external activity to request the data necessary to the achievement of its mission. While an external event is associated with a unique external service, an internal event can be associated with several internal services, leading to an *n producer–m consumer* relationship. In this, activity diagrams differ from conventional flowcharts relative to their capacity to represent concurrency. In Figure 72.7, the execution of the internal service V is followed by the simultaneous execution of the internal services W and Y.

Expressing sequential and parallel compositions of treatments is not always sufficient. The execution of a service can be affected by the state of the resources. The concept of version has been created with the aim of providing alternative versions of treatments that will enable the service to operate under nonnominal conditions. This is a means to take the fault-tolerance problem into account. All the versions of a given service will share the same request and produce the same output; but the inputs, procedures and/or resources will differ from one version to another. For example, a measurement service uses two transducers in a *nominal* mode of the service, to compute a data value using a sophisticated data analysis method. If a defect is detected in one of the transducers, the measurement service can continue to operate using a subset of the features extracted from the input data. Of course, the quality of the result will decrease. The versions are typically ranked and classified into internal modes like the nominal mode and the degraded mode. The management of the versions of a service can be straightforward: at time *t* when the request for service is emitted, the version to be carried out will be the one with the lowest rank whose resources are all nonfaulty [Staroswiecki-99]. As for the USOMs, the description of the internal modes can be made using a state diagram.

Having reviewed the generic formal model of the intelligent sensor, let us now turn to some validation aspects of the sensor.

Sensor Architectural Design

We have seen the mathematical properties underlying the intelligent sensor generic model of computation. These properties can be efficiently used to answer questions about system behavior without carrying out expensive verification tasks. The formal validation generally uses an automata-theoretic approach, modeling

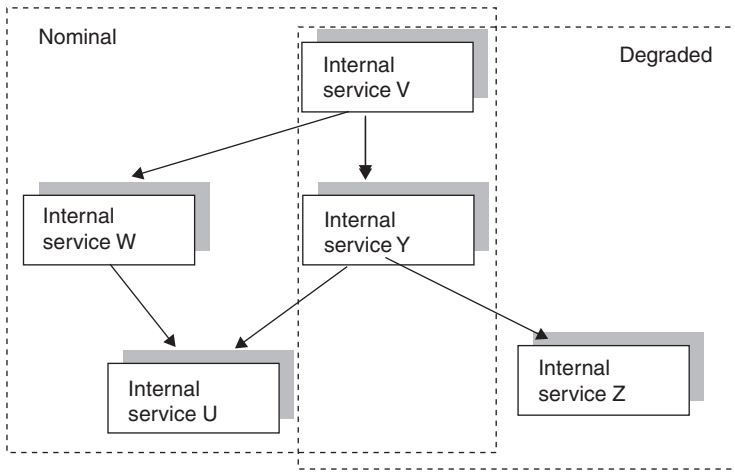

FIGURE 72.7 Version and internal mode concept.

© 2005 by CRC Press LLC

the formal description by FSM and the language of the automaton [Kurschan-94]. As stated earlier, the final implementation of the intelligent sensor should be made as much as possible, using automatic generation from the generic model, to ensure implementations that are "correct by construction." For example, the protocol defined at the high level of abstraction uses the concept of message passing, where a message is an abstraction of data and/or control information passed from one component to another. Various mechanisms (the message signature) can be envisioned at a lower level of definition, including a function call, an interruption, an event using a Real-Time Operating System (RTOS), an ADA rendezvous, or a Remote Procedure Call (RPC) in a distributed implementation. Consequently, a prototype of the sensor is also a useful means to validate the specification in the presence of the real-time inputs, with physical characteristics similar to those of the final implementation and that will be produced by the synthesis stage. Rapid prototyping aims at analyzing the performance of an implementation, to validate its capability of satisfying hard real-time constraints, etc. To do so, the key technologies are the use of software synthesis, hardware synthesis, and the synthesis of interfaces between software and hardware using programmable components.

The prototype to be generated will be highly dependent on the physical architecture selected and the physical communication links. The targeted architecture is itself strongly dependent on the cost of components and production. Consequently, as shown in Figure 72.8, there are some nontrivial aspects to be analyzed, to be in a position to produce a prototype:

- The definition of the hardware/software architecture (partitioning, mapping) and
- the sequencing of the software on each software processor (scheduling).

Figure 72.9 shows a typical hardware/software architecture for an intelligent sensor. We can observe the hybrid character of the intelligent sensors, combining analog and numerical components. Each component description can be refined to exhibit the detailed architecture of a component. In the figure, we can see an architecture organized around a microprocessor that processes the functionalities for which it is in charge. This processor can be a Digital Signal Processor, a processor that has a CPU customized for data-intensive operations such as digital filtering. Bidirectional communication is ensured through various means, using a serial link, a Controller Area Network, (CAN) an Ethernet link, etc. [Warrior-97]. Finally, memories (ROM, RAM, etc.) ensure the memorization of the information located inside the sensor. In the future, the hardware architecture will tend to combine more and more customized hardware with embedded software. The definition of a hardware/software architecture involves checking if the sensor can be schedulable, that is, if all the performance requirements can be guaranteed. A deadline (a point in the time or a delta-interval by which a system action must occur) is an example of a requirement that, when missed, constitutes an erroneous computation. Consequently, the definition of hardware/software architectures generally requires more complex modeling, by defining the external timing requirements of the messages. The requirement

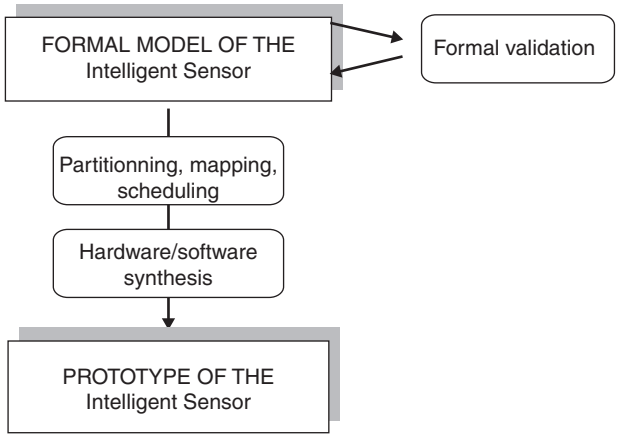

FIGURE 72.8 Design flow of an intelligent sensor.

© 2005 by CRC Press LLC

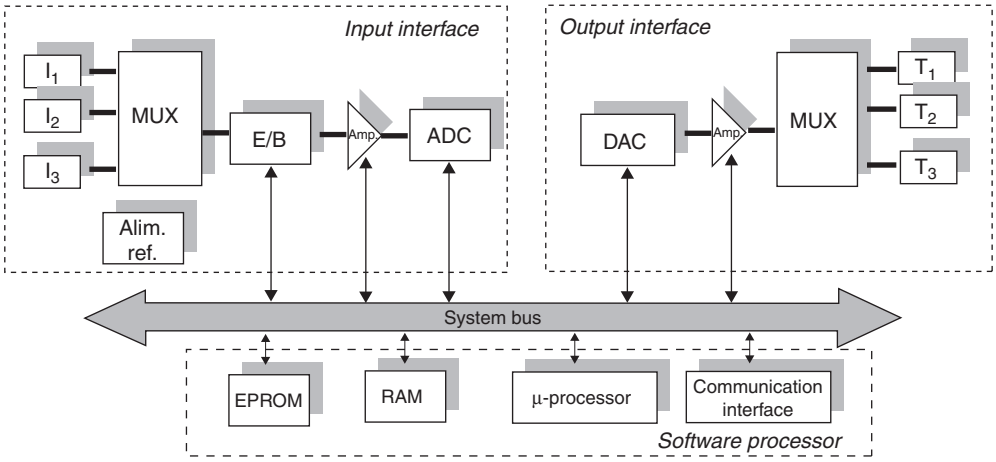

FIGURE 72.9 Typical model of an architecture for an intelligent sensor system.

of Quality of Service (QoS) of a message can be expressed using different means. For example, the response timing can be defined in terms of timeliness requirements (typically, deadlines) [Douglas-99].

Assigning an execution order to concurrent modules, and finding a sequence of instructions implementing a functional module are the primary challenges in software organization. These can be nontrivial issues to deal with, particularly when one must consider the performance, as well as the functional requirements, of the system. The software implementation can be facilitated by the use of real-time languages and their underlying executive kernel. Such languages provide a style of programming enabling the manipulation of events and/or state changes with constructions expressing the behavior through the parallelism, the synchronization, etc. Selecting a language to compute the model is not straightforward with basically several possibilities: developing a dedicated language or the use of an existing language, the use of a graphical or a textual input form, etc. The domain of applicability of a language must also be carefully studied with basically two approaches. The *synchronous* approach states that time is a sequence of instants between which nothing interesting occurs [Balarin-97]. In each instant, some events occur in the environment and a reaction is computed instantly by the modeled design. This means that computation and internal communication take no time. This hypothesis is very convenient, allowing modeling of the complete system as a single Finite State Machine with a totally predicable behavior. ESTEREL [Berry-92], [Esterel-www] and its graphical expression form, the SYNCCHARTS [Andre-96, Andre-01], are representatives of synchronous imperative programming languages. Like all language specialized to control-dominated systems programming, data manipulation cannot be done very naturally. In the asynchronous approach like in ELECTRE [Cassez-95], events are observed and processed immediately. This approach enhances the expression power of the language. Moreover, the design can be more efficiently implemented in heterogeneous hardware/software architectures. On the other hand, timing constraints are difficult to check.

72.3 The CAP Language

Description

The generic intelligent sensor model gave rise to a new language that can be akin to the category of asynchronous languages, the CAP language [Benoit-00]. Its ability of providing a rapid prototype of the intelligent sensor model on common microcontrollers available on the market has been one of the main reasons for developing this language. The developers have consequently limited the implementation to monoprocessors and to a sequential operation.

The CAP language is an incomplete language in the sense that it specifies only the interaction between computational modules (internal services), and not the computation performed by the modules. An

© 2005 by CRC Press LLC

interface with a host language specifies the behavioral contents of such units through C instructions. Like every conventional language, the grammar can be described using a backus naur form (BNF), also known as a metalanguage. Figure 72.10 shows a formal grammar defined by Bouras [Bouras-98]. Tailland [Tailland-00] complemented the language with the possibility of declaring internal services. As can be seen, the two parts of the model are normally successively expressed. The interface of the instrument follows the metavariable <instrument> with:

- A number referencing the instrument as a node in the network.
- Variables that can be exported or updated on the network.
- Communication links imported or exported to implement the command protocol.

The expression of the graph of the external modes is achieved through the set of vertices and the set of transitions. Each transition is then described by declaring the input vertex, the output vertex, and the link

EXTERNAL MODEL

<instrument> ::= <number_of_the_instrument>

of communication source of the event of transition. Variables of the imported or exported lists are defined according to a type in C. Finally, the expression of a list of external modes in the definition of a service can be noted. These modes are the only ones in which the service can be launched. The description of the internal model is close to the external one and can be easily understood. As shown in Figure 72.11, the principle of the operation of the compiler is relatively straightforward: after the lexical and syntactical analyses, a set of lists reflecting the formal model is produced by the code generator. After being generated, the code is compiled and linked with the user-defined libraries and the processor-dependent startup code. The generated data structures are split into two sets of list: a first set of lists contains the names of the objects and is subdivided into eight lists: external modes, internal modes, external services, internal services, variables, export links, import links, and internal events. A second set of lists contains the detailed description of each transition. The conformity of the description to the formal model will be analyzed using these lists. They also contribute to providing a level of abstraction between the software synthesizer and the real machine.

Let us illustrate these principles in an intelligent instrument designed to process Ultrasonic sounds in order to produce a distance measurement value.

Illustration

To illustrate the approach, let us consider the following example [Tailland-00]: a measurement system is composed of one ultrasonic transmitter able to emit a signal toward a target in order to compute the distance between this target and the sensor with the help of two receivers. Figure 72.12 shows the basic configuration of the measurement system.

The intelligent instrument delivers the two measurements of distance d_1 and d_2 , each of them with a validation degree d_{v1} and $d_{v2,}$ respectively. As shown in Figure 72.13, the basic principle of the measurement is the following: the ultrasonic emitter sends a sinusoidal waveform linearly modulated in frequency to the $\Delta F = (f_{\max} - f_{\min})$ interval with a rate of variation of the frequency : $\alpha = \Delta F/T_r$. Then, the instantaneous frequency $F_{received}$ undergoes an offset relatively to the frequency $F_{emitted}$ of $\Delta f = | F_{emitted} - F_{reçeived} |$. Mauris [Mauris93] has shown that the distance d can be determined by measuring the offset only inside the interval $[t_0, T_r]$, where its value is f_a. For this, the measurement is inhibited during the time t_a where the offset of the frequency has the value f_b.

The state space of the sensor is decomposed into two USOMs: the configuration mode (which is the default USOM) and the measurement mode (see Figure 72.14). The transition between each mode is triggered on the *cantcp_in* event.

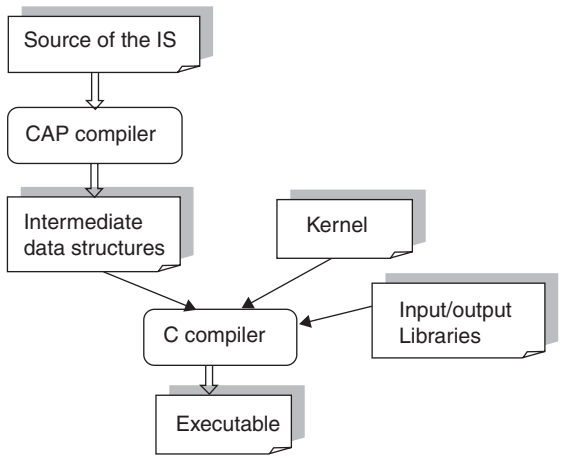

FIGURE 72.11 The CAP design flow.

© 2005 by CRC Press LLC

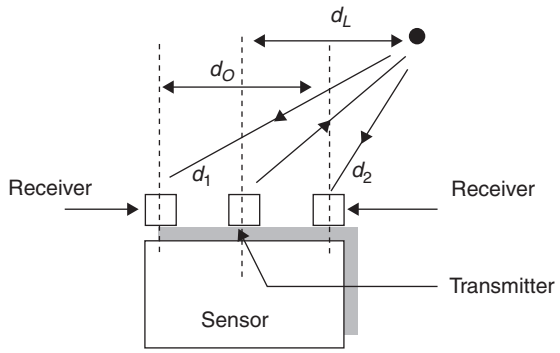

FIGURE 72.12 Configuration of the measurement system.

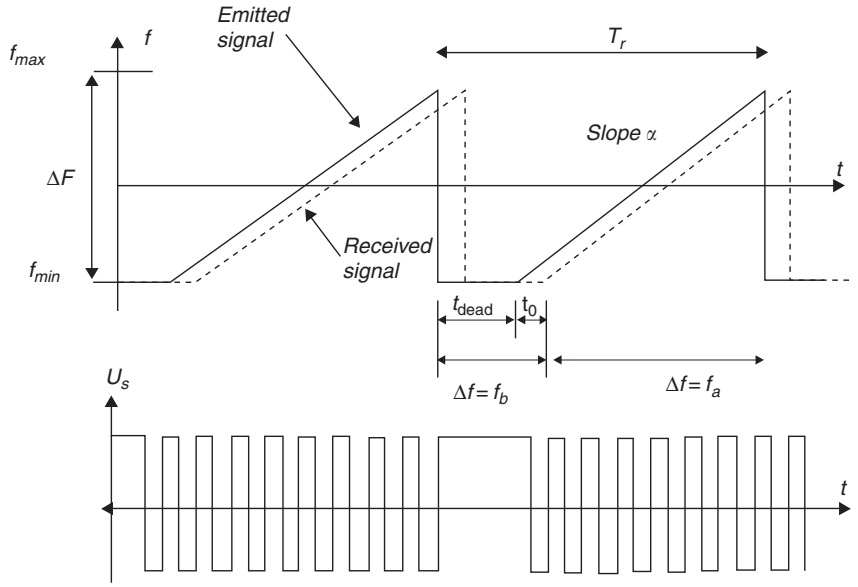

FIGURE 72.13 Principle for the measurement of f_a.

A number of internal services have been specifically developed for this application:

- Initialization and configuration services enable the modification of the parameter values used for the computation of d, duration of the slope T_r, slope p, time t_{dead}, voltage u_{min}. They take into account particular conditions of measurements (nature of the obstacle, environment, etc.).
- Internal services such as those depicted in Figure 72.15 contribute to the measurement elaboration; for example, the internal service for the *slope generation* has the responsibility of sending the signal in direction of the obstacle; *suppression of aberrant measurements* filters and keeps the impulsions close to the median f_{amoy} (average of the measured frequencies on T_r), while the others are discarded. The DPT service computes the pseudotriangular distribution of the possibilities.

Internal calculations are not very complex. For example, the *distance computation* service computes the distance on every f_a input. By doing this, there are N_{exp} measurements of d carried out during the interval T_r, using the following formula:

$$D = \frac{f_a}{2} \frac{T_r - t_{dead}}{\Delta F} * V \tag{72.1}$$

© 2005 by CRC Press LLC

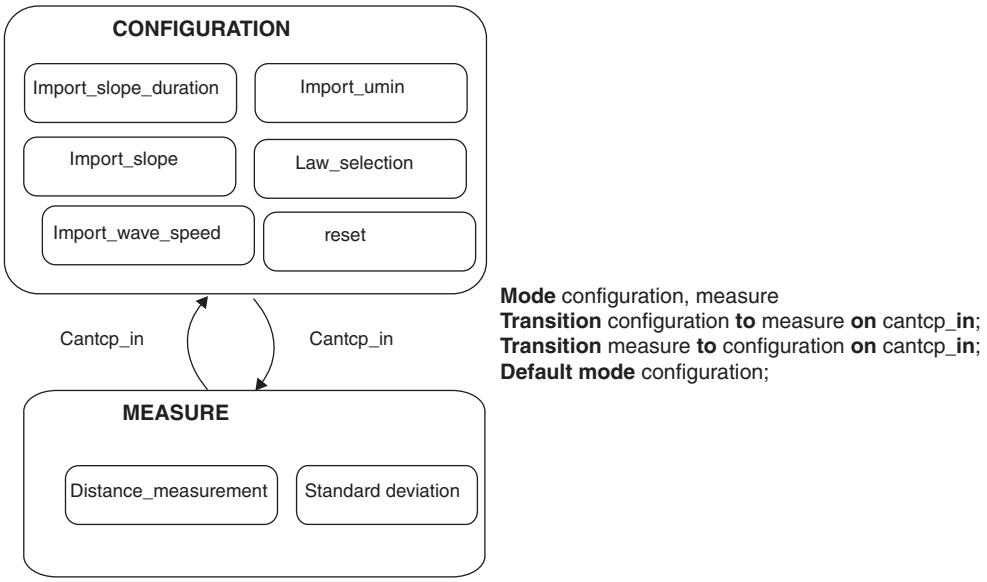

FIGURE 72.14 Graph of the USOMS and the corresponding CAP declarations.

The internal service named *validity estimation* computes a value in the [0,1] interval according to the following rule:

$$D_v = \frac{N_{exp}}{N_{th}} \tag{72.2}$$

where N_{th} is the theoretical number of the periods of f_a that are supposed to be observed by the instrument.

As shown, the declaration of the *distance_measurement* external service includes the request (on *cantcp_in)* and the USOM (in *measure)* where it is available. The measurement functionality can be carried out according to four internal modes: *nominal*, *degraded1, degraded2,* and *critical*. For example, when the validity of the measurement d1 (see Equation [72.2]) decreases below a given threshold in the *nominal* mode, the instrument can automatically switch in the *degraded1* mode.

Part of the synthesized code (Figure 72.16) presents an excerpt of the synthesized code. As stated earlier, these symbolic data structures will be used by the verification tool to verify the properties of the formal model. The data structures (array of services, etc.) will be typically stored inside a volatile memory (RAM or SRAM) of the hardware architecture, while the automaton, not reachable to the user, will be set in a long-term memory (EPROM, FLASH, etc.). Depending on the operating mode, development, or exploitation mode, the user program can be stored inside the volatile memory or set in long-term memory.

Implementation

The execution of the various services is handled by an automaton that has the responsibility to interpret the formal model. As shown in Figure 72.17, the execution machine runs a cyclic program that processes the inputs, updating a FIFO storing the pending events. Then, depending on the nature of the event, a transition can be fired or a call to a procedure is achieved. Permanent functions are then executed. The loop ends with the emission of the output messages. For each step, the detailed behavior is as follows:

1. Reading a message on each communication link: if the intelligent sensor is concerned by the message, it will be processed according to its type:
   (a) In case of a *data* message, the corresponding variable is updated and the associated event is triggered.

© 2005 by CRC Press LLC

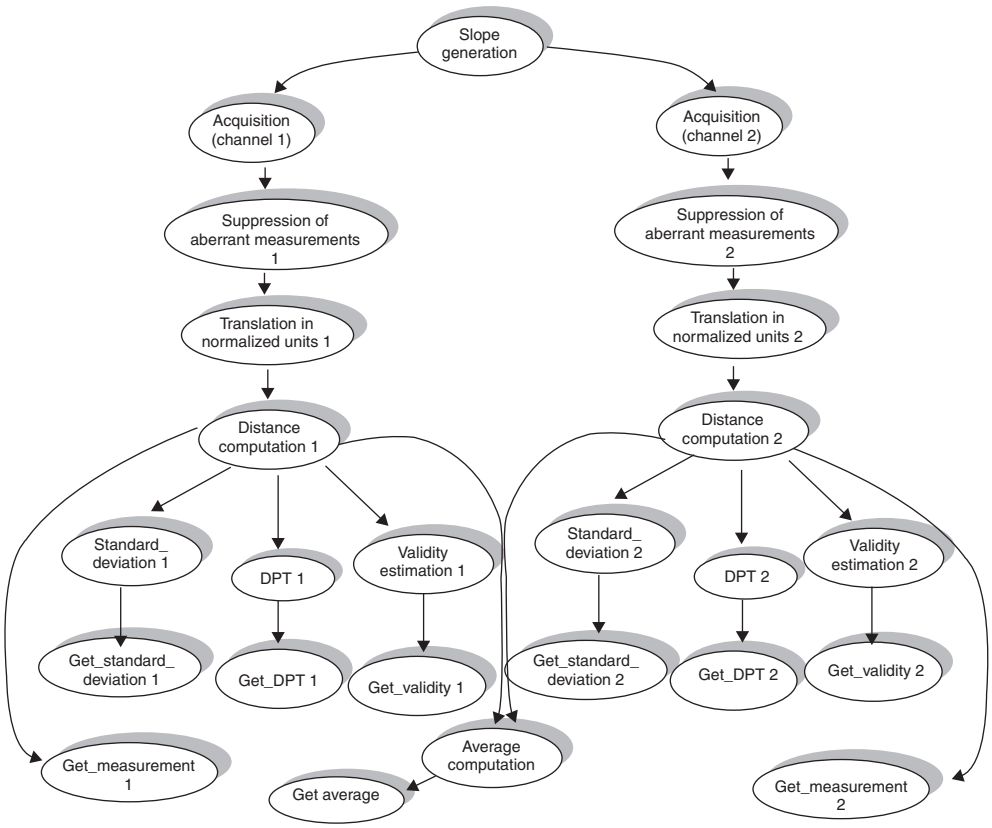

FIGURE 72.15 Functional decomposition of the measurement functionality.

(b) In case of an *event* message, the corresponding event is inserted inside the FIFO event for an ulterior processing
(c) In case of a *query* message, the current mode is exported on output links.
(d) In case of a *variable* message, the variable is linked to import an external variable.

2. Event queue processing: three situations can arise and be analyzed in the following order:
   (a) The event is a request of a change of the external mode. Provided this change is authorized, the internal variable is updated and the new mode is exported on output links.
   (b) The same occurs for an event corresponding to a request of a change of the internal mode.
   (c) The event is an execution request of an external service. Provided the service(s) is (are) enabled in the current mode, these services are executed using the procedural entry point.
   (d) The same occurs for an event corresponding to a request for executing an internal service. If defined, an event noticing the end of execution is inserted into the FIFO event.
3. Execution of the EVER services: these are services that run permanently.
4. Diffusion of the messages on communication links (exported variables, change of mode, etc.).

We have to notice the reduced portability of the application, because of the tight link that exists between the application and the hardware. Open software platforms (EmbeddedJava, JavaCard, etc.

© 2005 by CRC Press LLC

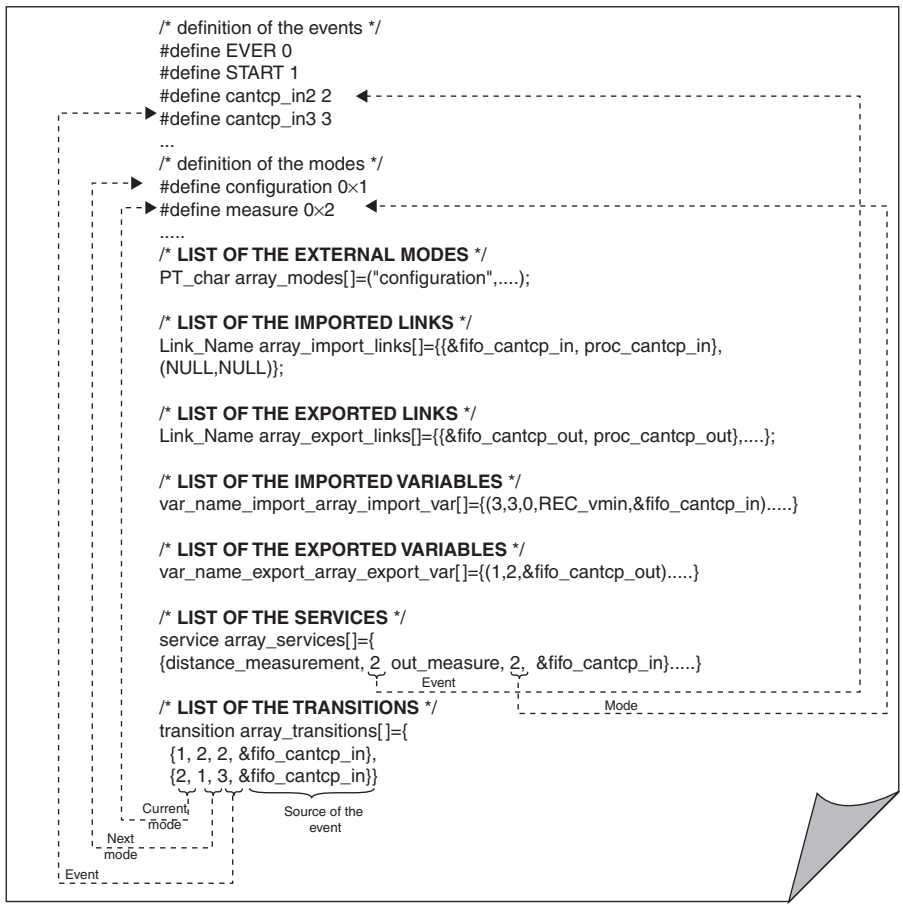

FIGURE 72.16 Part of the synthesized code.

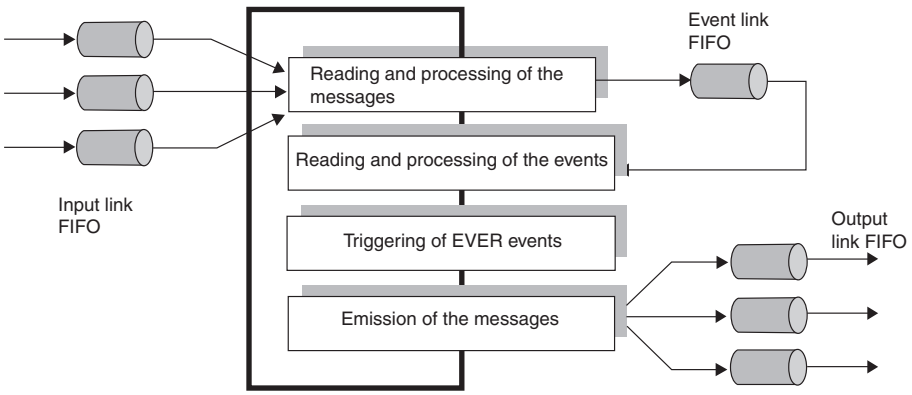

FIGURE 72.17 Principle of operation of the automaton.

[Sun-www]) can be considered as attractive solutions to this problem, by interpreting the applications via a virtual machine. But the designer has to be aware of the substantial performance penalty that could be paid by adopting this solution.

72.5 Conclusion

In this document, a generic model for the design of intelligent instruments has been discussed. In the formal model of the sensor, the specification of the external services is given from a user's point of view of the functionalities available in the sensor. The external model uses the concept of the USOMs to preserve the activation of services that are not available during the current external mode. Internal services define the basic units that will be assembled to describe the complex behavior of an external service, taking into account various temporal dependencies. Like the external services, the internal services can be gathered inside internal modes. Internal modes define the internal states of a service according to its possibilities of operating under various contextual situations. Some of the basic principles underlying the implementation of the model on hardware architectures have also been given. The advantages of the numeric instrumentation for the processing relative to the conventional instrumentation are well established today. We have finally discussed an implementation that can be generated automatically through the use of a language like CAP. The automatic generation of the implementation is conditioned to the formal verification of the properties underlying the generic model.

As stated earlier, the intelligent sensors to come will be composed of more complex and heterogeneous components. This trend will change the industrial landscape, making the trade and assembly of Intellectual Properties (IPs) embodied in layouts, RTL designs, and software programs indispensable [Balarin-97]. This aspect, not specific to the design of the intelligent sensors, is a considerable challenge. For example, hardware/software cosimulation is often performed with separated simulation models [Rowson-94]. This makes trade-off evaluation difficult because the models must be recompiled whenever a change in the architecture mapping is made. The *cofluent* system level design tool [CoFluent-www] introduces an intermediate level of abstraction, the functional level, between the specification and the architectural model of the sensor [Calvez-96]. As shown in Figure 72.18, this level defines the logical architecture of the system in terms of functional components (simply called *functions*) and the relations between them (*ports, shared variables, events* depending on the kind of relationship). Like in the Vulcan system [Gupta-94], the use of a control/data flow graph for the behavioral model facilitates the partitioning at the operation level. This environment has been used successfully for the design of an intelligent sensor for pattern recognition [Dekneuvel-01]. The functional model provides an environment for behavioral and performance analysis in a technology- and language-independent manner, which allows implementation of the same functionality on diverse physical architectures [Calvez-95]. Automatic synthesis can be achieved on hardware (VHDL descriptions) or RTOS primitives (VxWorks). A systemC simulation engine and code generator are also available for system-on-chip (SoC).

Robot Vision

Ray Jarvis
Intelligent Robotics Research Centre
Monash University

Seeing, in sighted humans, accounts for in excess of 85% of all sensory input data, the analysis of which supports our physical interactions with our everyday environment and our safe navigation through it as well as our appreciation of its richness as a quality-of-life component.

Not surprisingly, therefore, robot vision in its full realization would expand the scope of applicability of robotic systems, both manipulators and mobile vehicles, from the relative structure of classical industrial environments to the unstructuredness of natural and human-centered environments to embrace applications in mining, space exploration, undersea, service industries, healthcare, warehousing, mineral exploration, search and rescue, fire fighting, agriculture, forestry, recreation, catering, and domestic operations. Considerable research and development effort has gone into the theoretical as well as practical issues of robot vision (as a component of artificial intelligence). This effort continues today with the powerful support of rapidly improving and affordable sensor and computational technologies. This support promises an explosion of commercially viable vision-based robotic systems within the next decade.

Computer vision is usually distinguished from computer image processing by the explicit consideration of the three-dimensionality of the world of objects in the former case, even when the extraction of the depth dimension may be by the analysis of one or more two-dimensional images. However, this distinction is not always acknowledged and many image-processing procedures are claimed to be exercises in computer vision analysis.

Digital images are essentially two-dimensional arrays of values, each representing intensity. The dimensionality of the array specifies the spatial resolution of the image, while the number of data bits per cell specifies the intensity resolution. Each cell is referred to as a pixel (picture element). Three arrays of cells, one representing the red intensity, the second green, and the third blue, can collectively be regarded as a digital color image. Other color coding schemes such as hue, saturation, and intensity are also used. A typical digital color image may consist of three 512×512 element arrays with 8 bits per cell per array representing red, green, and blue values, respectively. The whole data structure is represented as 512×512×3 bytes (8 bits) of information. A color pixel is the set of three values at a particular spatial location in the arrays.

When range data are used or derived with respect to a single viewpoint, it is usually also represented in a rectangular array of cells, each being referred to as a rangel (range element). This type of representation is not strictly three-dimensional, as it represents distances from the viewpoint to surfaces visible from that location. The surfaces of objects not visible because of self-obscuration or obstruction by other objects cannot be ranged to from that viewpoint and are thus not represented in the range array. Since, for a typical 3D scene, approximately half the surface points cannot be ranged to from a single specific viewpoint, this representation is often referred to as 2½D.

A full 3D representation might take the form of a three-dimensional volumetric array with solid or surface occupancy indicated. Such a representation is composed of volume elements (voxels). Simple occupancy can be supplemented by values indicating color components or surface normal directionality

© 2005 by CRC Press LLC

or other property values of interest. A full 3D volumetric representation including surface properties such as color, normal directionality, and perhaps other attributes can take up a considerable number of memory locations in a computer. For example, a 512×5212×512 volume array with eight 8 bit property elements per cell would occupy 2^{30} bytes (≈8 billion bits of memory).

Robot vision can be interpreted as that part of computer vision that is ultimately intended to be used to guide the actions of robots. The quality of a robot vision system is judged in terms of it providing timely, reliable, and accurate information, extracted from visual or range data (or both), which can be used to direct correct action of a robot in carrying out a specified task and the extent to which its structure permits its use over a wider range of possible tasks. A superior system should also be affordable, physically robust, safe, and energy efficient.

While vision strictly refers to 3D perception derived from images, the analysis of directly acquired range data is usually accepted as part of this domain.

In the context of intelligent robotics (a cooperative interplay of perception, reasoning, and action; Figure 73.1), robot vision can be thought of as a powerful perceptual component. Since a robotic task can only be completed by also including reasoning (perhaps path planning and event sequencing) and action (perhaps following a planned path, avoiding obstacles, gripping an object, etc.), it is best to see robot vision as part of a whole system. In this way, its quality can be judged in relation to its contribution to the whole task.

Two robotic task scenarios are used to illustrate the functions of useful vision systems. While these examples are somewhat simplistic and traditional, they place vision unambiguously within a robot perception/reasoning/action loop to which humans can easily relate, thus improving the tutorial value of thus exercise.

The first example is a robot/camera "hand–eye" coordination task in which a robotic manipulator is used to pick up identified objects from a pile and sort them into groups of like objects (Figure 73.2).

A color camera and a rangefinder collect color intensity and range data in registered two-dimensional arrays, which collectively result in a 2½D representation of the 3D scene of the pile of objects to be dealt with. A database describing the types of objects likely to be encountered in terms of structure, geometry, and surface appearance is available.

Since for reasonably high-resolution color intensity/range, large amounts of data have to be processed, the usual first task of the vision system is to segment the scene into its major components without referring to the database of object descriptions. Some type of "semantic-free" clustering procedure can be used to group pixels/ranges together in clumps, which are homogeneous or continuous in some way. These initial clumps can be further refined, perhaps with some reference to broad distinguishing characteristics derived from the database. Once individual objects are more or less isolated, a search for a match with an object represented in the database can take place for each object in the scene. This is essentially a 2½D to 3D matching process and can be very difficult to carry out reliably, particularly for free-form objects. Some objects may be oriented so that they cannot be unambiguously matched, even if they are not severely obscured by other objects. Severely obscured objects cannot be identified, in general, until the objects obscuring them are removed. At the end of the first part of this process, a number of objects, mostly among those on top of the pile will be identified and their poses will be (placement geometry) determined. Even objects not yet identified have to be taken account of in a volumetric occupancy sense when determining possible grip sites with respect to identified objects and planning approach, grip, and withdraw trajectory components for the manipulator, all of which should preferably be collision-free and optimal in some sense (e.g., minimum path length, time, or energy).

Each identified object that can be reached for and withdrawn from the pile is sorted into groups by the robot once it is safely removed from the pile. This cycle of perception, reasoning (planning), and action is repeated until the entire pile has been sorted.

An interesting variation of the above cycle is to discover grip sites for object removal and to carry out trajectory planning and actuation prior to identifying the object. In this way, the object might be more easily identified once it is physically separated from the pole, as not only has segmentation been carried out physically, but the robot can present the object in various orientations to the vision system so that

© 2005 by CRC Press LLC

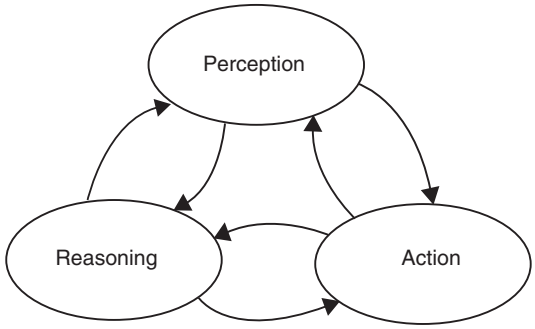

FIGURE 73.1 Intelligent robotics.

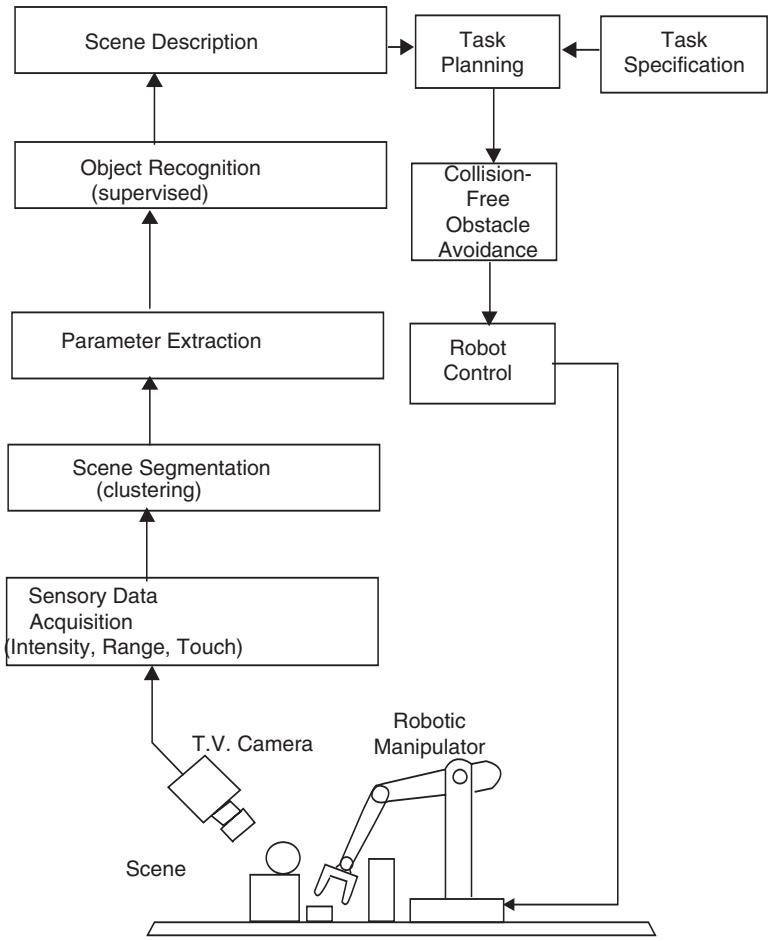

FIGURE 73.2 Hand/eye/touch coordination cycle.

unambiguous identification can be carried out before completing the sorting action. If all objects must be handled (as is the case for this example), this is a good approach; however, in a situation where only a particular object in a pile must be retrieved, this posthandling recognition approach will be cumbersome.

The type of vision system described above (both the pre- and posthandling recognition modes) is referred to as a model-reference system since an explicit database describing the various objects to be

© 2005 by CRC Press LLC

encountered is used for identifying scene objects by using matching search procedures. Most industrial robot vision systems are of this type since model parameters can usually be expected to be available from computer-aided design (CAD) data.

The second example concerns an autonomous mobile robot (Figure 73.3) equipped with beacon localization and range sensors, which is required to navigate through an initially unknown and slowly time-varying obstacle-strewn space from a specified start position to a specified goal position via a quasiminimal length collision-free path. Since a complete map of the environment is not initially available and any partial map generated incrementally using sensor data is subject to change, absolute global optimality of the path actually taken cannot be guaranteed; all that can be hoped is that what is known at any particular moment is taken fully into consideration at each stage of forward path planning.

At the start, the position and orientation of the robot are known; at any stage of its path toward its goal, position and orientation data (localization) can be determined using a bar code localizer, which determines the identity and angular placement of bar codes at known positions around the room (beacons).

The on-board rangefinder gathers position data from all surfaces visible all around the robot up to some maximum range measurable by the rangefinder. Obstacle identification is not required for the avoidance strategy. The floor projection of this range data is expanded in all directions by a distance equal to the radius of the robot (assumed circularly symmetric) plus a small collision tolerance amount that must accommodate the maximum range error. A high-resolution floor grid map of occupied and free space is built using the data available so far. Space whose occupancy status has not yet been determined is presumed empty until shown otherwise (the optimistic strategy).

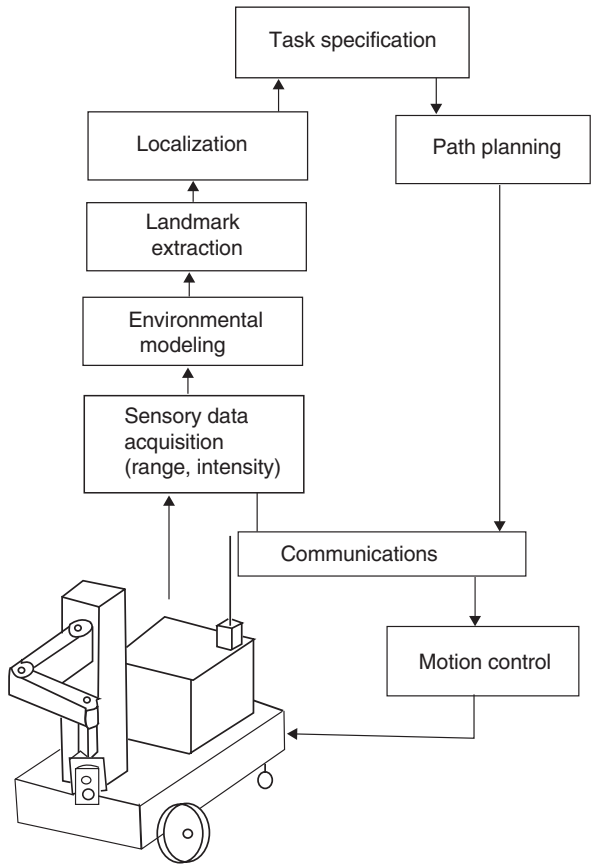

FIGURE 73.3 Sensory data driven mobile robot navigation.

© 2005 by CRC Press LLC

A minimal length collision-free path is determined and the robot follows this path for a specified distance. Localization data collected during the move can be used to adjust the actual path to closely follow the planned path.

Range collection and incremental environmental modeling followed by path planning and partial actuation continues until the goal is reached. Change of occupancy status due to movement of obstacles must also be accommodated in the incremental map-building process.

A more ambitious task would be to carry out the navigation task without the use of beacon localization, relying only on natural landmarks for localization. One way of doing this is to match range data against the map so far derived without actually identifying particular landmarks. The continuity of the robot's movement can simplify this process by constraining the search space of the match task. A more elegant approach would be to identify appropriate landmarks and to recognize these same landmarks as the robot moves; this clearly requires more of the vision system. Note that the recognition of a landmark for localization purposes does not mean that the landmark must be recognized in the model reference sense as was the situation for the first example.

From the above two examples, it is easy to see the important role that vision can play in supporting robotic hand/eye coordination and autonomous robot navigation. In both cases, it was the 3D nature of the problem domain that made vision a particularly appropriate perceptive mechanism to apply, especially since noncontact analysis of the scenes involved was an important aspect of the tasks involved. Note also that vision may be applied both for volumetric modeling as well as shape recognition or both according to what is needed to solve the problem.

While instrumenting a system to collect or derive range data is only one part of robot vision, clearly the quality of such range data in terms of spatial density, accuracy, reliability, and timeliness is critical to the whole analysis process if it is to lead to robust plans for robots to follow. It is of interest to consider the variety of ways by which range might be extracted from a 3D scene.

Humans use a wide variety of depth queues, usually in selective combinations, to disambiguate many competing hypotheses about how images acquired by the retinas of two eyes might be explained in terms of 3D structures in the scene. Human depth cues include texture gradient, out-of-focus blur, aerial perspective, stereo disparity, binocular vergence, size constancy, and relative obscurance. Many robot vision ranging schemes have been inspired by human (and other animals) range extraction mechanisms. Some of these are better suited to robot vision than others and combinations can often be used to produce better results than can be obtained by using one approach alone. However, there are many ranging systems that are based on visual mechanisms not enjoyed by humans; these are also worth considering.

Three dichotomies define eight range-finding domains, not all of which are populated by feasible realizations. These dichotomies are (see Figure 73.4):

1. active or passive,
2. image-based or direct, and
3. single (monocular) or multiple viewpoint.

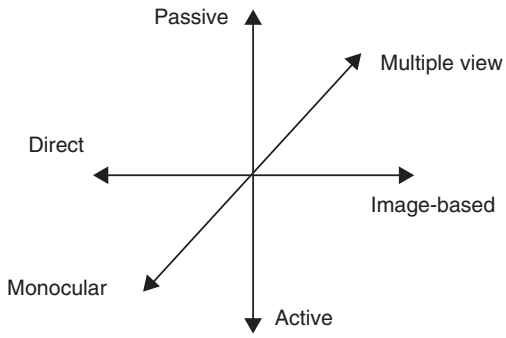

FIGURE 73.4 Range finder classification dichotomes.

© 2005 by CRC Press LLC

A passive method uses only ambient lighting sources, while an active system probes the scene with an energy beam or a structured light pattern. Image-based methods analyze pixel arrays to derive range, while direct methods measure time-of-flight of known velocity light or ultrasonic energy beams to calculate range. Single-viewpoint methods use one fixed camera or one time-of-flight system while multiple-viewpoint methods are essentially based on triangulation. The more popular ranging modes within this categorizing structure will be briefly described below.

In indoor industrial settings, where the intrusion of contrived energy sources is not a severe disadvantage and where the contrived light source can be discriminated from the ambient light, the two most popular ranging methods are laser time-of-flight and striped lighting systems. Ultrasonic time-of-flight systems are also of interest but are not covered here.

Laser time-of-flight range instruments either measure the time it takes for a short pulse of laser light to beam to and be reflected back from a point on the surface of an object or the phase shift encountered by a modulated continuous laser beam during the round trip. Since light travels at approximately 30 cm per nanosecond (10^{-9} sec), subcentimeter accuracy range measurement required time to be measured with approximately ±10 picosecond (10^{-12} sec) accuracy using the first approach. With both approaches, averaging over a number of cycles can be used to reduce range error but at the cost of increased measurement time.

A number of laser rangefinders are now readily available in the marketplace at modest cost ($2000–$7000). One supplier is Erwin Sick; another is Laser Optronix. Figure 73.5 shows the plot of range extracted using an Erwin Sick laser scanner that sweeps the laser beam in a single arc over 180°, capturing range to 50 m at several centimeter accuracy (improved models are now available). Figure 73.6 shows a large outdoor scene scanned in both pitch and pan dimensions, using a collimated color camera to associate each *x, y, z* point collected by two range finders with a particular surface color patch.

Striped lighting ranging methods are triangulation based and reply on analyzing the distortion in the image of a stripe of light projected on the scene obtained from a camera displaced from the contrived light source in a direction perpendicular to the stripe light plane (Figure 73.7). Using many stripes simultaneously can lead to ambiguity in identifying the individual lines in the image, while using only one line at a time and sweeping this across the scene can be slow for high-density ranging, particularly if a standard frame rate video camera is used. An elegant compromise consists of collecting a set of images for a stripe lighting pattern set, which allows each stripe to be binary coded among the images. For on stripes only $(\log_2 n) + 1$ images need to be collected; doubling the number of stripes requires only one extra image.

In terms of the categorization scheme introduced earlier, the laser time-of-flight ranging method would be regarded as in the direct/active/single-view class, while the striped lighting ranging method would be regarded as being in the image-based/active/multiple-view class. Other members of the active class are range from brightness (with contrived light sources) and range from attenuation (again with contrived light sources). Both time-of-flight and striped lighting systems have been used in industrial robotics for some years now.

Passive range methods have been actively researched over the last three decades, partly because their biological source of inspiration brings with it the confidence that these approaches have been tested through Darwinian natural selection over countless generations and partly because they promise a very wide application scope and are intrinsically safe. Computational and micro-electronic advances in recent times have brought fast and affordable general-purpose passive rangefinding to the marketplace for practical use in many industries and in the home with or without robotic implications.

Figure 73.8 shows a disparity map of a scene using a Digiclops stereo (actually three cameras are used) system available from Point Grey Research Inc. The larger disparities (separation of matching components in separate camera view) are shown as brighter. Disparity is inverse range related.

Passive stereopsis is clearly the most popular approach to passive rangefinding. There are two stereopsis modes. Lateral stereopsis (Figure 73.9) refers to methods that use at least two cameras in a known baseline configuration in a plane perpendicular to the depth coordinate to derive range, while temporal stereopsis refers to methods where time sequences of images from a camera moving through the 3D scene are used to derive range. In either case, there are two essential process components that must be dealt with

© 2005 by CRC Press LLC

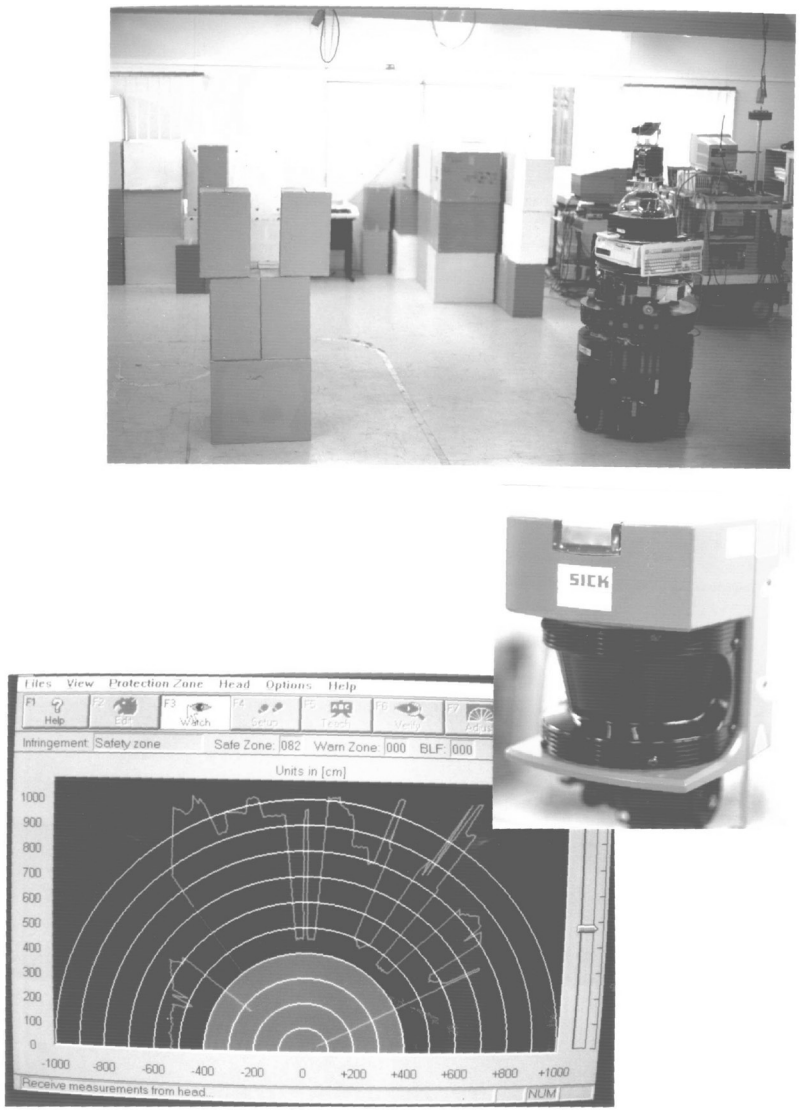

FIGURE 73.5 Erwin Sick scanning laser range finder scan and scene.

since both methods rely on matching elements among images, using the shifts of location (disparity) as inverse range measures (scaled appropriately):

1. The extraction or definition of the elements to be matched among images and
2. The search for correspondence between those selected elements among the images.

The image elements chosen for matching can be edge points, lines, corners, area patches, regions, object segments, or entire objects. More preparatory processing is required by choosing more complex elements, and, in the case of entire objects, the segmentation of these objects may be simplified by the use of range data, which is to be the result of the analysis, thus creating a potential deadlock situation. Thus, there is some advantage in matching the most primitive elements that can be discriminated clearly and matched unambiguously.

In recent times, mask correlation has been favored as a correspondence matching approach since the high computational complexity this entails now falls within the capacity of off-the-shelf computational resources.

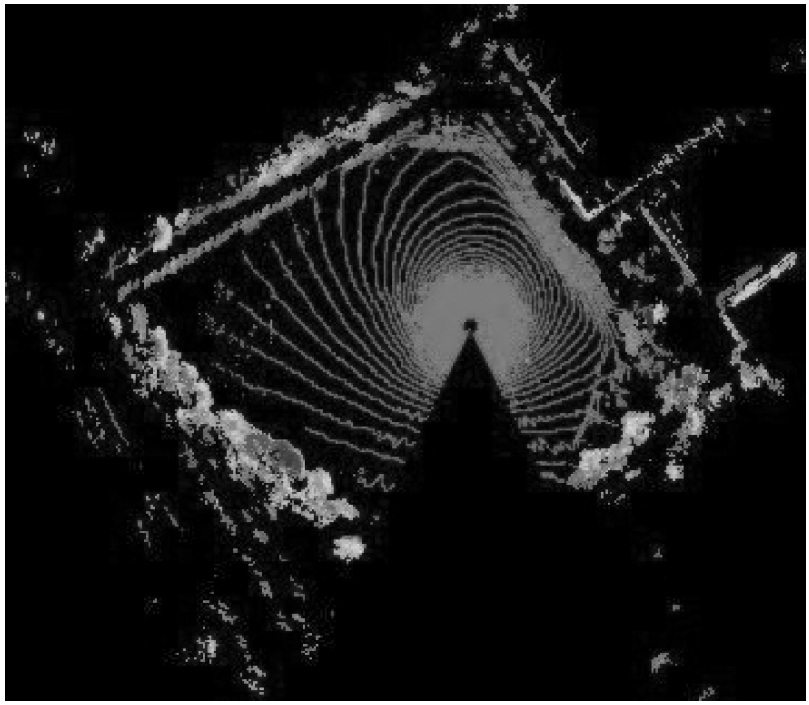

FIGURE 73.6 Large-scale laser range scan (using Laser Optronix device).

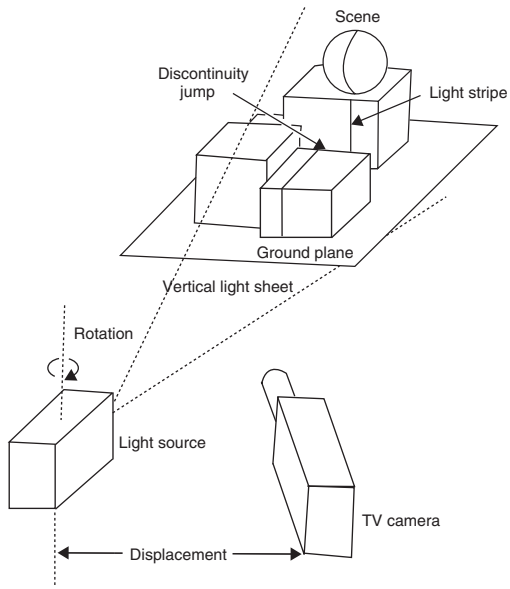

FIGURE 73.7 Striped light ranging principle.

For lateral stereopsis, the use of more than the minimum number of two cameras can improve both accuracy and reliability. Special hardware for very fast extraction of multiple camera stereopsis range data is under active research and development.

A variant of temporal stereopsis is known as optical flow; in this case, the vectors indicating the short-term movement of pixels are calculated from a video sequence with a single camera without explicitly

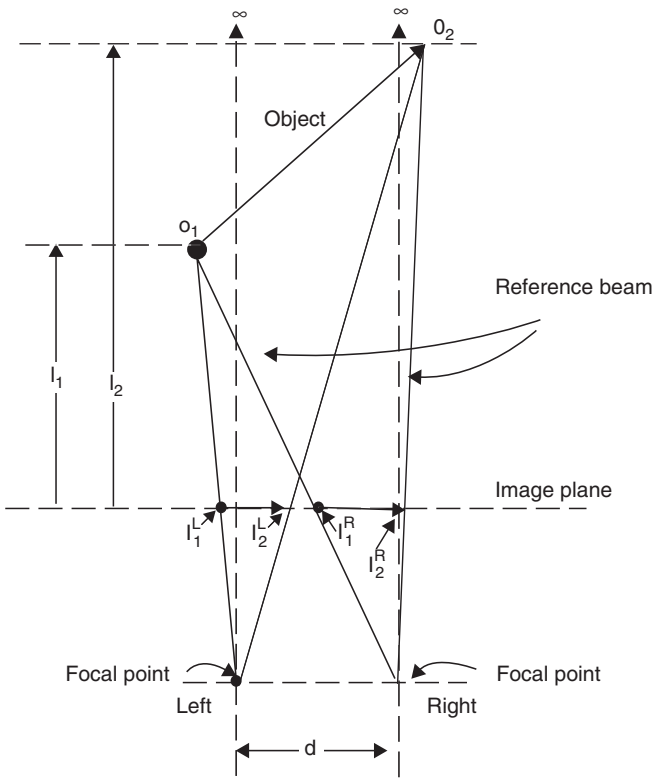

FIGURE 73.9 Geometry of passive stereopsis.

© 2005 by CRC Press LLC

solving the correspondence problem. Depth can be calculated from this vector flow field as can the egomotion of the camera through the scene. Analysis of moving objects in the scene can also be carried out using optical flow.

Once dense, accurate, and reliable range data have been extracted, the resulting 2½D representation of the 3D scene must be further processed. Full 3D scene representation can be in the form of an ordered or unordered set of 3D Cartesian coordinates with each point having a location in space as well as attributes such as surface color and normal vector data. Alternatively, a voxel-based representation may be preferred. Other data structures have also been proposed. The appropriateness of a data structure used to represent 3D scenes is measured in terms of compactness, lack of ambiguity, easy access, a modifiability, and its ability to support the application in mind.

The results of a complete scene analysis carried out by a robot vision system may take various forms, but would generally provide information on the identity, pose, and placement of individual items and their functional interrelationship (e.g., support, adjacency, occlusion, linkage, containment, etc.). In particular applications, perhaps a subset of this information would suffice; building vision systems to provide more than required is hardly a sensible thing to do for a specific task, but stretching vision methodologies toward generalization of applicability is also a worthwhile endeavor.

In summary, robot vision attempts to emulate human vision to the extent of correctly interpreting the makeup of 3D scenes, with the purpose of guiding robotic manipulators and autonomous mobile robots in fulfillment of useful tasks; many methods of range extraction support these ambitious goals and rapidly improving sensory device technologies and computational systems are likely to lead to an explosion of commercially available systems within the next decade.

Robot Tactile Sensing

74.1 Introduction
74.2 Whisker Sensors
74.3 Force/Torque Sensors
74.4 Skin-like Tactile Sensors
Opto-mechanical • Frustrated Internal Reflection • Piezoresistive • Ultrasonic • Skin-like Thermal Sensor • Slip sensing
74.5 Conclusion

R. Andrew Russell
Monash University

74.1 Introduction

As an aspect of robotics, tactile sensing covers any method of measurement involving physical contact between the sensor and sensed object. For this reason, it is also sometimes known as contact sensing. By its nature, tactile sensing is limited to contact and short-range situations. However, measurements gathered by tactile sensing usually require little processing to extract useful, unambiguous information. Mobile robots can use tactile sensing to warn of imminent collisions. The short-range but reliable information provided by touch is ideal as a last line of defense after obstacles have evaded longer-range sensors. Another aspect of tactile sensing is the measurement of contact forces. Many robotic tasks involve contact between the tool carried by the robot and external objects. By monitoring the resulting forces, the quality and safety of these operations can be improved. In robotics, there is considerable interest in producing touch sensor arrays that mimic the sensing abilities of the human skin. Such sensors can determine the regions of contact between robotic fingers and the objects they grip. Skin-like sensor arrays have also been developed to measure shear forces and the thermal properties of gripped objects. Individual, special-purpose sensors have also been designed to measure texture, slip, and incipient slip of a grasped object.

74.2 Whisker Sensors

A number of mobile research robots use whiskers as a short-range form of obstacle detection. The Stanford Research Institute's "Shakey" robot, developed between 1966 and 1972, was one of the first whisker-equipped mobile robots. This robot used its whiskers to detect obstacles and also the boxes that it pushed around its world. Whiskers have also been incorporated into legged robots, such as the four-legged robot Titan III built at the Tokyo Institute of Technology, to detect proximity between their feet and the ground (Hirose, et al., 1985). This allows the feet to decelerate before ground contact. Several researchers have mounted whisker sensors on robot grippers and have used them to locate small objects close to the gripper. Whisker sensors are simple and provide direct information about the close proximity of other objects. These attributes are also useful in mobile robotics.

© 2005 by CRC Press LLC

A simple whisker sensor may be no more complicated than a short length of piano wire passing through a small hole at the end of a metal tube. Figure 74.1 shows a cross-section view of such a sensor. When the wire is deflected, it touches the metal tube, thus completing an electrical circuit to signal the contact.

Whisker sensors only provide information about a single contact point and this limits the rate at which they can gather information. For this reason, it can appear that they are unsuitable for all but very slow robotic manipulation tasks. Biological studies indicate that it should be possible to gather considerable useful information from whisker sensors and to do this rapidly. The domestic cat is one of the few animals where the sensing capabilities of whiskers have been studied in any detail. A cat captures and manipulates its prey using its mouth. Objects held in the mouth are too close for the cat's eyes to focus on and are also partially obscured from view. Whiskers allow the cat to determine the position and movements of prey animals close under its nose or held between its jaws. The upper lip of the cat is well supplied with whiskers (vibrissae). Each whisker is provided with about 200 sensory nerve endings, which respond to displacement and velocity stimuli. Muscles position the whiskers to sense objects close to the mouth of the cat or fold them back to keep them out of the way while eating. When springing onto its prey, or when carrying something, the whiskers are angled far forward to envelop the object. A blindfolded cat can locate a mouse. Within one tenth of a second of a mouse touching the cat's whiskers, the cat grasps the mouse with a fast and precise bite to the nape of the neck. There is also evidence that the cat uses its whiskers to find the direction of hairs on a prey animal's body, which is an aid to cutting up and eating the animal. In an attempt to emulate the sensory capabilities of biological whiskers, there has been increasing attention focused on augmenting the information provided by robotic whisker sensors. Determining the point along the length of a whisker where contact is made would be useful additional information that would help to localize a sensed object. Several techniques are currently being investigated to allow this information to be gathered. These methods use a combination of some sort of actuation together with measurements at the root of the otherwise insensitive whisker to infer the point of contact. Sensing principles that are being considered include:

- Whisker resonant frequency — a rotary actuator causes the whisker to strike the sensed object. The natural frequency of the whisker during contact is used to estimate the contact point along the whisker (Ueno and Kaneko, 1994).
- Whisker deflection resulting from movement of the robot while the whisker tip touches an external object. The whisker is free to rotate at its base (Russell, 1992).
- Starting with a flexible whisker in contact with an external object. If the whisker is rotated at its base, the contact force is increased. Measurements of the amount the whisker is rotated and the torque required to perform the rotation allow the contact point to be determined (Kaneko, 1994).
- Sweeping a whisker over the surface of an object by rotating it about its base. By measuring whisker rotational angle and forces and torques at the whisker base, an elastica model can be used to predict the shape of the bent whisker and the contact point with the sensed object (Scholz and Rahn, 2002).

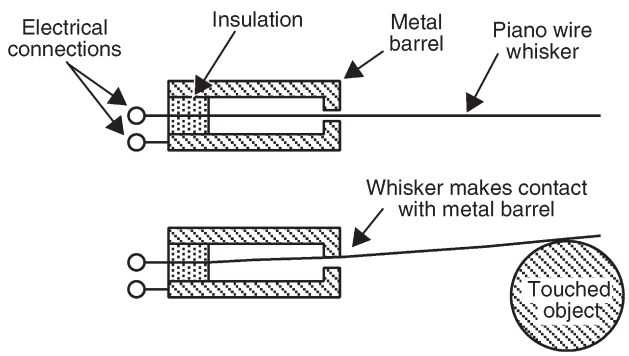

FIGURE 74.1 A simple whisker sensor.

© 2005 by CRC Press LLC

74.3 Force/Torque Sensors

When two objects touch, the forces and torques generated by contact can be resolved into forces along three orthogonal axes and torques about these axes. In robotics, it is often important to measure these six force/torque component and special-purpose loadcells have been designed for this purpose. In practice, force/torque sensing load cells are commonly located between a robot manipulator arm and its tool or gripper. Here, they can monitor and help control contact forces between the tool or gripper and external objects. In recent years, miniature force/torque sensors have been made for mounting in the fingertips of a robot hand. In this location, they can measure forces and torques generated during grasping and manipulation tasks. Applications for force/torque sensors are usually centered around tasks requiring manipulation. By measuring applied force, a force/torque sensor can also help maintain optimum contact during robotic fettling, grinding, and burnishing operations. During assembly operations, jamming generates characteristic reaction forces and torques. If these forces and torques are detected, then appropriate actions can be taken to free the parts and complete the assembly. In principle, data from a force/torque sensor can also be used to find the point of contact between a tool or gripper mounted on the loadcell and the outside world.

The load cell structure consists of a number of interconnected metal beams usually machined from a single piece of metal. Strain gauges are attached to the beams so that each gauge is sensitive to different components of the applied forces and torques. Figure 74.2 shows a force/torque sensor machined from a single block of aluminum in the form of a spoked wheel. The outer rim of the wheel A is connected to the robot arm and the inner hub B to the gripper. There are four semiconductor strain gauges attached to each spoke of the wheel and they are wired in pairs as half-bridge circuits. The load cell produces eight output signals and these can be related to the three components of force and three components of torque acting on the load cell. It is difficult to make a sufficiently ideal mechanical structure that the relationship between the eight output signals and applied forces and torques can be calculated accurately. For this reason, a transfer matrix relating eight output voltages to six applied forces and torques is determined experimentally. A pseudoinverse of this calibration matrix allows the sensor output voltages to be interpreted in terms of applied forces and torques.

74.4 Skin-like Tactile Sensors

Artificial sensory skins have been made containing arrays of contact sensors. These can give an image of the area of contact between a robotic finger and a grasped object and may produce a graduated response that depends upon the degree of indentation into the artificial sensory skin. Essentially, skin-like contact sensors measure deflection of the active sensor surface. Although numerous different designs of skin-like sensors have been developed over many years, they have seen little or no use in practical robotic applications. However, similar sensing technology has several biomedical applications including sensing the distribution of foot pressure on the ground and measuring the bite (the way in which the upper and lower teeth meet).

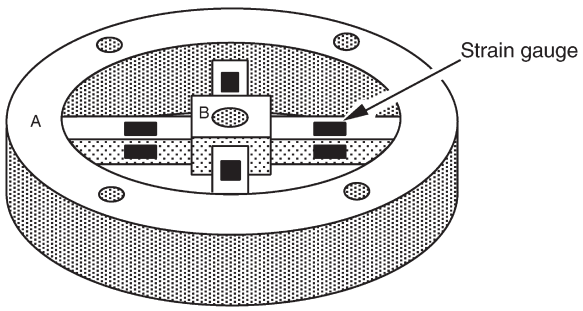

FIGURE 74.2 A 6-axis force/torque sensor.

© 2005 by CRC Press LLC

Here is a list of desirable performance specifications for a robot tactile sensory skin. Some of the criteria were proposed in an early paper on tactile sensing by Harmon (Harmon, 1982):

- spatial resolution 1 to 2 mm on a finger tip. Tactile sensation on other parts of the human body such as the back is only of the order of 10 to 20 mm
- array size — human fingertip contains approximately 10 × 15 points
- threshold sensitivity about 0.5–10 g
- sampling rate 100 Hz to 1 kHz,
- rugged
- inexpensive
- conformable to adapt to the exterior shape of the robot and
- compact and easily integrated into the robot structure.

It is perhaps an indication of the lack of maturity in this area of robotic sensing that many different transducer mechanisms have been tried and still more are continually being proposed. Skin-like contact sensors have been designed that are based on simple switches, piezoresistivity, piezoelectricity, optical, opto-mechanical, fiber-optic, photoelasticity, magnetic, magnetoelastic, ultrasonic, capacitive, and electrochemical sensing methods. In such a brief outline, it is impossible to cover the full field. However, four sensors will be mentioned. They are examples of devices that have shown sufficient promise to be developed to the stage of a commercial product.

Opto-mechanical

One commercially manufactured opto-mechanical sensor array employs a rubber skin with an array of mushroom-shaped projections molded into its surface (Rebman and Morris, 1986). The head of the mushroom concentrates the applied force and the stalk acts as an optical shutter to control light transmission between a light-emitting diode and a photodetector. As normal force increases, light transmission is reduced. Construction of this sensor is quite labor-intensive. All sensor sites contain a photoemitter and photodetector and they must be individually matched and trimmed with an associated resistor to equalize their responses. This sensing technique was used in the first commercially available tactile sensor. Although each sensor site is quite complicated, sensor arrays were constructed with sensor spacings as small as 1.8 mm (Figure 74.3).

For the opto-mechanical tactile sensor, spatial resolution and sampling rate are adequate. A major drawback for this design is its complexity and this also leads to a relatively expensive solution. Modifying the design so that the sensor conformed to even a simple curve would be difficult. A further drawback of this design is that this relatively thick sensor would take up considerable space, particularly in a complex structure such as a dexterous robot hand.

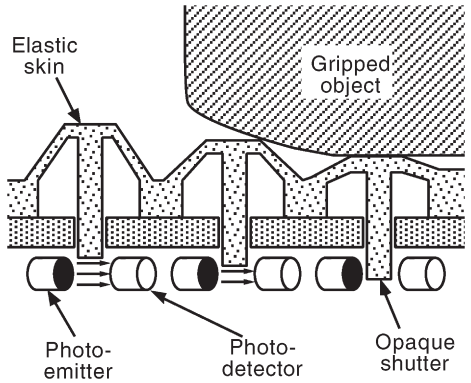

FIGURE 74.3 Opto-mechanical tactile sensor.

© 2005 by CRC Press LLC

Frustrated Internal Reflection

This optical sensing technique is capable of producing very high-resolution tactile images (King and White, 1985). A major component of the sensor is a light guide, which may be a sheet of clear glass or plastic. Light introduced at one edge of the light guide propagates through the sheet by total internal reflection and emerges at the opposite edge (Figure 74.4). For total internal reflection to occur, light must strike the surface of the light guide at less than the critical angle. A sheet of reflective rubber material is suspended close to, but not touching the light guide. This is the active area of the sensor. When an object presses against the rubber sheet, the sheet deforms making contact with the light guide. Over the area of contact, the critical angle changes causing light to leave the light guide and effectively illuminate the region of contact. Diffusely reflected light from the area of contact passes back through the guide and is detected by a video camera or a similar optical sensor. Using a flat rubber sheet gives a binary image, which can only distinguish between contact or no contact. However, by embossing a pattern into the rubber surface, a certain amount of force information can also be distinguished.

This transducer technique produces very high-resolution tactile images of the order of 256 × 256 taxels over a 2 cm × 2 cm area. The sampling rate is limited by the scan rate of the optical sensor. However, the inherently serial nature of most camera signals greatly reduces the number of electrical connections to the sensor. Frustrated internal reflection sensors have been built with flat sensing surfaces and also in the form of a hemisphere for mounting on a fingertip. Even with the advent of miniature camera chips, the optical paths make this type of sensor inherently bulky. There is also a tendency for the rubber skin to stick to the light guide after the external object has been removed. This is another relatively expensive form of tactile sensor and probably would not be economically viable for areas of a robot where large area, low-density sensing is required.

Piezoresistive

Piezoresistive sensors are relatively simple to make and provide a large electrical output that requires little or no amplification. Figure 74.5 shows a cross-section view of a single sensor element. The sensor consists of two sheets of polyimide plastic film. On the inner surface of the lower sheet, two metallic electrodes separated by a small gap are deposited. The upper plastic sheet is coated with conductive ink. Such inks consist of semiconducting particles like molybdenum disulfide held together with a binder material such as acrylic resin. In this sensor, the piezoresistivity is a surface effect. Pressure reduces the contact resistance between the electrodes and the ink. Resistance between the electrodes depends upon compressive force applied to the sensor. This technology can be used to make simple and low-cost touch sensor arrays by what is essentially a printing process. The sensors are thin (<1 mm) and can be bent around simple curves. In many cases, the piezoresistive sensor arrays could be directly attached to the outer surface of the robot structure (Figure 74.5).

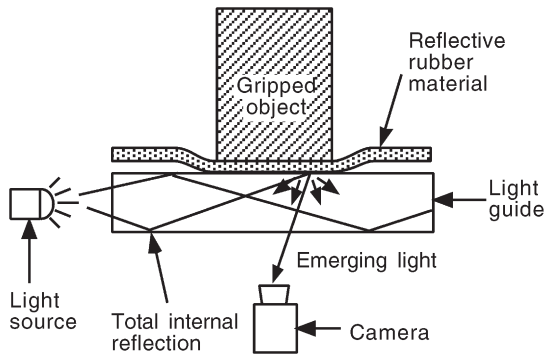

FIGURE 74.4 A tactile sensor using the principle of frustrated internal reflection.

© 2005 by CRC Press LLC

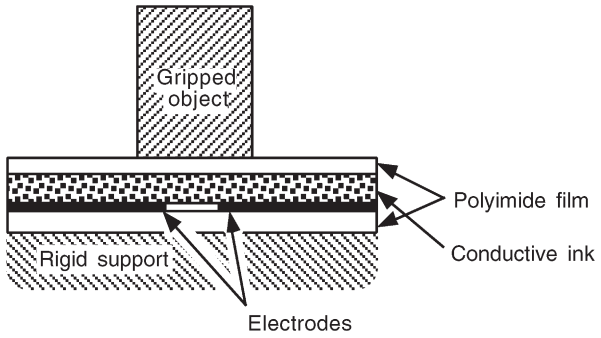

FIGURE 74.5 Cross-section through a single piezoresistive tactile sensor.

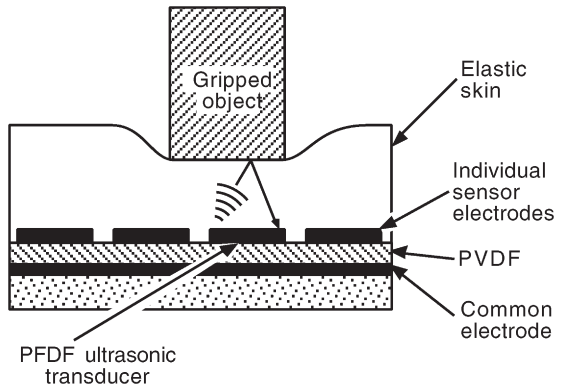

FIGURE 74.6 Cross-sectional view of a tactile sensor array using ultrasonic transduction.

Ultrasonic

Ultrasonic thickness gauges have been in use for many years to measure the thickness of paint layers, metal sheets, etc. An ultrasonic pulse is introduced into the sheet at one face, propagates through the thickness of the material, and is reflected from the opposite face. The returning echo has traveled twice through the thickness of the material. Knowing the speed of propagation of the ultrasound pulse and measuring the propagation delay allow the thickness to be determined. This principle has been used to construct a tactile sensor by using ultrasonic transducers to measure the thickness of a flexible elastomer layer at many closely spaced points (Grahn and Astle, 1984). The sensor is relatively simple consisting of a sheet of polyvinylidene fluoride (PVDF) piezoelectric plastic patterned with an array of electrodes. Overlying the sheet of PVDF is a layer of compliant elastomer, which changes shape as objects indent into it. The electronics associated with the sensor generate, detect, and time the ultrasonic pulses. Using this technology, a 16×16 element ultrasonic sensor array has been manufactured with 1.8 mm spacing between taxels (Figure 74.6).

The actual ultrasonic sensor array can be quite thin (most of the thickness is contributed by the elastic skin), and there seems to be no reason why the array could be molded around simple curves. Because measurements are based on time-of-flight, the readings of sensor indentation are very accurate and stable. A drawback is the large amount of support electronics required to generate high-voltage pulses to energize the ultrasonic transducers, amplify the returned echo, and measure transit time of the ultrasonic pulses.

Tactile Images

Figure 74.7 shows a wire-frame plot of a typical touch sensor image. The object pressed against the sensor, a slotted electrical lug, is small enough to fit entirely within the active area of the sensor. For most

© 2005 by CRC Press LLC

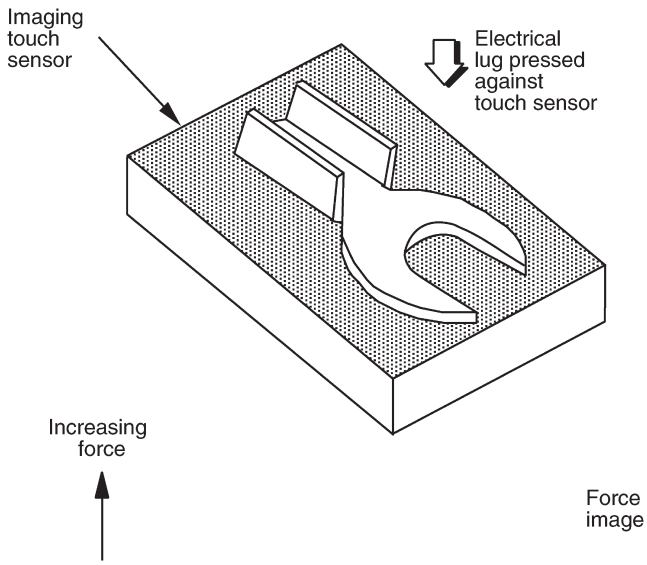

FIGURE 74.7 An example of a force image produced by pressing a slotted electrical lug against a 10 × 10 piezoresistive array sensor.

objects, this would not be the case. Tactile information about a larger object would usually be gathered by a process of active search. This implies that the sensor is attached to a gripper and that a computer program directs the gripper to search for the required information.

Skin-like sensors have been developed to measure other quantities besides deflection in the region of contact. When we touch metal, it feels cold while wood and polystyrene foam feel warm, even though these materials are all at room temperature. The feelings of warmth or cold are caused by different materials cooling our fingers at different rates. This gives us additional information about the kinds of materials things are made of and robotic touch sensors have been designed using the same principle.

Skin-like Thermal Sensor

The human skin contains nerve endings that detect increases in temperature (Ruffini endings) and others that respond to lowering skin temperature (Kraus corpuscles). Acting together, these nerve endings provide information about the temperature and thermal characteristics of grasped objects. Knowledge of temperature provides obvious safety information particularly for things that will be grasped or ingested. Measurements of the thermal characteristics of objects at room temperature give information about the nature of their constituent materials. Steel feels cold, while glass is not quite as cold and cork appears warm to the touch.

For a robotic skin-like thermal sensor, a temperature-stabilized heat source warms the sensor in the same manner that the blood supply warms the skin. In Figure 74.8, thermistor TH2 provides temperature feedback for the temperature control circuit and the actual heating element is a power transistor. As shown in the figure, a layer of material of known thermal conductivity couples this heat source to the touched object. A thermistor on the outer surface of the coupling layer measures the contact point temperature. The thermistor replaces the thermally sensitive nerve endings in the human skin. When this sensor touches an object, the temperature change in the thermistor TH1 gives information about the material properties of the object structure. A skin-like array of such sensors can measure the extent of the temperature disturbance caused by contact with an object and hence give the outline of the touched object (Russell, 1988).

Figure 74.9 shows the temperature variation measured by a thermal sensor in contact with a number of different materials. Each material produces a characteristic response depending on its thermal capacity and thermal conductivity. A number of known materials can be discriminated by comparing the sensor response with values recorded for each material. Alternatively, there is a strong correlation between

© 2005 by CRC Press LLC

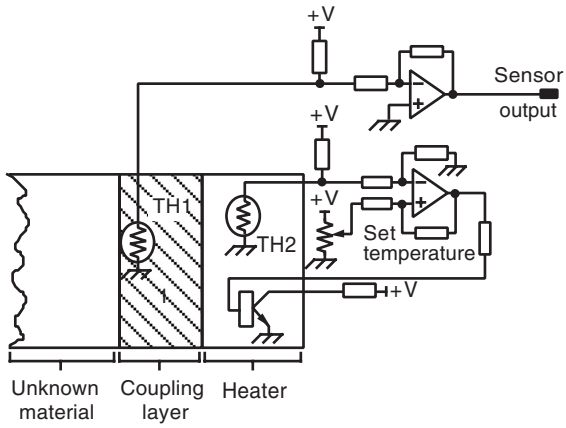

FIGURE 74.8 A schematic diagram of a thermal sensor.

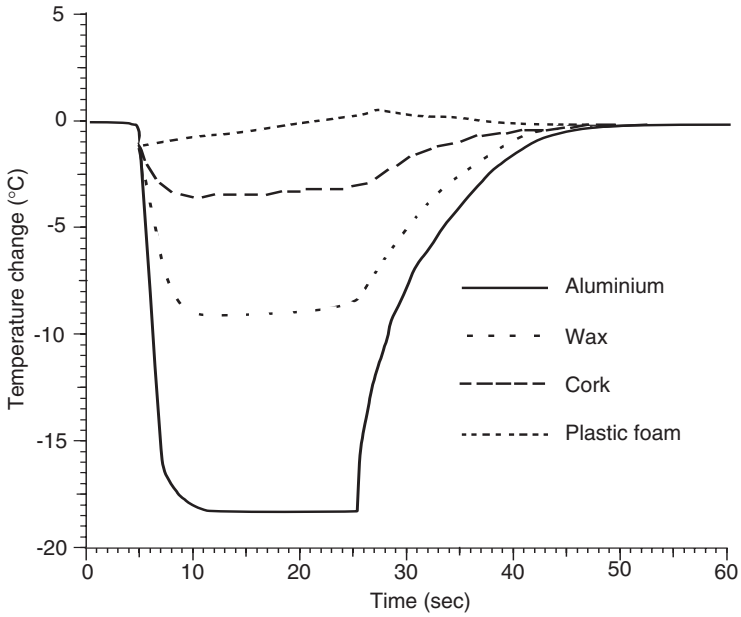

FIGURE 74.9 Thermal sensor output showing the response to contacting different materials for 20 sec.

the decline in thermal sensor temperature and specific mass of the material making up the touched object (Russell, 1990). This information about specific mass could provide information to help recognize an unknown object.

Slip Sensing

In addition to skin deflection due to contact and temperature change caused by the flow of heat between the skin and a touched object, the human skin can also gather more specialized information. Of particular interest during manipulation operations is the onset of slip that signals the imminent possibility of dropping a grasped object. Technological sensors have also been devised to give a robotic system information about the relative movement between a robot finger and the objects it is touching. As an example, Figure 74.10 shows a diagram of one form of special-purpose slip sensor (Ueda, et al., 1972). In this

© 2005 by CRC Press LLC

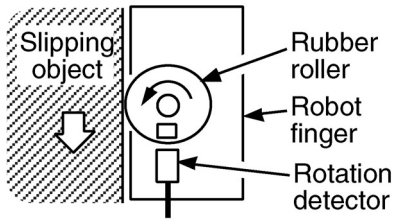

FIGURE 74.10 A sensor to determine slip.

example, a freely rotating rubber-coated wheel presses against the gripped object. As the object starts to slip, the wheel turns and a rotation sensor detects the movement.

Somewhat closer to the human slip sense is the incipient slip sensor described by Tremblay and Cutkosky (1993). The sensor is in the form of a highly compliant fingertip. A foam core provides compliance and this is covered by a rubber skin with an outer surface patterned with an array of raised bumps. Accelerometers attached to the inside surface of the skin measure skin vibration. Tangential forces acting on a gripped object tend to pull it from the grasp. As these forces increase, the skin distorts and some of the sensor bumps break free. The resulting skin vibration is detected by the accelerometers and can be used to identify the increased levels of tangential force that may lead to slip. It is thought that the fingerprint pattern on human fingers coupled with vibration-sensitive nerve endings provides a similar warning of incipient slip for humans.

74.5 Conclusion

Tactile sensing, like computer vision and many other aspects of robotics, all seem deceptively simple. As humans, we can use this sense with apparent ease. The reality is that it is extremely difficult to emulate the capabilities of the human sense of touch in a robotic system. However, we know from our own experience as to how useful touch sensing can be, especially when grasping and manipulating objects. For this reason, it seems certain that touch sensing will prove important for robotic systems also.

Many robotic tactile sensor designs have been proposed, particularly for skin-like touch sensing. Skin-like touch sensing is a very demanding application where a compact and sensitive sensor must be immune to severe thermal, chemical, impact, abrasion, and cutting challenges. Current designs fall well short of what is required. The large amounts of research and development necessary to bring an existing design to a suitable standard will only be committed when compelling applications appear. Particularly for robotic manipulation, the design of robotic grippers to carry the tactile sensors and the development of associated data processing and control programs are also important considerations. All of these elements will be required for successful tactile sensor-based robotic manipulation and object recognition. Perhaps less demanding but potentially very useful would be whole-body touch sensory skins for humanoid, mobile, and manipulator arm robots. These could warn of contact and collisions. Touching the tactile sensory skin of a robot could also provide an effective means of getting the robot's attention during human–robot interactions.

Finding the Source of a Chemical Plume Using the Dung Beetle Algorithm • Ant-like Pheromone Trail-Following • Locating the source of chemicals released underground

75.5 Conclusion

R. Andrew Russell
Monash University

Currently, few robotic systems have been provided with access to the rich and complex dimension of chemical sensing. In biology, the response to chemical stimuli was the first sense to evolve and it is the most widespread sensory modality over the whole spectrum of living creatures. For the majority of plants and animals, chemical stimuli are essential to every aspect of their lives. Chemical senses are involved in finding food, avoiding danger, and locating a mate.

It has been estimated that the human sense of smell has been degenerating steadily over the past 5 million years. This is probably mirrored by a corresponding improvement of and reliance on visual sensing. However, in situations where odor is important, other animals, most notably dogs, are used to help substitute for the relatively poor human sense of smell. Among other things, sniffer dogs are used to detect:

- plant matter, drugs, and other materials important to customs officials,
- truffles,
- victims of avalanches and earthquakes,
- escaped prisoners,
- chemical leaks, and
- mines and unexploded bombs.

One of the drawbacks of sniffer dogs is that it is difficult or impossible to find out exactly which chemical species triggers their response. In many cases, it is not the target chemical but an impurity or by-product that is detected. Another problem is that sniffing is a natural action for dogs; hence, even if their sense of smell is impaired, this will be hard for a handler to determine. Such a condition could have serious consequences in some situations such as during mine clearance operations. Animals require extensive training, they must be cared for by an expert handler, their attention span is short, and they suffer from fatigue.

© 2005 by CRC Press LLC

Robotic systems could perform tasks similar to those performed by sniffer dogs while offering a number of advantages including tireless operation, easy care, and supervision by relatively unskilled personnel. In addition, many new chemical sensing applications will be made possible by the varied forms that robots can take and their flexible capabilities. Robots of many different sizes can fly, swim, crawl, and burrow through the ground in search of chemical sources.

Among robotics researchers, interest in developing robots with a chemical sense is relatively recent. Larcombe and Helsall (1984) discussed techniques for utilizing chemically sensitive robots in a report to the European nuclear industry published in 1984. However, reports of the first practical experiments involving chemical sensing robots began to appear in the early 1990s (Russell, 1999a).

75.1 Application Scenarios

There are important economic, environmental, and humanitarian applications for systems that can find the source of a volatile chemical. Such sources could include pollutants being discharged by factories, leaking gas pipes, corroded underground chemical storage tanks, landmines, unexploded ordinance, and even victims of landslides and earthquakes.

As illustrated in Figure 75.1, a flying robot and a submersible are faced with a similar challenge of tracking a chemical plume in three dimensions in order to locate its source. Chemicals carried by the wind and by water currents are both subject to the effects of turbulence. Provided fluid velocity is high enough, then flow some distance away from the chemical source will be turbulent. When the plume of chemical enters this region, it will be torn into short segments. It then proceeds downwind/downstream as an irregular and expanding series of short chemical patches. Under these circumstances, interpreting the fluctuating chemical concentration to work out a path to the source is a significant challenge.

Terrestrial mobile robots are able to follow plumes of chemical released into an indoor environment or close to the ground. Such chemical plumes must be negatively buoyant if the robot is to detect them at a distance from their source. The terrestrial environment is often complicated by walls and other obstacles that deflect airflow and impede the progress of the robot. A chemical source locating robot must be able to deal with these complications. Mobile robots equipped to detect chemicals could patrol factories, chemical plants, and even homes searching for chemicals released into the atmosphere from sources such as leaks, spills, rotting food, and incipient fires (Figure 75.2).

Chemicals can be deposited on a solid surface in the form of a trail or percolate to the surface of the ground from an underground source. In both these situations, the location of the chemical source can be determined by detecting the traces of chemical released into the surrounding air (Figure 75.3).

Chemical markings on the ground could provide a trail for a robot to follow in much the same way that a worker ant follows an ant trail. Chemical percolating from the ground would signal the location of a buried

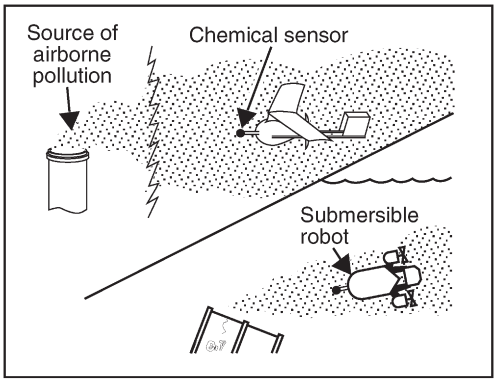

FIGURE 75.1 Both airborne and submersible robots track toward sources of an odor plume by maneuvering in three dimensions.

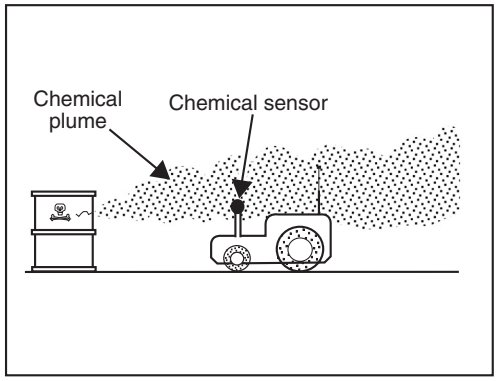

FIGURE 75.2 Chemical plumes released close to the ground can be traced by a terrestrial robot platform.

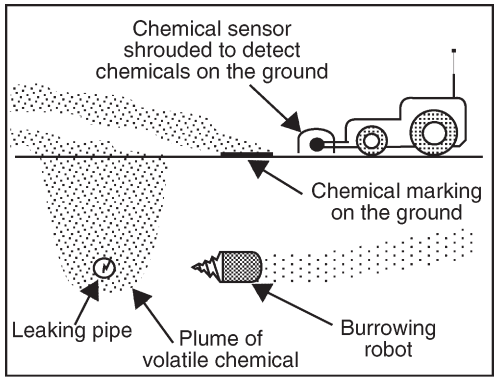

FIGURE 75.3 Locating the source of chemical markings on the ground or chemicals percolating out of the earth require specially designed sensor systems.

chemical source. In both these cases, careful control of airflow around the sensor is required to exclude chemicals released by distant sources and to ensure that chemicals from the ground are carried to the sensor.

The diffusion of volatile chemicals through the ground is much slower than through the air. Therefore, the belowground concentration of chemical from a buried source is much higher than the concentration in the air above the source. For this reason, it may be of benefit for the robot to burrow through the ground toward the source rather than trying to measure chemical concentration released into the air above.

As the scenarios presented in this Section have shown, there are many potential applications for chemical-sensing robots. An important first step in developing robots that can react to chemicals in their environment is the provision of suitable sensors.

75.2 Robotic Chemical-Sensing Technologies

There are many sensors available for detecting volatile chemicals. These range from the simple tin oxide sensors used by police to estimate alcohol consumption to mass spectrometers and gas chromatographs that analyze complex mixtures of chemicals. However, few of these sensors are suitable for robotics applications. Desirable attributes for robotic chemical sensors include:

- *High sensitivity* — increasing sensor sensitivity opens up many more application areas
- *Rapid response* — to provide real-time control of a robotic system, a response time of fractions of a second to a small number of seconds would usually be required

© 2005 by CRC Press LLC

- *Low power consumption* — power for sensor systems will be drawn from the robot's power supply and must not impose an unreasonable power drain
- *Robustness* — robot sensor systems may be used in unconstrained environments and therefore should resist physical damage due to collisions and being poisoned or otherwise damaged by the chemicals it is likely encounter in its environment
- *Compact size* — space is usually limited; hence, a small size is preferable and would be related to the dimensions of the robot.

In addition, it would be of benefit if the sensor was inexpensive and commercially available or at least easily constructed from common materials. A number of sensors meet these requirements reasonably well and have been tested in robotic systems.

Tin Oxide Gas Sensors

The commercially available tin oxide sensors manufactured by companies such as Figaro Engineering Inc. have been used in the majority of robotic experiments. They are inexpensive, small in size, easy to interface, and the latest miniature devices made by thick-film technology have relatively low power consumption (the heater of the Figaro TGS2600 'air quality' sensor consumes 210 mW). The tin oxide sensor element is heated to about 300°C, where the presence of reducing gasses leads to a drop in sensor resistance. Sensitivities of the order of 1 ppm are available and sensors have been developed with responses optimized for solvents, halocarbons, and a range of combustible gasses. As an approximation sensor output resistance varies with gas concentration as follows:

$$\frac{R}{R_0} \cong KC^{\alpha} \tag{75.1}$$

where

R = sensor resistance in the presence of a reducing gas,
R_0 = sensor resistance in clean air,
C = gas concentration, and
α and K are constants relating to the particular sensor.

Quartz Crystal Microbalance

Quartz crystal microbalance sensors use a quartz crystal as a sensitive balance to weigh odor molecules. A chemical coating on the crystal is chosen to have a specific affinity for the target odorant molecules. When air containing molecules of this odor is drawn over the crystal, some of the molecules become temporarily attached to the coating. This increases the mass of the crystal and lowers its resonant frequency. A simple model proposed by Sauerbrey predicts the effect of small amounts of added mass:

$$\Delta f = -\frac{2f^2\Delta m}{\rho v} \tag{75.2}$$

where

Δf = change in crystal resonant frequency,
f = crystal resonant frequency,
Δm = increase in the mass of the crystal per unit area,
ρ = density of crystal material, and
v = velocity of sound waves in the crystal material,

It is interesting to note that the change in crystal frequency resulting from added mass is proportional to the square of the crystal resonant frequency. Therefore, increasing the crystal resonant frequency has a very beneficial effect on its sensitivity as a chemical sensor.

© 2005 by CRC Press LLC

Conductive Polymer

Conductive polymers can also be used to make chemical sensors for applications in robotics. An inexpensive and safe way of making polypyrrole has been reported, which uses electrochemical polymerization of pyrrole between a pair of electrodes. The resulting polypyrrole sensors have good sensitivity to common and relatively nontoxic chemicals such as ethanol and ammonia that can be used in robotic experiments. However, there are problems of consistency between sensors and of stability and aging.

If a robot is operating in a constrained environment and can be guaranteed to only encounter a single chemical, then the robot may be required to detect but not to recognize the chemical. In most other situations where the robot must respond to a specific chemical in the presence of other chemical species, the robot needs the ability to discriminate between different odors.

Odor Discrimination

In a number of commercial situations, assessing the quality of an odor is important. The aroma of foodstuffs such as bread, biscuits, coffee, beer, and wine are all important to the consumer. In the nonfood area, the success of perfume and scented products such as soap, washing powder, and air freshener all depend on their smell. Currently, quality control of these products is performed by humans. The human sense of smell is affected by age, health, and eating habits. There would be a number of commercial applications for an artificial odor discrimination system that could perform these quality-control tasks.

Odor discrimination systems are being developed, which have the structure shown in Figure 75.4.

The system comprises a number of odor sensors that are exposed to the odorant. Each sensor has a peak sensitivity to a different chemical species. However, their sensitivity is broad and overlaps between sensors. One specific odor will give a unique pattern of response from the odor sensors. This pattern is interpreted, in this case by a trained neural network, to identify the odor. The neural network may be trained using the back propagation algorithm by repeated exposures to the range of odors which the system will be required to discriminate. This kind of system is called an electronic nose, and several commercial versions are available on the market for assessing odors. The individual sensors used in an electronic nose would typically be tin oxide or quartz crystal microbalance chemical sensors. Electronic noses are used in robotic systems where an odor recognition capability is required.

Chemical sensors are not directional and do not form an image. They are only able to measure chemical concentration at a location in space. A robot requires additional information if it is to move in the direction of the chemical source. In some source location experiments, chemical gradient information has been used to determine the path that the robot must take. Because of the rapidly fluctuating nature of turbulent odor plumes, it is difficult to obtain reliable gradient information either by having widely spaced sensors on the robot or by taking chemical readings at different locations in the robot's environment. If the

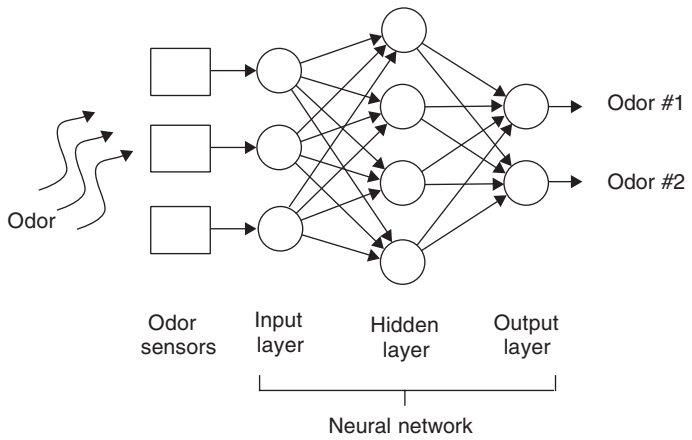

FIGURE 75.4 An odor discrimination system.

© 2005 by CRC Press LLC

chemical plume is constrained, perhaps by passing down a narrow corridor, then provided the walls do not absorb the chemical, there will be no concentration gradient at all. For these reasons, it is often necessary for a plume tracking robot to have additional information about local airflow.

75.3 Airflow Monitoring

Since the early days of meteorology, wind direction has been commonly measured by wind vanes or wind socks. By contrast, many techniques are used for measuring wind velocity. These include turbine flowmeter, three-cup anemometer, pitotstatic tube, and hot-wire/film anemometer. In many applications, robots will be operating indoors involving wind velocities of well below 1 m/s. Using conventional techniques, measuring velocity and direction becomes difficult at these air speeds. A number of airflow measurement techniques have been developed especially for use by robots in an indoor environment.

Rotating Paddle

At Monash University, a novel active airflow velocity and direction sensor has been developed (Russell and Kennedy, 2000). This device works at low wind velocities and its simplicity, potential for miniaturization, and low power consumption make it suitable for mounting on small robots (10 cm diameter and smaller). The key feature of the sensor is a flat plate or paddle rotated by a precision dc motor (see Figure 75.5). In still air, the rotational speed of the paddle will be constant. However, when situated in an airflow, the paddle will slow down when moving upwind and speed up when moving downwind. The difference between the maximum and minimum paddle speed is proportional to wind velocity. Airflow direction can be inferred by noting the rotation angle corresponding to maximum or minimum paddle velocity and applying the appropriate 90° offset. A prototype version of this sensor was able to provide reliable airflow information with wind velocities below 0.1 m/sec.

Measuring Both Chemical Concentration and Airflow Direction

A group at Tokyo Institute of Technology has developed a number of innovative robotic sensor systems for use in locating the source of a chemical plume. These systems measure a combination of airflow direction and chemical concentration . Hiroshi Ishida and coworkers (1994) describe a system using four anemometric and four gas sensors mounted on a small mobile robot. As illustrated in Figure 75.6 the four anemometric sensors are sheltered by a square central pillar and for this reason the sensor that is located downwind records the lowest wind velocity. This effect can be used directly to determine the wind direction to within 90°. For a more accurate indication of airflow, patterns of anemometric sensor reading were normalized and recorded for wind directions rotated in increments of 45°. Wind direction could then be estimated to within 45° by finding the best match, based on minimum Euclidean distance,

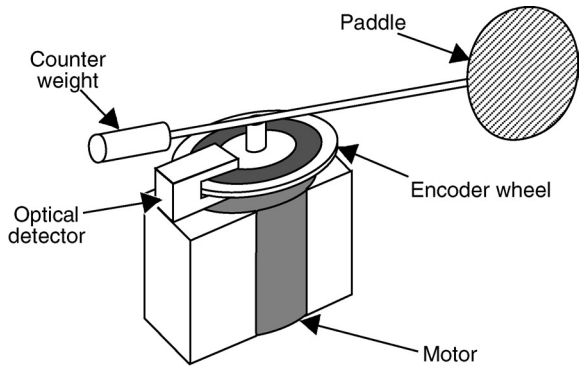

FIGURE 75.5 A diagram of the paddle airflow sensor.

© 2005 by CRC Press LLC

between actual and stored anemometric readings. Once wind direction is established, then the chemical concentration gradient perpendicular to the flow direction can be estimated. This concentration gradient is found by subtracting readings from the two gas sensors that are at right angles to the measured wind direction. Airflow and concentration gradient information is then used to control the movements of the robot.

It has been observed that male silkworm moths flutter their wings when stimulated by the female pheromone Bombykol. Fluttering of the wings draws air over the moth's antennae and expels it behind the moth. It has been proposed that this flutter-induced airflow helps the moth to work out the direction to the pheromone. When the moth is facing toward the pheromone source, wing fluttering draws odor over the moth's antennae and an increase in pheromone is detected. If the moth is facing away from the source, then wing fluttering blows the pheromone away and less will be detected. Hiroshi Ishida and coworkers (1996) designed an active sensor based on this principle. In this sensor a small electric fan generates airflow and a TGS822 gas sensor detects the ethanol vapor used as the target odor. A diagram of the sensor is shown in Figure 75.7.

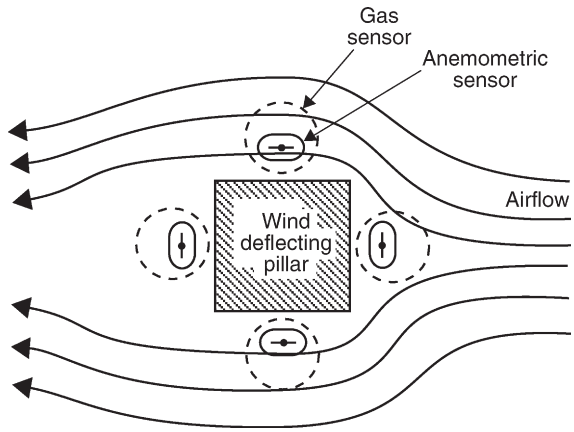

FIGURE 75.6 Plan view of a combination of gas and anemometric sensors used to estimate wind direction and chemical gradient.

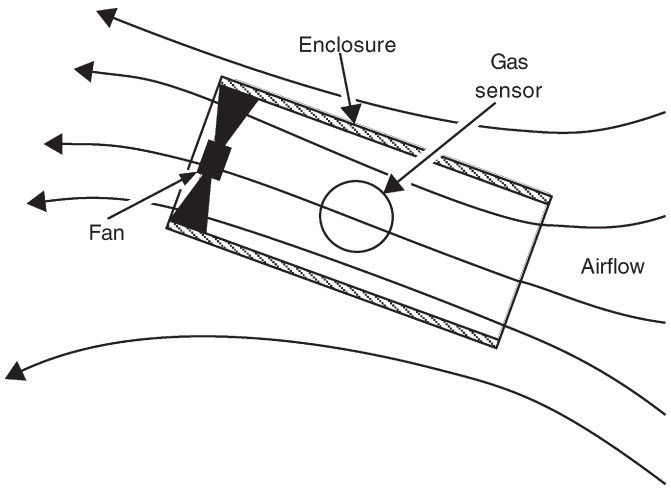

FIGURE 75.7 By rotating the active-sampling sensor the direction to the chemical source can be determined.

Whisker sensors to measure airflow

Humanoid robots will require a rich set of sensory inputs if they are to work effectively in a human environment. Chemical sensing in the form of an electronic nose would be a natural choice for part of a humanoid robot's sensor suite. In many cases, once a chemical has been detected and identified by the electronic nose, the task of the robot will be to locate the source. For this, the humanoid robot will need some means of determining airflow direction. It is a reasonable requirement that sensors carried by a humanoid robot blend in with its humanoid form and for this reason a wind vane is not appropriate. At Monash University, a sensor for determine airflow has been developed that is compatible with the humanoid form (Russell and Purnamadjaja, 2002). It consists of an array of sensory whiskers attached to a sweat band worn by the humanoid head (Figure 75.8). Turbulence in the airflow around the head causes the whiskers to vibrate and this is detected by an optical switch. Over a limited range, the frequency of whisker vibration is proportional to airflow velocity and the distribution of activation of the whisker sensors around the head provides information on the direction that airflow is incident on the head.

Sensing and Airflow

During experiments to develop robots that can follow chemical trails deposited on the ground, it has been found that unenclosed chemical sensors give very unreliable information. Sometime a sensor hardly responds at all when positioned immediately above the trail. In other situations, a strong but widely fluctuating response can be measured when the chemical marking is some distance away. These problems were found to be caused by air currents close to the floor. By careful control of the airflow around the sensor, these problems can be overcome. Figure 75.9 shows a cross-section view of a sensor that generates an air curtain to exclude odors carried to the sensor from some distance away (Russell, 1995). At the same time, air is drawn from the floor surface and over an odor-sensing quartz crystal. The airflow generated within and around the sensor is illustrated in Figure 75.9.

In addition to chemical and other sensors, a robot also requires control algorithms to allow it to make use of its sensory information. The insect world is an excellent source of simple algorithms for implementing chemical searching and tracking behaviors in robot systems, and some examples are given in the next section.

75.4 Examples of Robotic Chemical Sensing

Finding the Source of a Chemical Plume Using the Dung Beetle Algorithm

The dung beetle *Geotrupes stercorarius* is reported to use a very simple strategy to follow the odor plume from a cow pat. Initially, the beetle flies across wind to give it the best chance of finding a plume of cow pat odor. Upon detecting this odor, it zigzags diagonally across the plume in an upwind direction turning back each time it leaves the edge of the plume. When the odor plume ends, as it does immediately above the cow pat, the beetle flies down and usually lands on or near its goal. In order to implement this algorithm, a robot requires information about the direction of airflow as well as chemical concentration. For the experiment illustrated in Figure 75.10, a small mobile robot was equipped with polypyrrole conducting polymer sensors that show a very strong response to ammonia (Russell, 1999b). The conducting polymer sensors had an initial resistance of about 25 kΩ and exhibited a maximum resistance change of almost 20% on exposure to concentrated ammonia vapor. In addition, the robot had a rotating paddle airflow sensor and tactile whiskers to detect contact with the odor source. The odor source consisted of a 1 l/min flow of air. The flow of air carried with it ammonia vapor resulting from bubbling through a flask of 5% ammonia solution. To establish an airflow in the laboratory, a cooling fan was run at a reduced voltage to give an airflow of 0.3 m/sec at a distance of 2 m from the fan.

In order to make contact with the ammonia plume, the robot starts by searching across wind. The dashed line in Figure 75.10 shows the path of the robot when the ammonia source was not present. This line is at right angles to the direction of airflow from the fan. The solid line marks the path of the robot as it detects the plume and then zigzags toward the source. The robot halts when it collides with the source.

Ant-like Pheromone Trail-Following

The trail-following algorithm used by the ant *Lasius fuliginousus* seems to be very simple. The normal mode of trail-following for the ant is to curve to the left until the right antenna detects the trail and then to curve to the right until the left antenna contacts the trail. In this way, the ant maintains the trail between its two antennae. An important feature of the ant's tracking algorithm involves turning back toward the trail after an extended period even if the appropriate antenna does not detect the pheromone. This prevents the ant walking in circles when it loses the trail. Instead, the ant moves forward in the general

© 2005 by CRC Press LLC

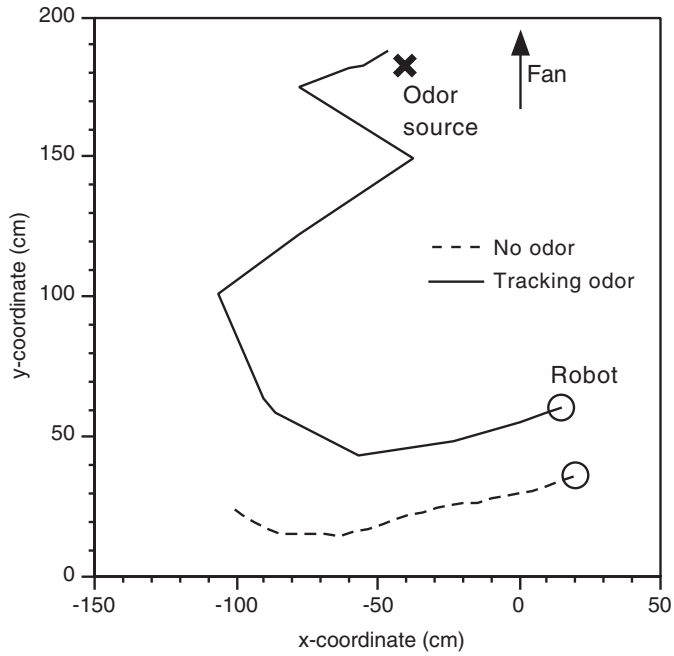

FIGURE 75.10 The path of a mobile robot as it locates the source of an ammonia plume using the dung beetle algorithm.

direction of the trail sweeping widely to left and right, which gives a good chance of picking up the trail again. The following algorithm was derived from this and implemented on a six-legged robot having two chemical sensors mounted ahead of the robot-simulating antennae (Russell, 1999c).

The ant trail-following algorithm:

- Take 8 paces bearing to the right until completed or until trail detected by the left antenna
- Take 8 paces bearing to the left until completed or until trail detected by the right antenna
- Repeat.

(If the left sensor detects the chemical trail, then the sequence of 8 paces to the left is started or restarted and stimulation of the right sensor starts or restarts the sequence of 8 paces to the right.)

Chemical trails were laid on the ground using a solution of camphor dissolved in ethanol. A few seconds after the trail was laid, the ethanol evaporated leaving a relatively long-lived layer of camphor. Chemical sensors were of the quartz crystal microbalance type consisting of an unencapsulated 10 MHz crystal coated with Silicone OV-17. The output of an oscillator incorporating the sensor crystal was subtracted from a reference oscillator to give a low-frequency difference signal that could be counted by a microcontroller.

One of the important advantages of the *Lasius fuliginousus* algorithm is the ability to accommodate large gaps in the chemical trail. This is not surprising because the pheromone trails produced by biological ants are made up of many discrete odor patches and probably have many gaps. To test the capabilities of this algorithm, a camphor trail was laid on the floor consisting of a 55 cm straight section, a gap of 40 cm, and then a further straight section finishing with a curve. The ant robot successfully followed the camphor trail in both right to left and left to right directions. Figure 75.11 shows the trajectory of the robot.

Locating the source of chemicals released underground

There are significant economic and humanitarian applications for methods of locating underground chemical sources. Such sources include land mines as well as chemicals leaking from gas pipelines and

© 2005 by CRC Press LLC

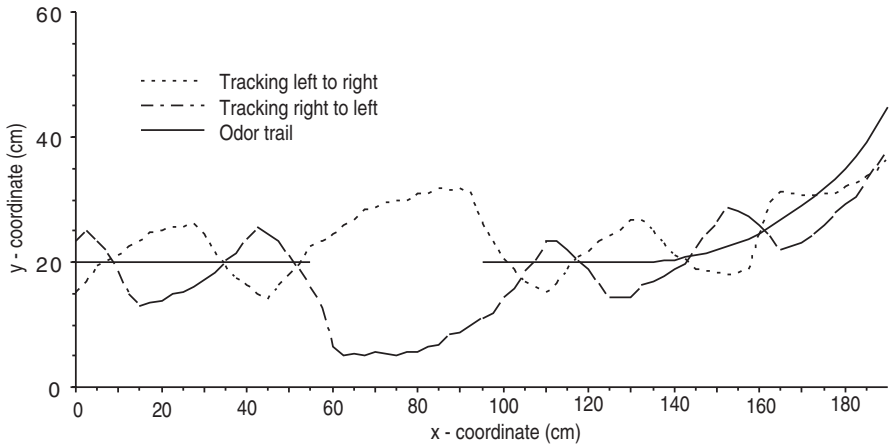

FIGURE 75.11 Practical results of robot chemical trail-following based on the ant *Lasius fulginousus*.

chemical storage tanks. If there is no pressure difference, chemicals are transported through the ground by diffusion. This provides a smooth distribution as opposed to fluctuating concentration produced by turbulence in air or water flows.

For the application of finding a chemical source, sensor readings must be taken in undisturbed soil and therefore the robot control strategy should take widely spaced readings. The following algorithm has been especially developed in the Intelligent Robotics Research Center at Monash University for this application.

The hex-path algorithm:

repeat

{

if (intensity at *n-2* > intensity at *n-1*) and (rotation direction at *n*-1 was anticlockwise) or
(intensity at *n-2* < intensity at *n-1*) and (rotation direction at *n*-1 was clockwise)

then rotate anticlockwise 60° and move forward *m*

else rotate clockwise 60° and move forward *m*

}

After burying the chemical source, a period of three hours was allowed to elapse for the chemical concentration to stabilize throughout the volume of sand. An airflow was established over the surface of the sand using a cooling fan to ensure that the surface concentration of ethanol was essentially zero. Without the fan, negatively buoyant ethanol vapor tends to concentrate above the surface and distort the chemical distribution in the sand.

Experiments were performed in a plastic container 60 cm long by 40 cm wide and filled to a depth of 10 cm with dry sand. The chemical source consisted of an open topped metal can 4 cm diameter and 2 cm deep half-filled with ethanol. A covering of cotton material over the open top of the can exclude sand while allowing the ethanol vapor to escape. This source was buried and covered by 4 cm of sand. To detect the ethanol vapor, a TGS2600 tin oxide sensor was used. In this experiment, the robot manipulator arm was used to guide a probe containing the sensor through the sand. Only the sensing tip of the probe penetrates the sand.

For the hex-path algorithm, two moves must be made before the algorithm can take over control of the robot. These two movements are shown by the dashed line in the plotted robot trajectory. These moves are deliberately chosen so that initially the robot is heading away from the source. Figure 75.12 shows a typical robot trajectory. When the probe is first inserted, a chemical reading is taken and then the robot proceeds by moving forward 3 cm, taking a chemical reading and then turning either clockwise 60° or anticlockwise 60°. The measured chemical sensor output is indicated by the size of the circle at each turning point. Recording stops when the sensor probe makes contact with the source.

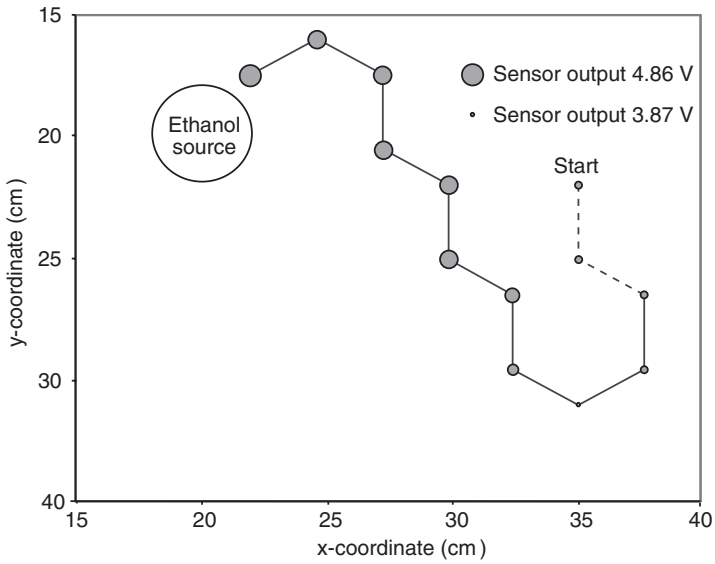

FIGURE 75.12 Experimental results showing sensor probe path as the robot locates the buried ethanol source.

75.5 Conclusion

Robots could use the ability to detect chemicals as part of an interrobot pheromone communication system. This would serve the same purpose as animal and insect pheromones to help organize large groups of robots and to pass information between them. Obvious applications include the laying of trails to aid navigation and the release of plumes of chemical to act as a distress call. In a manner similar to the use of sniffer dogs, chemical sensing robots could be used to enhance and project the human sense of smell.

The vital elements required to add chemical sensing capabilities onto robotic systems are appropriate sensors together with algorithms for processing the sensor data. It will be apparent from this survey that robotic odor sensing technology is still at an early stage of development. A small number of chemical sensors have been found suitable for use in robotics research. However, their sensitivity and selectivity are very poor compared with biological systems. The ability to follow chemical trails on the ground, to find an underground chemical source, and to locate the source of a chemical plume have been demonstrated experimentally. There are many important applications for this kind of capability but current systems have not been developed beyond an early experimental stage. The eventual availability of more sensitive, selective, and faster responding sensors will be one of the major factors governing the creation of chemically sensitive robots.

Ultrasonic Sensors in Robotics

76.1 Introduction
76.2 PRM Enhancements
76.3 Piezoelectric Sonar Ring
76.4 Advanced Sonar Sensing

Lindsay Kleeman
Monash University

76.1 Introduction

SOund NAvigation and Ranging (Sonar) sensing is a popular method for range measurement in robotics applications based on the active transmission of ultrasonic acoustic energy and the timed reception of the echo. The range to a reflector is computed from half the time of flight multiplied by the speed of sound, c. The speed of sound varies with temperature, humidity, and pressure. Detailed formulae for these effects can be found in [6]. The temperature dependence is most significant and is approximated by

$$c = 20.05\sqrt{T_C + 273.16}\ \text{msec}^{-1}$$

where T_C is the temperature in degrees Celsius. At 20°C, the speed of sound is approximately 343 msec^{-1}.

Sonar systems are popular in robotics applications due to their widespread availability, low cost, and ease of use. The most common form of sonar is the Polaroid 6500 Ranging Module (PRM) [12], which was originally designed for auto-focus cameras. The PRM uses pulse echo sonar whereby a short pulse of acoustic energy is transmitted and the same transducer acts as a receiver. The Polaroid ranging module reports the range to the nearest reflector based on a time-of-flight estimator using a fixed threshold on a received signal whose gain is increased in steps from the firing time. The position of the reflector is uncertain since the bearing angle to the reflector is only restricted to within the beamwidth of the transducer that can be as large as 30°. The PRM thus has poor angle measurement capability. Moreover, the echo amplitude is not directly measured either.

More recently, however, a technique has been developed by Roman Kuc [13], which can recover some echo amplitude information from the Polaroid ranging module by immediately resetting the thresholding circuitry when an echo is detected, thus allowing additional echo detections. The number of times the echo exceeds a threshold provides an estimate of the echo amplitude and this approach has been applied to differentiate specular targets (high amplitude) such as smooth walls from diffractive targets (low amplitude) such as edges. This approach is described in more detail in Section 76.2 of this chapter.

By processing the received signal using matched filtering on a Digital Signal Processor (DSP), significant improvements have been achieved in the estimation of time of flight [8]. Combining this time-of-flight

© 2005 by CRC Press LLC

estimation with the use of two transmitters and two receivers, an "advanced" sonar has been developed with the following enhancements. By using two receivers, the bearing angle to the reflector can be accurately estimated to an error standard deviation of approximately 0.1° in relatively still air conditions. Range error standard deviations are around 0.2 mm. Furthermore, by deploying two transmitters, reflectors can be classified into the geometric types of planes, concave corners and convex edges. One transmitter is fired a precisely controlled delay from the other (usually 150 to 500 μsec) to enable the echoes to be associated with the correct transmitter and also to enable interference from other sonar systems to be rejected on the basis of the arrival time separation. This advanced sonar system can classify reflectors, determine range and angle, and reject interference in a single transmit/receive cycle time. Processing can be achieved in near real time using DSP technology. Advanced sonar is described in more detail in Section 76.4 of this chapter.

An alternative approach to transmitting a short acoustic pulse is to use a Continuous Transmission Frequency Modulated (CTFM) approach. CTFM can allow greater energy to be transmitted compared to pulse echo techniques and hence the possibility of detecting weaker echoes exists. Arrival time is estimated from the frequency difference of the transmitted and received signals. Some researchers have also used this technique to classify plants for use as navigational beacons for mobile robots [3]. CTFM techniques are also described in [14].

A domestic vacuum cleaner robot is available from Electrolux [11], which incorporates a sonar system with a wide horizontal beamwidth of approximately 180° and a narrower vertical beamwidth of approximately 20° that reduces spurious reflections from floor surfaces. The transmitter is an electrostatic device 25 mm wide and covering 150° of the front of the robot. The transmitter operates at 60 kHz and echoes are detected with four microphones spaced around the front and recessed into the robot using tubes to further narrow the vertical beamwidth. More details are provided in [11].

Teruko Yata et al. [16] have developed a 360° ring of 30 transmitters and 30 receivers [15]. The transmitters are fired simultaneously to enable the surrounding environment to be sensed rapidly. Received signals are threshold with a decreasing voltage as a function of time from transmission, and receiver data are segmented to find the location of targets. The vertical beamwidth is narrowed using exponentially shaped wings. This system is described in more detail in Section 76.3.

76.2 PRM Enhancements

The PRM [12] provides a popular, low-cost, and simple to use sonar system. A single electrostatic transducer acts as a transmitter and receiver. A digital interface is provided whereby transmission of 16 periods of a 49.4 kHz square wave are emitted when the INIT digital input is asserted. On receiving of an echo, the digital output ECHO is asserted and the time of flight can be measured by timing the asserting of the INIT signal to the ECHO output. The echo signal is obtained from the same transducer used to transmit the ultrasonic pulse and is amplified with a time-varying gain. The gain is increased from the time of transmission in discrete steps. Rectification and lossy integration (for noise suppression) are used in the receiving electronics. When the result exceeds a fixed threshold, the ECHO output is asserted. Detailed modeling of the effect of beamwidth and thresholding is given in [12], which can assist in localizing reflectors given many PRM time-of-flight readings taken by scanning the direction of the transducer.

The PRM can be used to extract primitive echo amplitude information [13]. This works by applying a reset (using a pulse on BLNK input to the PRM) when the ECHO output of logic 1 is detected. Figure 76.1 taken from [13] illustrates the effect of this strategy. Notice that the number of ECHO pulses that appear are then related to the amplitude of the echo. Lines in Figure 76.2 represent ECHO pulses generated with this technique for various strength reflectors as the PRM is scanned across the scene.

76.3 Piezoelectric Sonar Ring

Piezoelectric transducers with wide beamwidth have been deployed in a ring of diameter 220 mm. Thirty transmitters and 30 receivers are alternatively positioned around the ring. The transmitters are fired simultaneously with a common drive voltage of 150 V that results in a receiver waveform lasting approximately

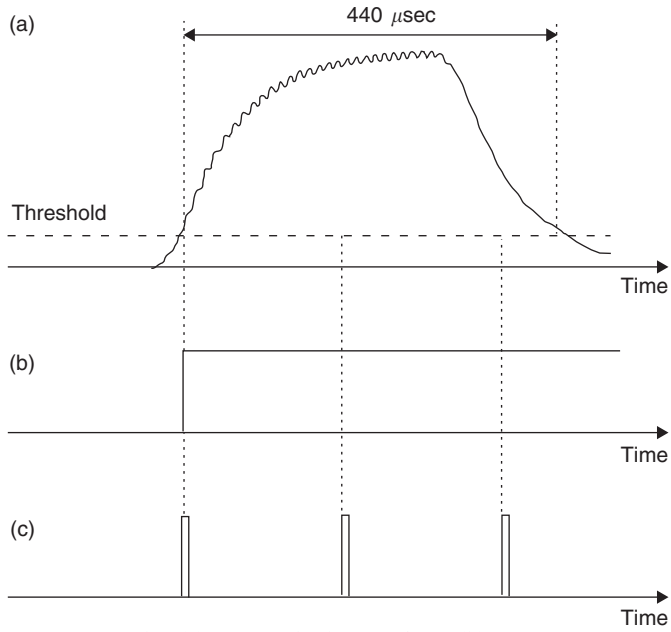

FIGURE 76.1 PRM operation modes: (a) processed echo waveform, (b) ECHO output produced in conventional time-of-flight mode, and (c) ECHO output produced in pseudoamplitude mode (taken from [13]).

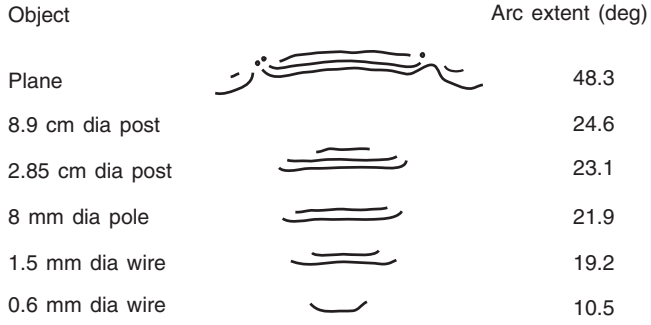

FIGURE 76.2 Pseudoamplitude sonar maps of six objects located at 1 m range. The sonar is located below the figure (taken from [13]).

700 μsec or 28 cycles at 40 kHz. The operation of the ring is illustrated in Figure 76.3 taken from [15]. A variation in echo amplitude of 2:1 around the ring for the same reflector is reported. This variation can be attributed to sensitivity differences in the transmitters, receivers, and constructive and destructive interference between neighboring transmitters. The received signals are amplified and compared with a threshold that decreases with time. The binary result from the comparison is stored in memory every 1 μsec for each of the 30 channels. The binary echo results are processed to determine the leading edge of each echo and associated across different channels into groups, each of which corresponds to a reflector in the environment. By fitting geometric models to the echo arrival times in each group, the range and bearing to reflectors are determined. One practical problem that is addressed in the design is removing "cycle hopping" artifacts — that is, the arrival time estimation based on a threshold is susceptible to signals that just fall below the threshold in one cycle on one receiver yet achieve the threshold on an adjacent receiver. This may mean that errors of close to a full cycle can appear in the data and this is explicitly recognized, and discrete trials of one cycle error compensation are instigated to bring about better matching with the geometric models. Standard deviations of 0.4° in bearing angle errors for 1.5 m range to 45 mm diameter rods have

© 2005 by CRC Press LLC

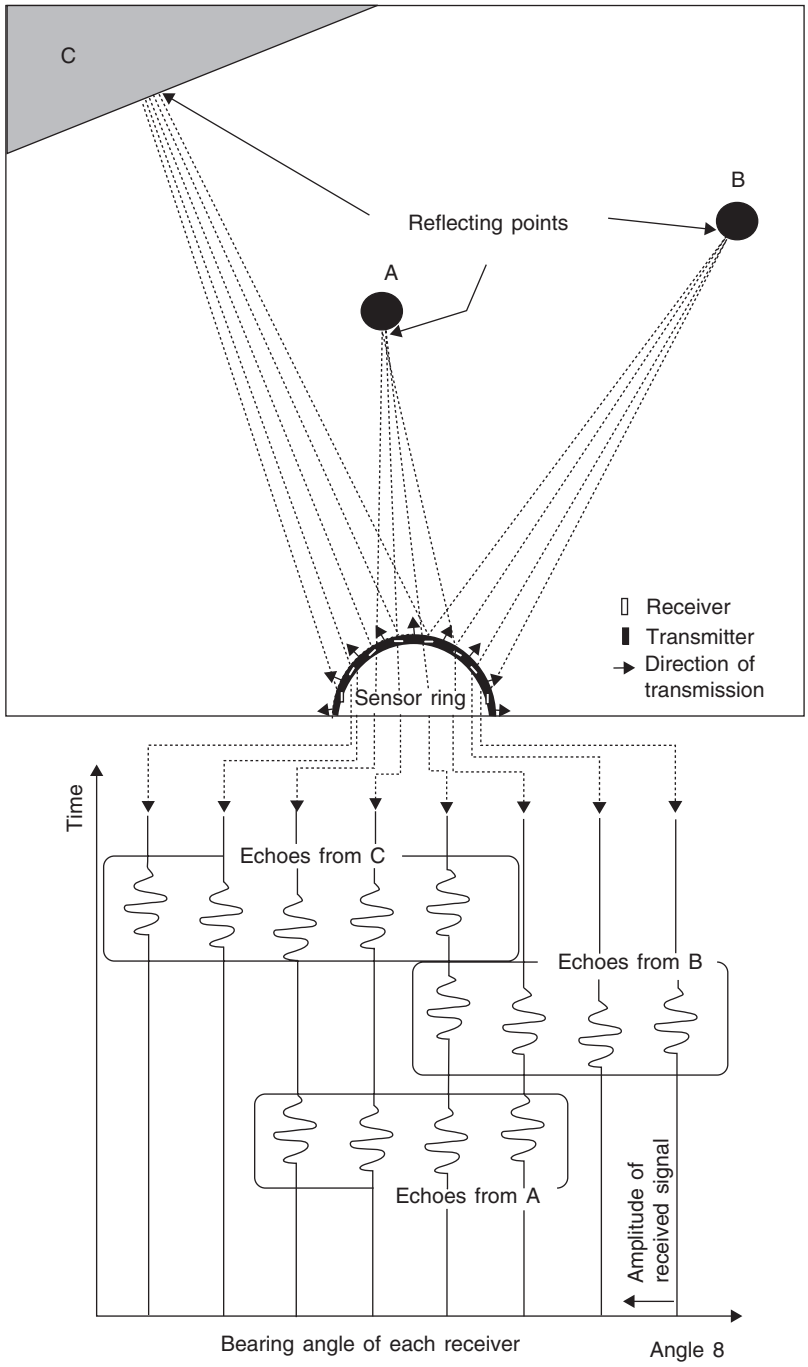

FIGURE 76.3 Representation of echo signals in a sonar ring due to three reflectors in the environment (taken from [15]).

been measured. Ranges beyond 2 m are not apparent in the experimental data. The system also has problems discriminating closely spaced targets, since the pulse duration of 700 μsec corresponds to approximately 240 mm in air. Thus, a second reflector closer than 120 mm in range would be masked by the first reflector due to pulse overlap.

76.4 Advanced Sonar Sensing

The term "advanced" sonar sensing refers to sensing that provides range, bearing, target classification, and interference rejection. This section describes how these features can be achieved and also the minimum sensor requirements. Range estimation can be achieved with a single transducer acting as a transmitter and a single receiver. Estimating the bearing angle in two dimensions of an echo can be achieved by two approaches.

The first approach uses just one receiver and estimates the angle based on the amplitude of the echo [16]. The echo amplitude at the receiver is a symmetrical function of the angle to the normal direction of the transducer, and consequently, only one side of the transducer beamwidth can be used to unambiguously measure the angle. By modeling the amplitude response of a circular transducer as a function of angle and range, an estimate can be achieved of the angle of reception from high reflectance targets. This approach is only practical for ranges less than 2 m due to the variation of absorption losses in air due to variations in humidity and temperature. Errors as low as 1° have been reported with this approach [16]. When the reflectance is low, it is difficult to differentiate the reduction in echo amplitude due to reflectance from angle reduction, unless an angular scan of the environment is taken and the amplitude model is fitted to the scan [7].

The second approach for bearing estimation uses two receivers and accurate time-of-flight estimation on each receiver. From the difference in arrival times of an echo, the angle of arrival can be accurately estimated. The accuracy is limited by the air conditions, such as turbulence and temperature gradients, and typical errors of 0.1° standard deviation have been reported in office-type environments [8]. The estimation of accurate arrival time is achieved by sampling the analog echo signal at 1 MHz with a 12-bit analog to digital converter and applying matched filtering digital signal processing. Matched filtering consists of calculating the correlation of the echo with an echo template for different positions of the template relative to the echo. The position of maximum correlation corresponds to the arrival time. The resolution of the arrival time can be improved over the signal sample time by fitting a parabola to the correlation as a function of time shift and using the peak of the parabola as the arrival time [8]. The template echo shape can be derived from a calibration procedure performed *a priori* that collects an echo from a plane reflector perpendicular to the transducer normal. This zero degree echo shape is distorted to account for different angles of arrival by double convolution with an elliptical impulse response with width proportional to the angle from normal [8]. A set of templates for different angles are generated and used in the matched filter of receiver data. The template shape also varies with range due to the dispersion of sound in air and this can be modeled to generate different template sets for each meter of range. When many echoes are received on the two receivers, the correspondence problem must be solved in order to extract bearing measurements. The correspondence problem is how to associate an echo on one receiver to an echo on the other. The problem can be alleviated by positioning the receivers as close together as the transducer dimensions allow, so that echoes on different receivers will be as close as possible in time, thus reducing the number of associations possible. Echo amplitude, template match angle, and other features can be used as attributes to assist in solving the correspondence problem. Nevertheless, certain reflector configurations can be constructed to produce ambiguous correspondences, but in practice, these occurrences are rarely found. A pragmatic approach is to flag any ambiguous correspondence and allow the resolution of the correspondence at a higher level in the data interpretation of even ignore these readings altogether.

Target classification with advanced sonar can be achieved with the following target types: plane, concave right angle corner, and point feature (often called an edge). A plane is analogous to a flat mirror in that a virtual sonar image is generated. Similarly, with a corner, two plane reflections occur and a reversed sonar image is formed. With a point feature, the echo appears to come from one position independent of the transmitter position and can correspond to high curvature objects such as table legs, or correspond to small concave corner reflectors where the dimensions of the corner are smaller than the transducer diameter. In order to classify targets into plane, corner, and point types, two transmitter positions and two receivers are required [8]. The classification process is analogous to observing one's image in a flat mirror, a corner mirror, and a shiny table leg. The image is reversed between the flat and corner mirrors, and the image is compressed into a small width in the table leg. In terms of sonar classification, one transmitter is fired and the angle of the echo is noted and then the other transmitter is fired

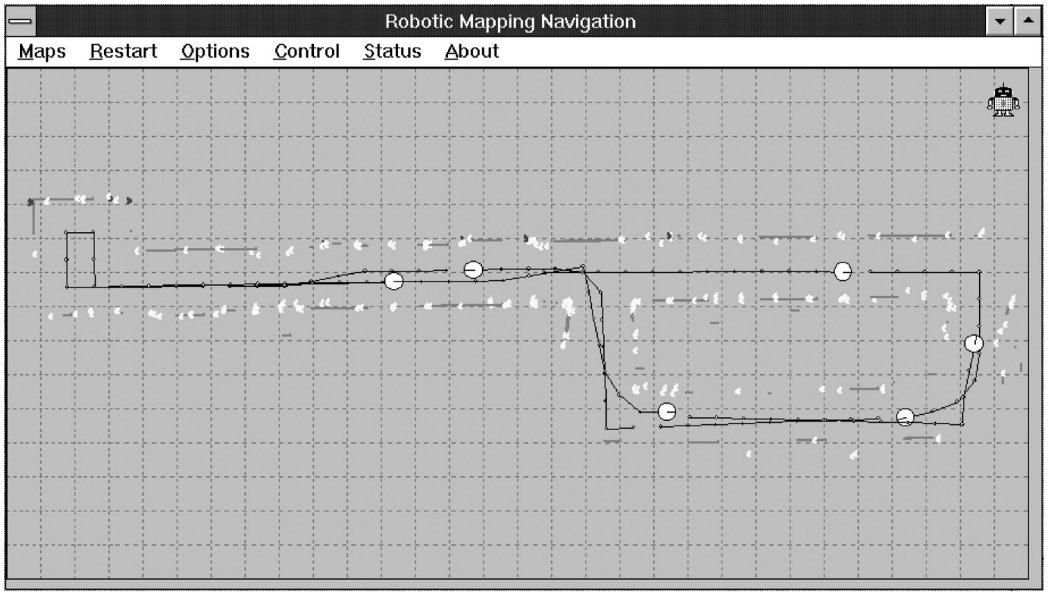

FIGURE 76.4 A large-scale sonar map generated by an advanced sonar sensor mounted on a mobile robot. Measurements are taken every 1 m of robot travel. A 1 m grid is marked with dashed lines and planes are shown as straight line segments, edges as "<" oriented marks, and corners by "<" oriented marks (taken from Figure 19 in [2]).

and the difference in angle is calculated. This angle difference can be used to determine the target classification. Large-scale simultaneous mapping and localization with a mobile robot have been achieved using this classifying sonar system [1, 2]. An example of a map constructed using advanced sonar is shown in Figure 76.4 taken from Figure 19 in [2].

Interference rejection allows multiple advanced sonar systems to operate in the same acoustic environment. The transmitter source of an echo needs to be identifiable. A double pulse coding approach is adopted in [10], whereby two pulses are transmitted separated in time by typically 150 to 500 μsec. Should two sonar systems interfere with each other, by examining the echo time-of-flight separations, the other sonar's transmissions can be rejected if they operate with different double pulse separations. One obvious problem is that echoes may overlap in time causing the arrival time estimation to fail. The echo energy has been concentrated into approximately 80 μsec or five or six cycles of 60 kHz to minimize this problem.

Classification and interference rejection have been combined into one sensing cycle [4], whereby two transmitters fire as the first and second pulses, respectively, of the double pulse code. In practice, the receiver arrival times can be associated with a transmitter by examining the relative timing. Moreover, double pulse spacing outside the expected range can be deemed to be interference and can be rejected. This approach has been implemented on a Digital Signal Processor (DSP) and runs in close to real time at 25 Hz repetition rate for ranges out to 5 m [9, 5].

77.1 Introduction

Mobility is an essential function for serving people; thus, mobile robots are expected to be useful tools for this purpose. However, many problems remain to be solved to utilize mobile robots in this way. One of the biggest problems for a conventionally architectured mobile robot is that of localization. Unlike robot manipulators, a mobile robot does not have a fixed base. Thus, a localization method with boundary errors is required, and the robot should possess a variety of sensors to localize itself [1]. Unfortunately, however, most methods used so far are not efficient when encountering disturbances, for example, slipping of wheels, parameter changes, and collisions. Although GPS is considered a robust method for localization, only outdoor mobile robots are able to use this system. To navigate in an environment, a mobile robot needs to have sufficient information about the environment. However, to handle such information and sensors for localization, high computational power would be needed by each robot. Even if a robot adopts subsumption architecture [2], the computational complexity does not decrease much. Moreover, it is thought that mobile robots in subsumption architecture have not been developed sufficiently for practical use.

Another problem is in importing the mobile robot into the environment. If we want to utilize different types of mobile robots in a particular circumstance, we need to prepare different software for each robot, according to its resources. Thus, a mobile robot, tuned up for a particular circumstance, cannot be used easily and immediately in a different environment. If the robots use active sensors and the signals interfere with each other, countermeasures must be considered; in the case of mobile robots using laser or ultrasonic sensors, this can often occur. Static information in robots also causes problems; even though a robot contains a perfect map of its working area, the actual environment, especially when there are people around, varies dynamically and the static information becomes useless. Adding to these drawbacks,

© 2005 by CRC Press LLC

there are many others such as obstacle avoidance and path following. To solve these problems involving classical mobile robots, the Intelligent Space [3] concept is adopted.

77.2 Intelligent Space

What is an Intelligent Space?

In recent years, computers and computer networks have proliferated, becoming important parts of our daily lives. Research on computers and computer networks, as well as computer-aided research has rapidly proceeded in a variety of ways in the recent past. The concept of an intelligent environment is one example. Intelligent environments are able to monitor what is occurring in them, to build their own models, to communicate with their inhabitants, and to act on the basis of the decisions they make. Especially, the capability of the environment to act as a context-sensitive user interface (e.g., to respond to gestures) and react in certain situations (e.g., accidents, intruders) promises a range of application scenarios such as intelligent hospital rooms, offices, factories, and asylums, such as for the aged. We concluded that such a system is a natural outcome of technological progress, and have been developing the concept of an "Intelligent Space" since 1996.

The main purpose of an Intelligent Space is to be a human-centered system. Up to now, many intelligent systems have been developed; however, when humans want to use such systems, they first need to learn how to operate the system. Moreover, since most of such systems have no mobility capabilities, humans should move in front of them to operate. In an Intelligent Space, humans can express their will by intuitive actions or by unconscious usual actions so that they do not need to learn how to use the Intelligent Space. Since humans are in the Intelligent Space, they do not have to move around to interact with it. Even other intelligent systems can be operated through the Intelligent Space; they are its agents.

Classification of Space

According to its affordance [4], we can classify a space into three classes; Figure 77.1 describes these. In Figure 77.1(a), there is a road in the midst of a forest. Only local and simple information of the space is afforded to the client of the space. Most of our natural environment belongs to this type of space. We call it "Potential Information Space." This space includes some information; however, to acquire it from the space, a client needs to have high intelligence. A natural environment is a representative example. In Figure 77.1(a), a person is able to recognize that it is a road intuitively. However, it is ambiguous as to where this road goes to, and a person who wants to use the road should prepare map-like things to obtain additional information on this space.

From Figure 77.1(b) people can understand where the roads lead to by the road sign. Whether there is a road sign or not, it does not change the fact of where the road leads. A space with artificial signs is called "passive information space." In this space, artificial signs are included in the natural space. A client needs to have less intelligence than in a potential information space, to acquire the information from this space; but only a client who has enough intelligence to gain the information from the sign can know where this road goes. An example would be our general living environment. However, the sign affords only limited information, whether the client needs the information or not. Artificial signs help people to understand the affordance of the space that cannot be found in a potential information space. However, to comprehend the meaning of an artificial sign, the user should study it in advance.

In Figure 77.1(c), active devices are distributed in the space and the devices inform affordance of the space in the relevant format for clients. Therefore, the clients of the space do not need to study to understand the affordance of the space in advance. This is called "Active Information Space." In this space, clients are able to request information of the space and the space replies to those requests. Since the space itself has intelligence, a client needs the least intelligence, of the three examples, to gain information from the space. Information of the environment in potential information and passive information spaces is too difficult to be understood by robots. Although in a passive information space, artificial signs and symbols help to understand affordance more easily, such things are not designed for robots but for humans. However, in an active information space, information is transformed into an easy format for robots.

© 2005 by CRC Press LLC

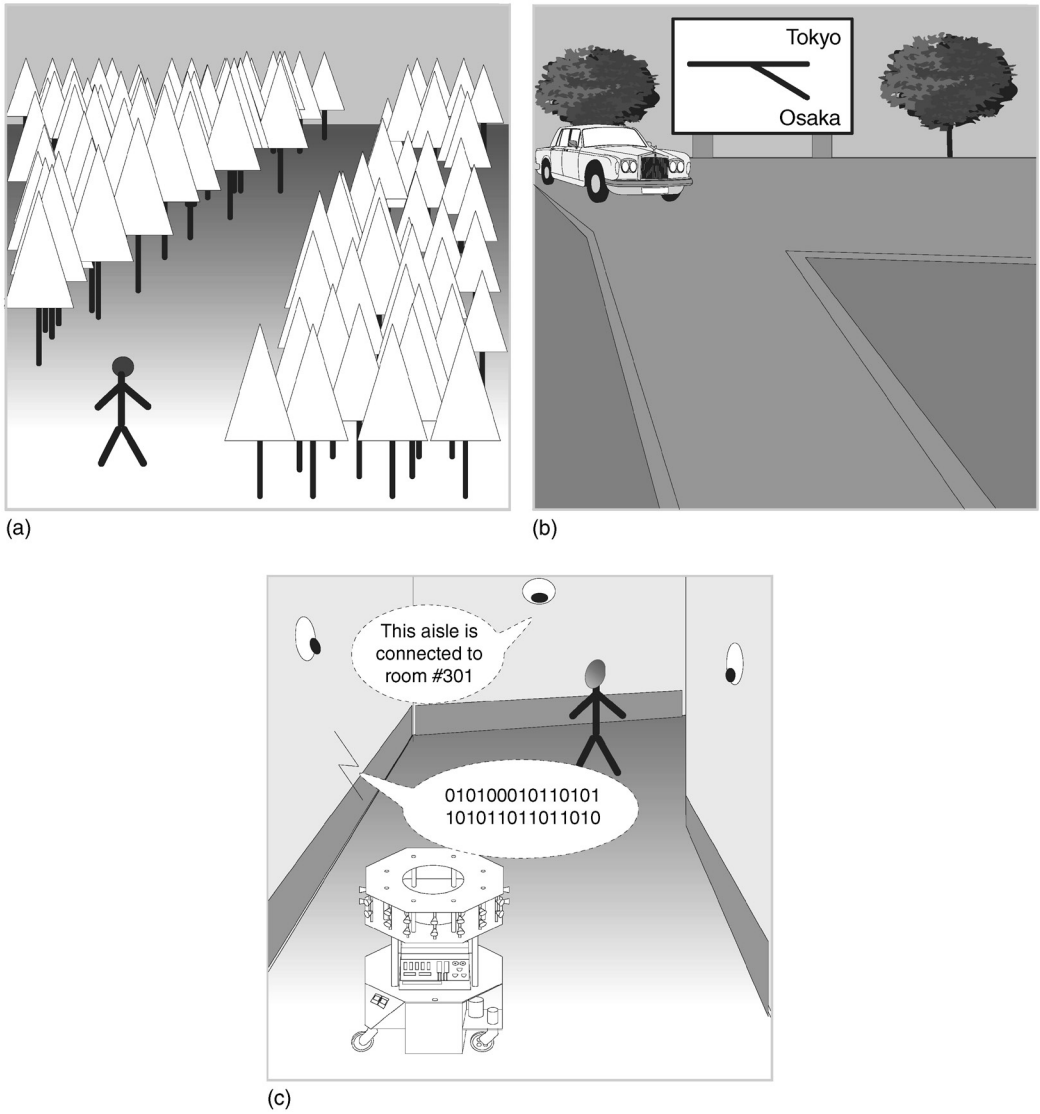

FIGURE 77.1 Classification of spaces: (a) Potential information space, (b) Passive information space, (c) Active information space.

The former two spaces are easily found in everyday life. However, the last space is hardly ever found around us. An Intelligent Space belongs to this active information type space. Due to the feature that the space adapts itself to clients, the Intelligent Space is a soft environment, not only for humans but also for artificial systems including robots.

Architecture Required for an Intelligent Space

The most important required property of an Intelligent Space is the scalability of the system. Since an Intelligent Space is a spatial system, it must be adaptable to any shape or size of space. An Intelligent Space should be coherently and easily applicable to the general environment that people live in. Therefore, large changes in environments will be undesirable for the application of an Intelligent Space. Incompatibility should also be considered, since the environment is not for the system, but for the people who inhabit the

© 2005 by CRC Press LLC

space. A designer of an Intelligent Space should make an effort to ensure that people do not feel an incompatibility with the system.

From the standpoint of Intelligent Space development, several points need to be satisfied. Since the functions of an Intelligent Space are continuously being developed, new or revised functions should be easily applicable to the Intelligent Space. If both hardware and software are made as modules, the Intelligent Space might be easily renewed. It should be simple to integrate existing intelligent components or services into a room. As many intelligent components are needed, the cost of a single component should be low. This requires the use of industry standard-type hardware. Setting up and maintaining an Intelligent Space should be possible with minimal effort. The space must be able to learn about itself (e.g., model building, autocalibration) and site-specific adaptation has to be easily achieved. In addition to the above properties, Intelligent Spaces should also be easy to administer.

Intelligent Space with Distributed Devices

To satisfy the required architecture described above, we devised the Intelligent Space based on Distributed Intelligent Network Device (DIND), which is composed of three basic elements [3]: Sensors, processors (computer), and communication devices. DIND is a small device based on three functions that the sensor watches: the dynamic environment, which contains people and robots; information, which is processed to be known easily by the clients by the processor; and the DIND communicates with other DINDs through networks. Figure 77.2 shows the basic structure of a DIND. By installing this DIND into the whole space, it can recognize objects inside the space easily, and it is enabled to perform informational exchanges and informational sharing by communicating through the network. Further, since such functions are obtained by just attaching DINDs, the space, where people live, is altered into an intelligent environment, without much effort.

Related Works

Integrated intelligent environments have their origin in ubiquitous computing. In 1991, Weiser introduced the area of ubiquitous computing where people could use computational resources everywhere in the environment [5]. Ubiquitous computing promises more than just infrastructure. It suggests new paradigms of interactions inspired by widespread access to information and computational capabilities. From the mid-1990s, research into intelligent environments has been undertaken. The recognition and awareness of people in environments are more focused in intelligent environment research than in other forms of ubiquitous computing research [6–9]. However, these studies have focused only on supporting humans.

Combined research on distributed sensor networks and network mobile robotics has recently appeared [10,11]. Horling et al. proposed Distributed Sensor Networks with early experimental results. The system consists of a set of reconfigurable sensors at fixed locations, each having local processing and low-bandwidth communication capabilities with other sensor nodes. The objective of the sensors is to track objects

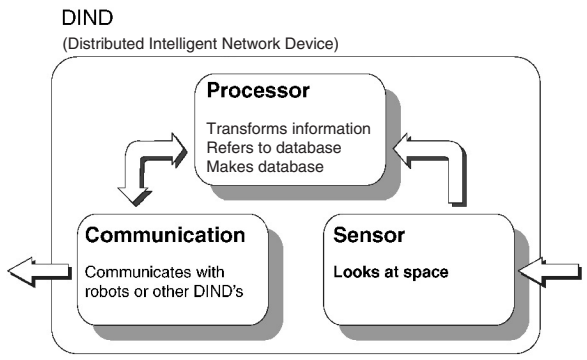

FIGURE 77.2 Architecture of DIND.

moving in the environment. Hoover and Olsen located video cameras in the environment to guide mobile robots to avoid collisions. This resembles some parts of the functions of an Intelligent Space. However, their system has some drawbacks in that the system needs several cameras to observe an area. Moreover, how to identify a mobile robot, which enters into the area within the system, is unclear. The main difference between their system and mobile robots in our Intelligent Space is the independence of the distributed devices. Their system is a centrally integrated system, where as each of the sensor devices in the Intelligent Space operates independently.

77.3 Intelligent Space for Mobile Robots

Among the functions of the Intelligent Space, in this chapter we focus on functions for mobile robots. As far as we know, the Intelligent Space is a unique system to guide mobile robots utilizing distributed intelligent sensor devices.

There are many situations where mobile robots are required. In homes, offices, hospitals and factories, robots are expected to play important roles, mostly supporting people. However, to be able to use a robot in such an environment requires many problems to be overcome (some reasons are described in Section 77.1). Among those situations, a factory is different from the others, since production lines and warehousing facilities in factories are well equipped with infrastructure and the center of the space is not focused on humans. Often, productivity and efficiency are the most important items in factories, so that the Intelligent Space, which needs to change the environment, is more easily adopted than in other environments.

Currently, most factories utilize AGVs for unmanned transportation. However, to use an AGV, some methods of guiding AGVs must be prepared. The representative method is one that uses special tapes as a guide-rail. In this case, it is difficult to cope with frequent structure changes in a factory. All the guide tapes must be restuck to the floor every time there is a structure change. To detect obstacles, which are mainly human, an AGV needs range sensors. If more than one robot is in the same area, some sensors such as an ultrasonic sensor or a laser rangefinder, must be used carefully. Since such sensors are easily interfered, some methods to overcome interference are required. Adding to these, there are many disadvantages in using AGVs in flexible and complex production lines.

In the Intelligent Space, all such kinds of problems are solved. Because there are no guide-rails in the Intelligent Space, the paths for robots are easily changed according to the change in the factory structure. The mobile robots do not require sensors for detecting obstacles since the Intelligent Space monitors the inside of the space. Obstacles, including humans, can be detected and information about them can be given to robots by the Intelligent Space. Apart from these points, there are many other positive reasons for adopting affordance. Figure 77.3 describes the differences between a conventional AGV and an AGV mobile robot in an Intelligent Space factory.

77.4 System Design of an Intelligent Space for Mobile Robots

We developed an Intelligent Space with mobile robots in a factory in cooperation with Toshiba IT & Control Systems Corporation [12]. Unlike other experimental systems in laboratories, this required a high degree of robustness for the components of the Intelligent Space. We developed the system based on the standards of the Japanese Standards Association (JSA) [13]. According to these standards, the maximum speed of mobile robots in factory is about 30 cm/sec and the minimum illumination is 200 lux.

Hardware Architecture

The factory is divided into several areas and each is monitored by a DIND. According to the placement of the DIND, important parameters, including size of the area covered and tracking precision, vary, since for the moment we adopt a vision camera as a sensor for a DIND. Therefore, the disposition of DINDs is one of the most important problems in composing an Intelligent Space. There is an on-going study to ascertain the optimal disposition of DINDs in any particular place [14].

© 2005 by CRC Press LLC

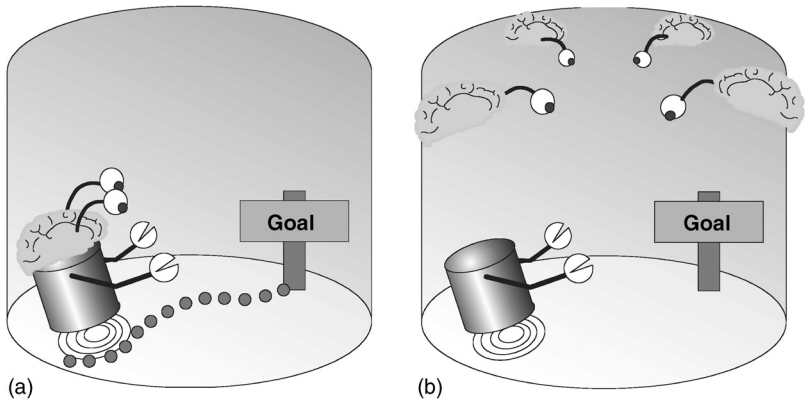

FIGURE 77.3 Mobile robot in environment: (a) conventional AGV and (b) AGV in Intelligent Space.

DIND

As explained in a previous section, Intelligent Space is composed of DINDs. In an actual system, a cheap CCD camera and a general bt848-based image capture board is adopted as a sensor. For the processor, an industrial standard Pentium III 500 MHz PC is used and a general 100baseT LAN card is used as the network device. With these components, one actual DIND can be assembled for less than 400 U.S. dollars.

Robots are able to use the resources of DINDs as if their own parts [24]. However, we could also consider that the robots in the Intelligent Space are a part of a DIND.

Color Bar-Codes

To find mobile robots in an Intelligent Space, four yellow targets are placed around the body of each mobile robot. These targets are found by DINDs, but since it is difficult to match the found blobs correctly, further clues are required to identify each target. For this, color bars, located under the targets, are utilized. A color bar consists of several colored fields. Each of the fields can have one of the eight predefined colors. With this technique, we are able to distinguish the mobile robots and localize that robot by considering the geometrical relations. There are some other methods to localize mobile robots with camera sensors, but the best way to localize the mobile robots is judged to be without adding any other artificial equipment to the robots. However, to achieve a high robustness for the system, we adopted color bars. A trade-off relationship exists between using additive equipment and robustness; but in this case, there were positive reasons, such as identification of mobile robots, and high precision positioning gained by using an energy-free passive piece of equipment.

Mobile Robots

Neither range sensors to detect obstacles around them nor positioning sensors to estimate their pose themselves are needed by mobile robots in the Intelligent Space. Robots only require passive color bars and a communication device to communicate with DINDs. Due to the communication between robots and DINDs, robots are able to freely use sensors in the DINDs. This is a kind of resource sharing, and this feature leads to lower cost robots, since expensive sensors, such as gyroscope sensors, and laser rangefinders are not needed. A simple Programmable Logic Controller (PLC) board, motors, and a wireless LAN (IEEE 802.11b) were installed in the robot that we used in this system.

Software Architecture

Linux was adopted as the operating system in the DINDs, and all software algorithms were written in C++ and the GUI parts were written in TCL/TK. In this application, the required functions of the Intelligent Space are summarized into two. One is to detect humans and unknown obstacles and the other is to handle mobile robots.

© 2005 by CRC Press LLC

Localization procedures for humans are shown in Figure 77.4(a). A pair of DINDs are needed to generate the 3D position of humans or obstacles [15]. However, in this chapter, since we are focusing on functions for mobile robots, a detailed explanation is omitted. In the case of obstacles, whatever it is, background separation is used.

For the calibration of a DIND, we adopted Tsai's calibration algorithm [16] and made a GUI calibration module. The calibration module is an application module that is interactively launched by an operator. It uses a graphical interface to specify the points of the grid and their coordinates.

Localization of Mobile Robot

Unlike the case of detecting a human, to localize a mobile robot in the Intelligent Space, only one DIND is required. Because the height (z-axis) of the targets is known, only one camera is needed for a precise 3D construction. The procedure is shown in Figure 77.4(b). From the acquired image, a search for the color region and the background separation is performed simultaneously. In this system, since the color of the target is yellow, the yellow regions are searched. The background separation module compares the current image and the background image, and selects only that region where movement has occurred. We chose an adaptable background to make the background separation module work robustly. Changes in

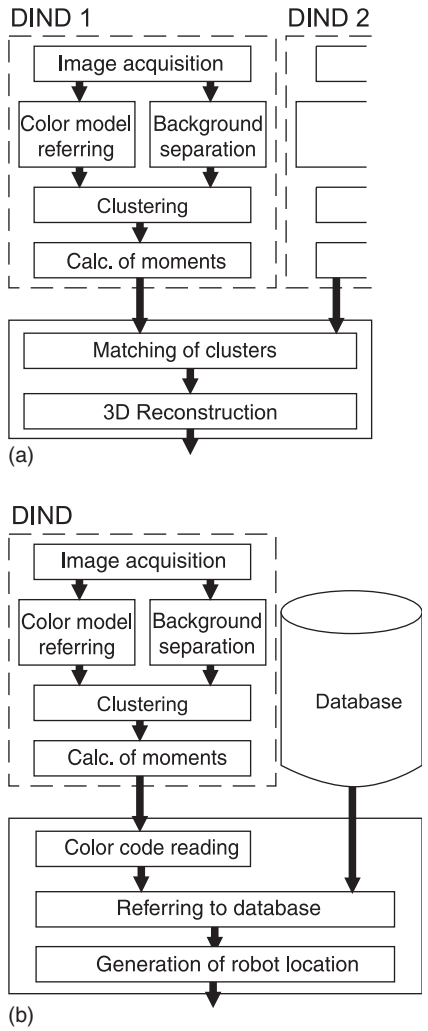

FIGURE 77.4 Localization module: (a) procedure for human or obstacles and (b) procedure for mobile robots.

© 2005 by CRC Press LLC

lighting, moved objects, and camera signals will alter the image slightly and to cope with these, a continuously updated background model is needed. Since the captured background image gradually changes into the current image, the background image can always be retained in the current background. Outputs from color region searching and background separation are compared in the clustering process. Only common regions are conveyed for the calculation of the movement module, and 2D positions of the regions are calculated. Since a DIND has a database of the height of the color bar, one DIND is able to estimate the position of a colored target. The 2D positions of color targets in the image coordination are converted to 3D positions in the camera coordination. After the target detection procedure, to get rid of errors, the 2D euclidean distances between detected targets are checked. If the distance is too long or too short, the detected targets are neglected. Even after this, the result may still contain recognition errors. According to the DIND's database, each color code, placed below the yellow target, is checked. If color codes, which are not shown in the database, are detected, they are removed from the list. From this process, the DIND is able to recognize which robot it is detecting.

The geometrical relations, stored in the database, are compared between the color codes and it generates the pose of the robot. The pose of the robot is calculated from the pairs of color codes, with the same time stamp. The pose of a robot is estimated from the geometrical relation, if at least one pair is recognized. Below are equations to estimate positions and directions of robots. The parameters are described in Figure 77.5.

$$x_r = \left(\frac{x_1 + x_4}{2}\right) - \frac{l_2}{2}\cos\theta_r, \quad y_r = \left(\frac{y_1 + y_4}{2}\right) - \frac{l_2}{2}\sin\theta_r \tag{77.1}$$

$$x_r = \left(\frac{x_2 + x_3}{2}\right) + \frac{l_2}{2}\cos\theta_r, \quad y_r = \left(\frac{y_2 + y_3}{2}\right) + \frac{l_2}{2}\sin\theta_r \tag{77.2}$$

$$x_r = \left(\frac{x_1 + x_2}{2}\right) + \frac{l_1}{2}\sin\theta_r, \quad y_r = \left(\frac{y_1 + y_2}{2}\right) - \frac{l_1}{2}\cos\theta_r \tag{77.3}$$

$$x_r = \left(\frac{x_3 + x_4}{2}\right) - \frac{l_1}{2}\sin\theta_r, \quad y_r = \left(\frac{y_3 + y_4}{2}\right) + \frac{l_1}{2}\cos\theta_r \tag{77.4}$$

$$\theta_r = \tan^{-1}\left(\frac{y_1 - y_2}{x_1 - x_2}\right) = \tan^{-1}\left(\frac{y_4 - y_3}{x_4 - x_3}\right) \tag{77.5}$$

$$\theta_r = \tan^{-1}\left(\frac{y_4 - y_1}{x_4 - x_1}\right) + \frac{\pi}{2} = \tan^{-1}\left(\frac{y_3 - y_2}{x_3 - x_2}\right) + \frac{\pi}{2} \tag{77.6}$$

where (x_r, y_r, θ_r) is the pose of a robot and (x_n, y_n) is the position of a color bar $(n=1,2,3,4)$. Actually, there exist six possible pairs in four color bars. However, only four pairs are utilized in the system due to an empirical decision.

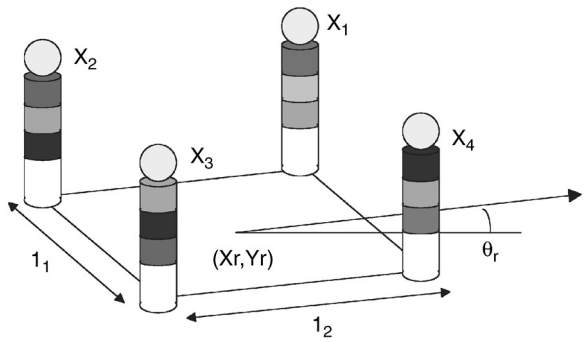

FIGURE 77.5 Color bar codes and parameters.

Mobile Robot Control with DIND

The mobile robot control module produces control input for the mobile robots. A DIND senses the mobile robots, and a vision server module estimates its pose. According to the desired path and the estimated pose, control inputs for mobile robots are generated and transferred to the mobile robots through the wireless LAN (IEEE802.11b). The flow of information is closed. Based on the current pose of the robot, the velocity generator module in the DIND generates both linear and angular velocity for the mobile robot to approach the target position. When the robot position is estimated clearly and the distance between the robot and the subgoal is larger than a defined value, the velocity generator produces maximum velocity and when robot detection is incomplete, it makes the robot stop. Therefore, when more than three color bars of a robot are occluded, the velocity generator module stops the robot.

Network Communication

DINDs and mobile robots organize a network and there are two kinds of communication within it. One is communication between DINDs; because each DIND only monitors its own area, other DINDs do not know that an event occurs at the other area. However, the real space is continuous to the clients of the DINDs, whether they are humans or robots. Thus, to supports themselves, DINDs should inform others of any event in their area that is apt to be shifted to adjacent areas. To guide mobile robots in the Intelligent Space, the dominant contents of communication between DINDs are mainly negotiations for control authority over mobile robots and information on the robots.

The other is communication between DINDs and the mobile robots. The mobile robot informs its internal state to the DINDs, and they mainly offer control signals.

Handing Over of Control Authority

A DIND is an independent device, and its functions, including localization and control of mobile robots, are performed completely within it. Thus, if a mobile robot is moving in the area that one DIND is monitoring, the robot is guided without any difficulty. However, to guide robots in wider areas, which a single DIND cannot cover, we defined the DIND that has control authority of a robot as the dominant DIND for that robot. When a robot moves from an area to a different area, the dominant DIND for the robot is changed automatically. We called this handing over of control authority. The dominant DIND has control authority of the robot and only one dominant DIND exists for a particular robot at one time. Therefore, the control authority should be smoothly handed over to the next DIND at the proper time and at the proper location. To solve this problem, a reliability rank is devised. High reliability stands for that DIND can guide a robot robustly and precisely. Generally, an area near the DIND and a center area of an image, which a DIND captures, have the highest reliability rank, and the boundary of the image and an area far from the DIND have the lowest reliability, since a vision camera is adopted as a sensor of a DIND. There are two cases for becoming a dominant DIND. One is that when a DIND finds a robot in its area and there is no dominant DIND for the robot. The other case occurs when there is a request to be the dominant DIND made to the robot from the current dominant DIND.

Figure 77.6 introduces how the reliability rank is determined. Figure 77.6(a) is an area monitored by a DIND and it is divided into four parts according to distance from the DIND. In Figure 77.6(b), the image is divided into three areas. Even though a good calibration algorithm is adopted, the outskirts of the image are greatly distorted since a vision sensor with a lens is used. Based on these two partition methods, actual reliability ranks in the monitored area are determined as shown in Figure 77.6(c).

Handing over of control authority on a robot is performed as follows. When DIND(n) is the dominant DIND for a robot, the dominant DIND(n) requests other DINDs about the reliability rank of the robot. The other DINDs reply with their reliability rank for the robot, and the current dominant DIND(n) compares those values with its own rank. If another DIND has a higher rank, then the current dominant DIND(n) transfers authority of control to that other DIND(n+1) that has a higher rank for the robot. Then the new dominant DIND(n+1) controls the robot. However, if authority of control is shifted to a

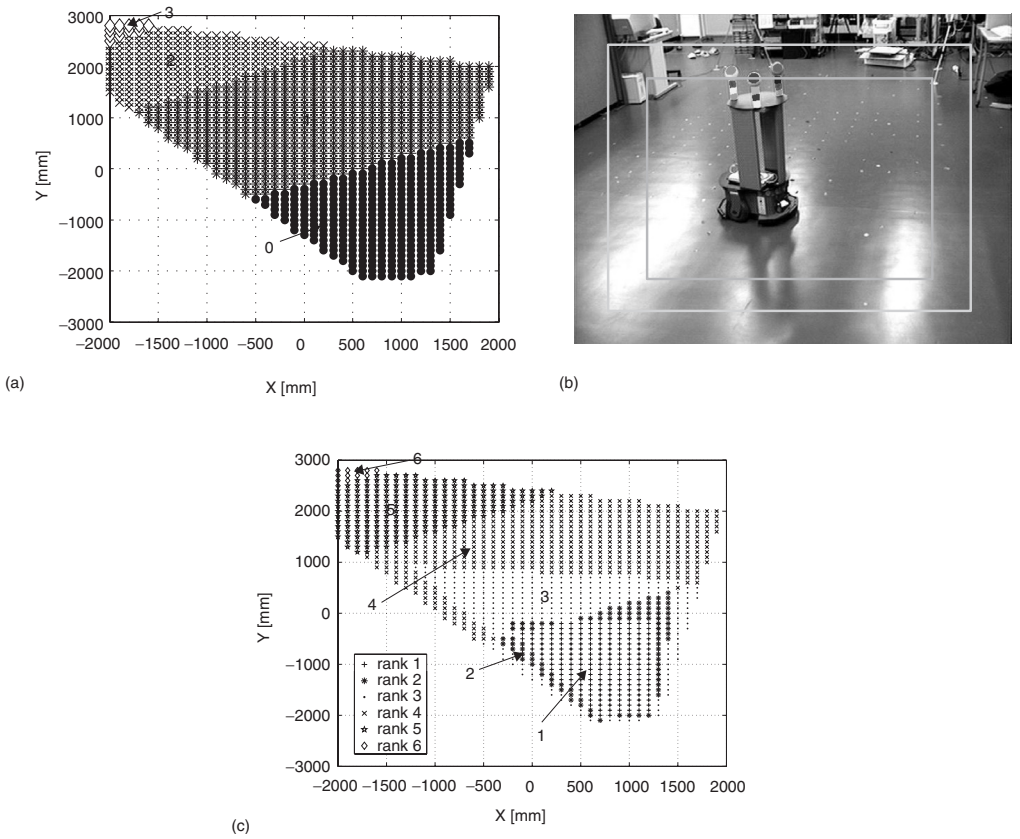

FIGURE 77.6 Reliability rank map: (a) based on distance from DIND, (b) based on capturing image, and (c) combined reliability map.

new DIND with the condition,

$$R_d > R_{other} \tag{77.7}$$

chattering may occur in handing over of control authority, where R_d and R_{other} are the reliability ranks of the dominant DIND and another DIND, respectively. Therefore, instead of (77.7), the following condition is used to avoid chattering:

$$R_d > R_{other} + \alpha \tag{77.8}$$

where α is the offset value to avoid chattering. Empirically, α is set to 1 in an actual system.

77.5 Demonstrations

Since the system that we describe in this chapter is obviously targeted at practical use, its operating characteristics need to be thoroughly examined and tested.

Position Estimation

When DINDs are distributed over an environment, the precision of 3D detection of robots should be considered. A visible area does not mean a serviceable area for a DIND. It is natural that the precision of an estimated position is very much related to the distance between robots and the DIND. The further

© 2005 by CRC Press LLC

away a target is from the DIND, the more the precision worsens. To divide areas in a space, and in order to allocate such areas to DINDs, we should measure estimated position errors all over the space. Based on the results, the areas are divided and their DINDs are determined.

We located two DINDs in our experimental space. Figure 77.7 shows the coordination and locations of those DINDs. To find a serviceable area for detecting robots, we located a robot at several points in the visible area of the DINDs and measured errors between real and estimated values. This process is performed over and over in the various directions of a robot. A robot was located at 15 different points and the two DINDs were located at (−200, 4980, 2140) and (8500, −180, 2050). Illumination conditions were dependent on time and position, and varied from 200 to 1000 lux. According to the measured results, directional error was less than 3.5° and the position error was less than 17 cm within the entire serviceable area.

Mobile Robot Control

A robot was controlled by a DIND to follow a path and the DIND is able to guide the mobile robot to reach a goal; but actually, goals are not always in a DIND serviceable area. The work area is divided into several serviceable areas of the DINDs. To enable a robot to reach a goal, which is not in the same serviceable area of a DIND, more than one DIND needs to cooperate. In this case, a DIND guides a mobile robot to reach an adjacent supervisory area of another DIND, and the control authority is handed over to the adjacent DIND. Thus, the robot can move freely and seamlessly go everywhere in the Intelligent Space. Figure 77.8 shows an example of this. Figure 77.8(a) and (b) show monitor windows of DIND A and DIND B, respectively (refer to Figure 77.7). Some recognition errors and failures of recognition are found in each monitor window. However, since the control authority is handed over according to the reliability rank value, the robot was properly supported by the two DINDs. In the monitor window, the line is the trajectory of the mobile robot. The circle and arrow indicate the mobile robot and its direction, respectively. The ladder shape is the expected progressing area of the mobile robot. The thick-lined square represents the workspace of the mobile robot.

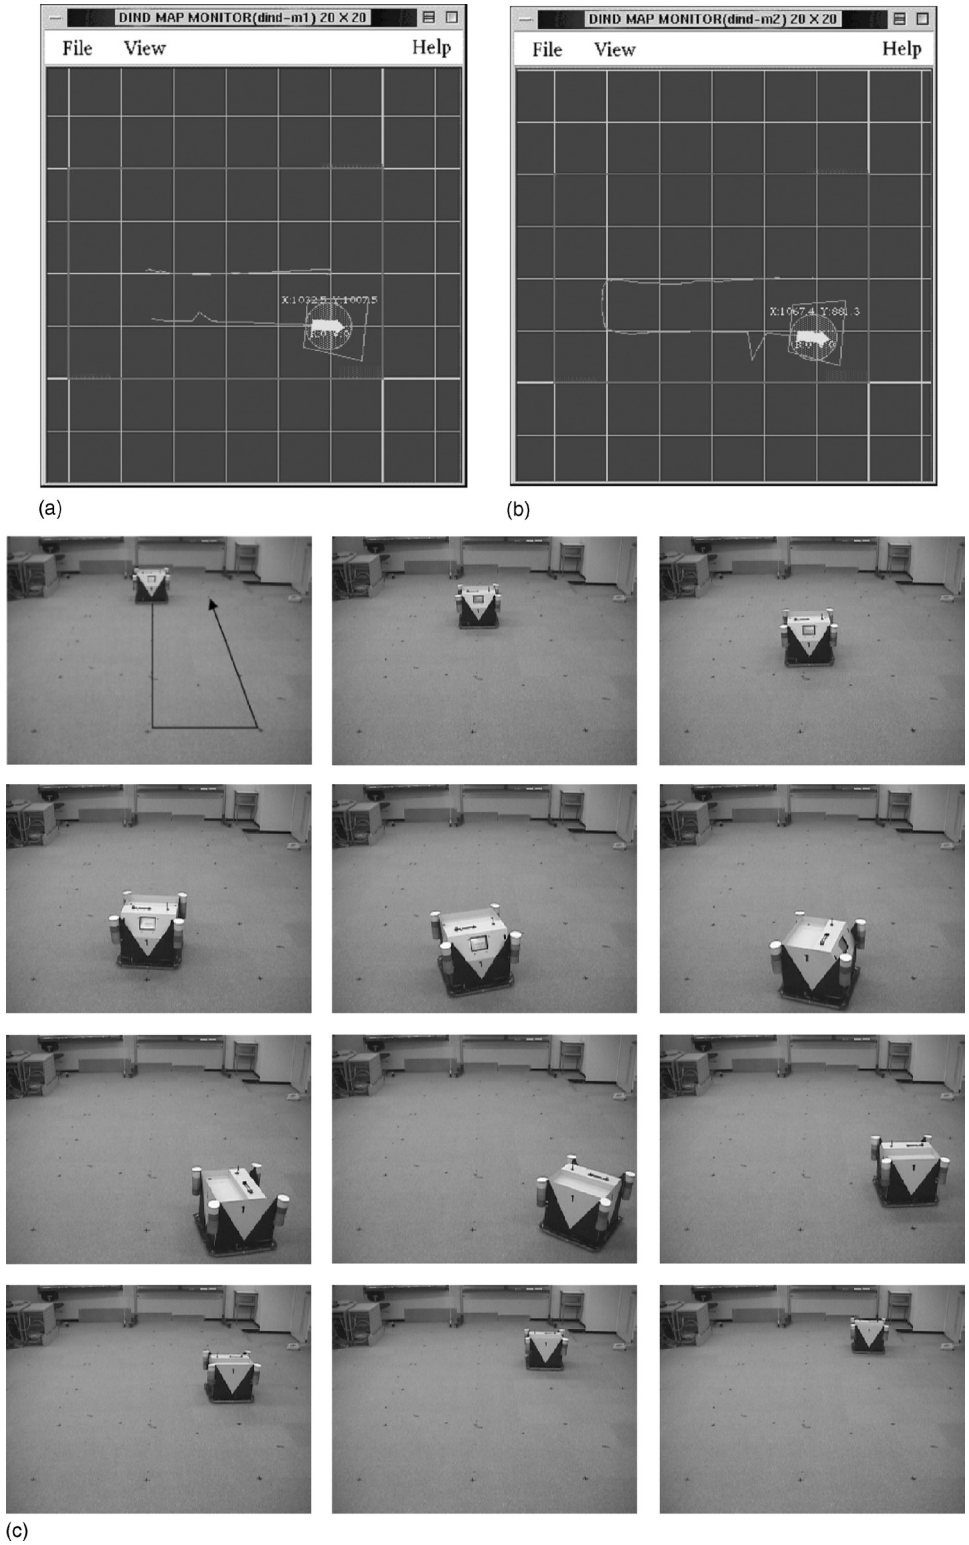

FIGURE 77.8 DIND's handing over of control authority: (a) monitor window of DIND A, (b) monitor window of DIND B, and (c) handover demonstration.

© 2005 by CRC Press LLC

The length of the path in Figure 77.8 is about 8000 mm. The approximated serviceable areas of DIND A and DIND B are the right and left sides of the space, respectively, as shown in Figure 77.7. Figure 77.8(c) shows the actual movement of the robot. The photos in Figure 77.8(c) were captured from video stream with about a 3 sec interval. The robot was guided to follow a path that is shown in the first figure. The robot started from the area where DIND A monitors and moved to the area where DIND B monitors. The robot was controlled to change its direction and returned back to the area where DIND A monitors. The cycle of the control loop is 300 msec. This does not mean that the loop of the image processing is 300 msec, as it is not fixed, but it takes about 60 msec to find a robot from the camera image. It is possible to decrease the cycle to be faster than this. However, currently, since a real-time OS is not used, extra time is required to maintain a regular interval for the control cycle.

When DINDs guide more than one robot, a priority level among the robots exists, and it is contained in the database of the DINDs. According to this priority, one robot should give way when it blocks another's

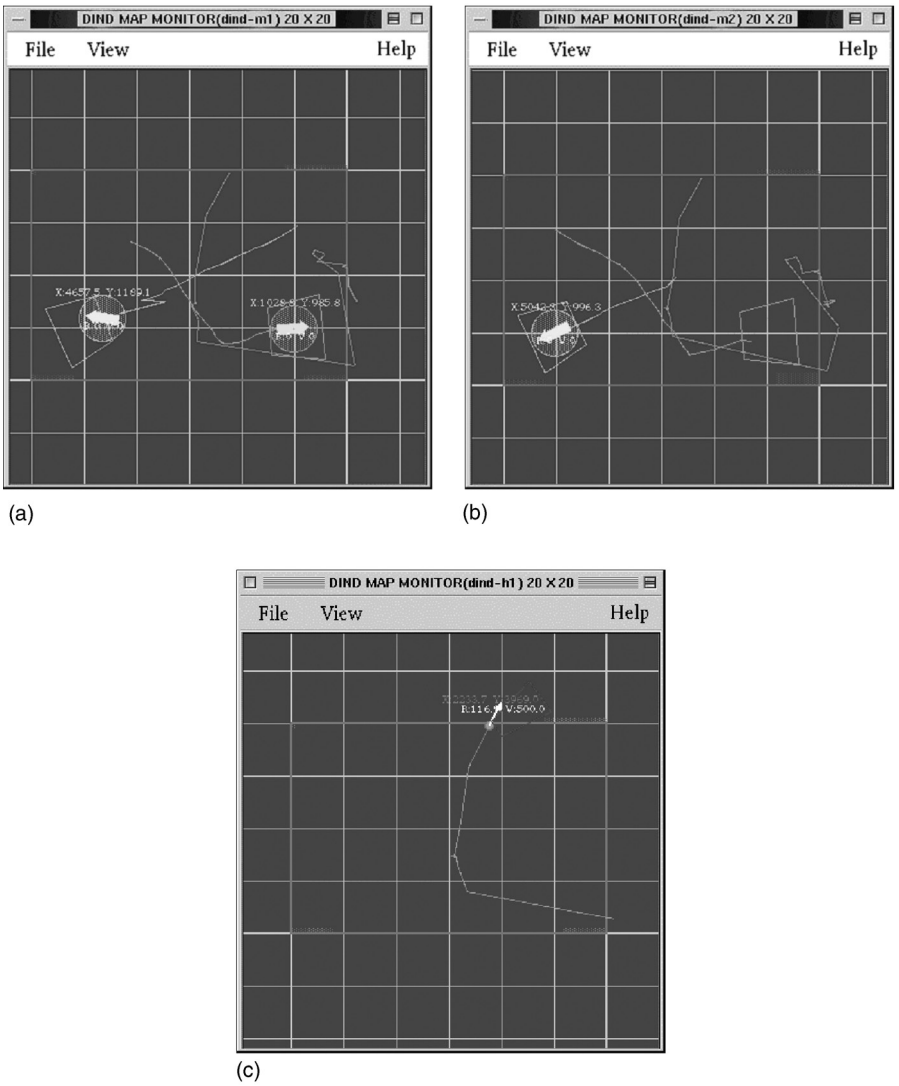

FIGURE 77.9 Trajectories of robots and a human: (a) monitor window of DIND A, (b) monitor window of DIND B, and (c) monitor window for a human.

© 2005 by CRC Press LLC

path. A path for a robot with high priority is modified to avoid the other robots, which wait for the other robot to pass by. Similar situations occur when the ways of robots are blocked by dynamic obstacles, mainly humans. According to each situation, paths are modified or robots stop for the obstacles to pass by. We demonstrated this situation; first, a man blocked the way of a mobile robot, and then two mobile robots blocked each other's way. DINDs understood the situation and guided the mobile robots based on this. Figure 77.9 shows the monitor windows of DINDs for trajectories of both robots and the human.

77.6 Conclusion

In this chapter, an Intelligent Space for mobile robots was presented. The architecture of Intelligent Space, mobile robot localization, and control in an Intelligent Space were described and demonstrated. The research field of this study is well-known in computer engineering, but not in robotics. Even though an intelligent environment itself is not deeply related to robotics, robots coming under an Intelligent Space have many good features and people should focus on this.

Since the sensors, which monitor the mobile robots, are fixed at constant positions outside of the robot, a localization method that provides a bounded position error becomes possible. Due to the resource-sharing feature of the DINDs, sensors and high computational power are now not necessary elements for mobile robots. This feature leads to lower-cost mobile robots.

Since only camera sensors are used, interference problems do not occur. Even if there are many robots in a room, only a fixed number of DINDs are required. By experimentation and simulation, we concluded

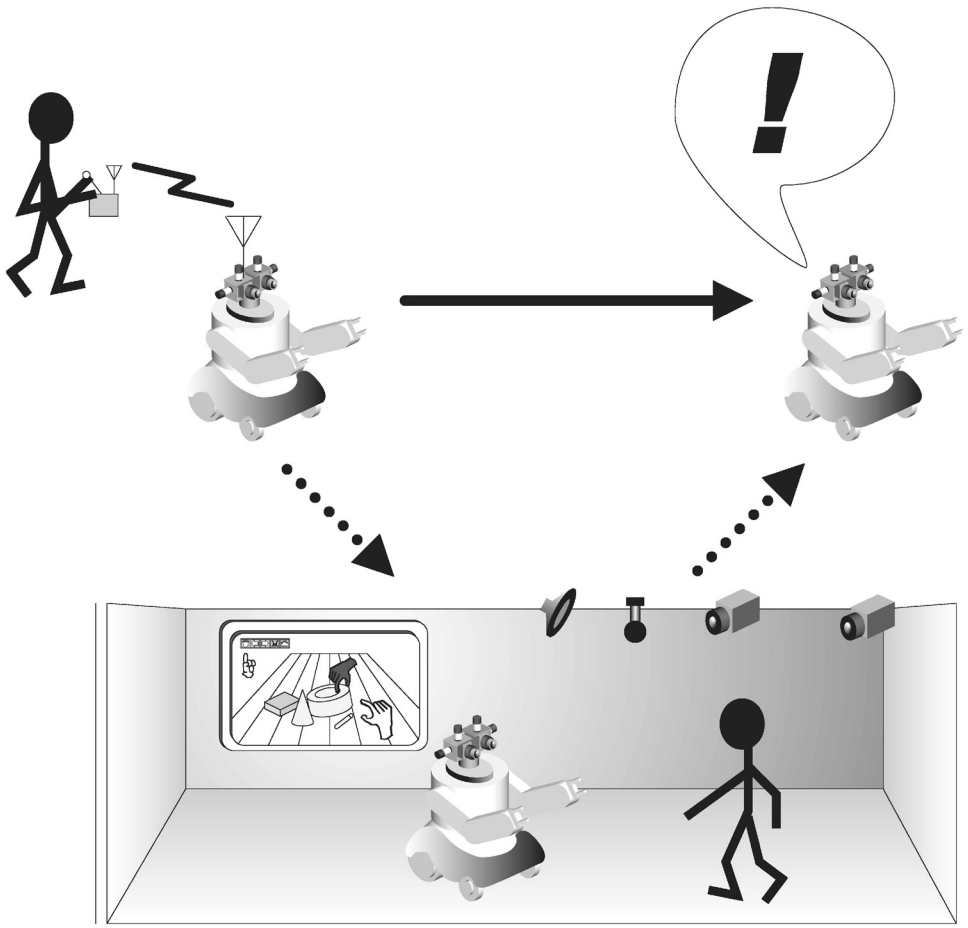

FIGURE 77.10 Flow of robot research.

© 2005 by CRC Press LLC

that there are no limits on the number of robots, only on the performance of the system, which decreased according to the number of robots and was caused by occlusions and blocking of other robots' ways; but the system worked reliably. Especially, differing from an AGV, the routes are changed easily and no hardware changes are required.

This combination results in a proposal for modifying the robot research flow with the inclusion of an additional step before achieving a full autonomous intelligent robot. The new flow is expected to accelerate robot research and bring better results. As shown in Figure 77.10, several researchers are trying to create a full autonomous robot. However, this goal is far from being achievable with current technology. Currently, robots are utilized by borrowing human intelligence or by moving in very simple environments in which only low-level intelligence is needed to navigate. Since the goal of robot research is far ahead of the present stage of robot technology, robots in the Intelligent Space might be a valid and achievable subgoal. In this case, robots get intelligence/information that the robot lacks from the space. When a human operator wants to operate the robot, he communicates with the Intelligent Space and the space translates it to the robot. Especially, we want to emphasize that the intelligent space is an intelligent system to support robots as well as humans.

It can be considered that making such an environment may cost more than the savings achieved by reducing the numbers of sensors and computational power from the robots. However, the following two points should be considered. One is that the Intelligent Space is a system for supporting humans as well as robots. The other is the development of social surroundings. Computer networks are not unfamiliar concepts anymore in most people's daily lives. Currently, the target of the system described in this article is one where the infrastructure is well organized. However, as our living environment gets better infrastructure it will become easier to install an Intelligent Space in such an environment.

78.1 Introduction

Due to advances in integrated circuits (ICs), fabrication technology, and Micro Electro Mechanical Systems (MEMS) [8, 11], it is now commercially feasible to manufacture ICs with sensing, signal processing, memory, and other relevant components built into them. Such ICs enabled with RF communication bring forth a new kind of networks, which are self-organizing and application-specific. These networks are referred to as wireless sensor networks.

A sensor network is a static *ad hoc* network consisting of hundreds of sensor nodes deployed on the fly for unattended operation. Each node consists of [1, 9, 10] sensors, processor, memory, radio, limited power battery, and software components such as operating system and protocols. The architecture of a sensor node is completely dependent on the purpose of the deployment. But we can generalize the architecture [11] as shown in the following Figure 78.1.

Sensor nodes are expected to monitor some surrounding environmental phenomena, process the data obtained, and forward these data toward a base station located on the periphery of the sensor network. Wireless sensor networks have numerous applications in fields like surveillance, security, environmental monitoring, habitat monitoring, smart spaces, precision agriculture, inventory tracking, and health care [9].

The main advantage of sensor networks is their ability to be deployed in almost any kind of remote terrain. Their unattended mode of operation makes them a preferable choice over ground-based radar

© 2005 by CRC Press LLC

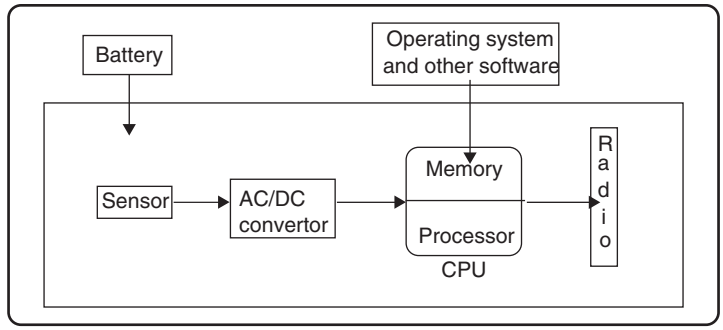

FIGURE 78.1 Sensor node architecture.

systems [10]. The spatial distribution of sensor nodes ensures greater Signal to Noise Ratio (SNR) by combining signals from various sensors. Furthermore, a higher level of redundancy allows greater fault tolerance. As sensor nodes are expected to be manufactured for a very less price, they can be deployed in large numbers. As a result, sensor networks can provide a large coverage area through the union of individual nodes' coverage area. Since sensor nodes are expected to be deployed close to the object of interest, obstruction of the line of sight for sensing activity is ruled out.

To illustrate the above-mentioned advantages, consider an example of seismic detection [9]. The earth generates seismic noise, which becomes attenuated and distorted with distance. Hence, to increase the probability of detection, it is advisable to have sensors closer to the source. To accomplish this, we need to detect the exact location and time of the seismic activity, which happens to be the goal of deploying sensors. If a distributed network of sensors was deployed across the entire geographical area of interest, then there would be no requirement to pinpoint the locations where sensors need to be deployed.

Sensor Networks Vs Mobile *Ad hoc* Networks

Wireless sensor networks are significantly different from *Mobile Ad hoc Networks (MANETS)* [7] due to the following reasons:

- *Mode of Communication*: In MANETS, potentially any node can send data to any other node. But in sensor networks, the mode of communication is restricted. In general, a base station will broadcast commands to all sensor nodes in its network and sensor nodes send back sensed data to the base station. Sometimes, sensor nodes may need to forward sensed data to other sensor nodes, if the base station is not reachable directly. Depending on the application, some sensor networks will use data aggregation at designated nodes to reduce the bandwidth usage. Most of the sensor network's messages are routed to base stations. Hence, sensor nodes need not maintain explicit routing tables.
- *Node Mobility*: In MANETS, every node can move. In general, sensor nodes are static and some architectures have mobile base stations [28].
- *Energy*: Nodes in MANETS have a rechargeable source of energy. Thus, energy conservation is of secondary importance. However, sensor networks consist several hundreds of nodes, which need to operate in remote terrain. Hence, battery replacement is not possible, due to which energy efficiency is critical for sensor networks.

Apart from the above-mentioned differences, sensor nodes have low computational power, and less cost as compared to *MANETS* nodes. Protocols designed for sensor networks should be more scalable, since they are expected to be deployed in hundreds.

© 2005 by CRC Press LLC

The remaining part of this chapter is organized as follows. In Section 78.2, we describe system models used in the literature. Section 78.3 presents design issues in sensor networks. In Section 78.4, medium access layer issues and a few solutions proposed in literature are described. In Section 78.5, we move on to flat routing protocols and hierarchical routing protocols. We then describe other important issues like security, location determination, lifetime analysis, power management, and clock synchronization.

78.2 System Models

Various system models proposed in the literature can be classified based on the following factors:

1. Mobility of base stations.
2. Number of base stations.
3. Method of organization (Heirarchical/Flat).

System models considered by researchers until now consist of static sensor nodes randomly deployed in a geographical area of interest. This geographical area of interest is often referred to as a sensor field. Most of the models considered had a single, static base station [4, 7, 24, 22, 25]. In [30], the author evaluates the best position to locate a base station and proposes to split large sensor networks into small squares and move the base station to the center of each square to collect the data. In [28], the authors propose to deploy multiple, intermittently mobile base stations to increase the lifetime of the sensor networks.

Operational Model

Research on sensor networks done until now considered various operational models of the sensor nodes. These models can be broadly classified as below:

1. *Active*: In case of active sensor networks [4, 7, 22, 24, 25, 29], each sensor node would be sensing its environment continuously. Based on how frequently these sensed data are forwarded toward the base station, sensor networks can be further classified as
   (a) *Periodic*: Based on the application for which the sensor network is deployed, it might be required to gather the data from every sensor node periodically [4, 22].
   (b) *Event Driven*: Sensor networks that are deployed for monitoring specific events gather data only when an event of interest occurs [25, 27, 29]. For example, sensor nodes deployed to monitor seismic activity in a region need to route data only when they detect seismic currents in their proximity.
2. *Passive*: In the case of passive sensor networks, data forwarding would be triggered by a query from the base station. Passive sensor networks can be further classified as follows:
   (a) *Energized on Query*: In this operation mode, sensor nodes switch off their sensors most of the time. Only when a query is generated for the data would the sensor node switch on its sensor and record the data to be forwarded.
   (b) *Always Sensing*: This category of sensor nodes have their sensors running all the time. As soon as there is a query for data from it, a sensor node would generate the data packet based on the observations until now and forward the packet.

Radio Propagation Model

Most researchers assumed that energy spent in transmission over wireless medium is in accordance with the first-order radio model [4, 25]. In this model, the energy required to transmit a signal has a fixed part and a variable part. The variable part is directly proportional to the square of the distance. Some constant energy is required to receive a signal by a receiving antenna.

78.3 Design Issues in Sensor Networks

Most sensor networks encounter operational challenges [2] like *ad hoc* deployment, limited energy supply, dynamic environmental conditions, and unattended mode of operation. Any solution proposed for sensor networks should consider the following design issues:

1. Energy: Each sensor node is equipped with a limited battery-supplied energy. Sensor nodes spend more energy in comunication than local computations.[1] As sensor nodes are deployed in large numbers, it is not feasible to manually recharge the batteries. Thus, sensor nodes should conserve their energy by minimizing the number of messages that are to be transmitted. Based on the energy source, sensor nodes can be classified as follows:
   (a) *Rechargeable*: Sensor nodes equipped with solar cells can recharge their batteries when sunlight is available. For such sensor nodes, the main design criterion would be to maximize the number of nodes operational during times when no sunlight is available.
   (b) *Nonrechargeable*: Sensor nodes equipped with nonrechargeable batteries will cease to operate once they drain their energy. Thus, the main design issue in such sensor networks would be to maximize the operational time of every sensor node.
2. *Bandwidth*: Sensor nodes need to communicate over the Industrial, Scientific, and Medical (ISM) band. When many nodes make an attempt to use the same communication frequency, there might be a requirement to use the available bandwidth optimally.
3. *Limited Computation Power and Memory*: As the processing power at each sensor node is limited, proposed solutions for sensor networks should not expect sensor nodes to carry out computationally intensive tasks.
4. *Unpredictable Reliability, Failure Models*: Sensor networks are expected to be deployed in inaccessible and hostile environments. As a result, it is possible for sensor nodes to crash or malfunction due to external environmental factors. The proposed solutions should be based on failure models that account for such a possibility. Furthermore, failure of a few nodes should not bring down the network.
5. *Scalability*: Sensor nodes are expected to be deployed in thousands. As a result, scalability is a critical issue in the design of sensor networks. Any solution proposed should be scalable to large-sized sensor networks.
6. *Timeliness of Action (Latency)*: Latency is an important issue in sensor networks deployed for critical applications like security and surveillance. Hence, the time elapsed between the time an event is detected and the time the event is reported at the base station has to be minimized.

To address these design challenges, several strategies like *Cooperative signal processing, Exploiting redundancy, Adaptive signal processing, and Hierarchical architecture* are going to be key building blocks for sensor networks [1].

In the near future, we believe that sensor networks would find wide acceptance in day-to-day activities similar to computers. To attain such a wide-scale acceptance, sensor nodes should be affordable, easily available, easily configurable (plug and play) and deployable. To accomplish these objectives, we need to come up with suitable Medium Access Control (MAC) layer protocols, routing protocols, location discovery algorithms, power-management strategies, and solutions to other relevant problems. Some of these design problems are well studied by researchers. In the next section, we present a brief overview of existing solutions for each of these design problems.

78.4 MAC Layer Protocols

MAC layer provides topology information and channel allocation to the higher layers in the protocol stack. Channel allocation is critical for energy-efficient functioning of the link layer. Energy-efficiency

[1]To take an example of ground-to-ground communication [7], it takes 3 J of energy to transmit 1 kb of data a distance of 100 m. A general-purpose processor having a processing capability of 100 million instructions per second would execute 300 million instructions for the same amount of energy.

© 2005 by CRC Press LLC

and scalability [56] are main issues in developing MAC protocols for sensor networks. Fairness, latency, and throughput are also important performance measures for channel allocation algorithms. A channel could be a time slot in Time Division Multiple Access (TDMA), a frequency band in Frequency Division Multiple Access (FDMA), or a code in Code Division Multiple Access (CDMA). Channel allocation algorithms should try to avoid energy wastage through:

- Collisions: When two or more nodes, which are in direct transmission range of each other, transmit packets in the same channel.
- Overhearing: Nodes receive data destined for other nodes.
- Idle listening: Unnecessarily listening to the channel when there are no packets to be received.
- Control packet: Bandwidth wastage due to exchange of too many control packets.

The existing solutions to channel allocation in *ad hoc* networks can be divided into two categories: contention-based and contention-free methods. In contention-based solutions, the sender continously senses the medium. *IEEE 802.11 Distributed Coordinated Function* (DCF), *MACAW* [58], and *PAMAS* [57] are examples of contention-based protocols. Contention-based schemes are not suitable for sensor networks because of energy wastage due to collisions and idle listening [31].

Sensor networks should use organized methods for channel allocation. The organized methods of channel allocation determine the network topology first and then assign the channels to the links. A channel assignment should avoid *cochannel* interference, which avoids two consecutive links being assigned to the same channel. Sensor networks channel allocation algorithm should be distributed because network-wide synchronization for calculation of a schedule would be an energy-intensive procedure. Another reason for distributed algorithms is that they scale well with an increase in network size and that they are robust to network partitions and node failures.

In [7], the authors proposed a Self-organizing MAC protocol (SMACS) for sensor networks. *SMACS* is a distributed protocol, which enables nodes to discover their neighbors and build a network topology for communication. SMACS builds a flat topology, that is, there are no clusters or cluster heads. In SMACS, each node allocates channels to links between itself and neighbors within a *TDMA* frame referred to as a *super frame.* In a given time slot, every node communicates with only one neighbor to avoid interference. Nodes communicate intermittently and hence they can power themselves off when they have no data to send. The *super frame* schedule is divided into two periods. In the first bootup period, nodes try to discover neighbors, and rebuild severed links. The second time period is reserved for communication between nodes. Authors in [7] also proposed an Eavesdrop and Register (EAR) protocol to handle channel allocation with moving base stations. In Piconet [59], authors used periodic sleep cycle to save energy. Here, if a node wishes to communicate with neighbors, then it has to wait until it receives a broadcast message from neighbors. Wei et al. [56] proposed an energy-efficient MAC protocol known as *S-MAC,* which saves energy by avoiding *collisions, overhearing,* and *idle listening,* and increases *latency.*

78.5 Routing

As stated earlier, each sensor node is expected to monitor some environmental phenomena and forward the corresponding data toward the base station. To forward the data packets, each node needs to have the routing information. Here, we would like to state that the flow of packets is mostly directed from sensor nodes toward the base station. As a result, each sensor node need not maintain explicit routing tables. Routing protocols can in general be divided into flat routing and cluster-based routing protocols.

Flat Routing Protocols

In flat routing protocols, the nodes in the network are considered to be homogeneous. Each node in the network participates in route discovery, maintainance, and forwarding of the data packets. Here, we describe a few existing flat routing protocols for the sensor networks.

© 2005 by CRC Press LLC

Sequential Assignment Routing

Sequential Assignment Routing (SAR) [7] takes into consideration the energy and Quality of Service (QoS) for each path, and the priority level of each packet for making routing decisions. Every node maintains multiple paths to the sink to avoid the overhead of route recomputation due to the node or link failure. Multiple paths are built by building multiple trees rooted at the one hop sink neighbors. Each tree grows outward by successively adding more nodes to one hop sink neighbors, while avoiding nodes with lower QoS and energy reserves. Each sensor node can control which of the neighbors can be used for relaying a message. Each node associates two parameters, an additive QoS metric and energy measure, with every path. Energy is measured by estimating the maximum number of packets that can be routed without energy being depleted if this node is exclusively using the path. SAR then calculates a weighted QoS metric as the product of the additive QoS metric and a weighted coefficient associated with the priority level of the packet. The SAR algorithm attempts to minimize the average weighted QoS metric in the lifetime of the network. A periodic recomputation of paths is triggered by the sink to account for any changes in the topology. Failure recovery is done by a handshaking procedure between neighbors.

Directed Diffusion

Estrin et al. [3] proposed a diffusion-based scheme for routing queries from the base station to sensor nodes and forwarding corresponding replies. In directed diffusion, an attribute-based naming is used by the sensor nodes. Each sensor names data that it generates using one or more attributes. A sink may query for data by disseminating interests. Intermediate nodes propagate these interests. Interests establish gradients of data toward the sink that expressed that interest. For example, a seismic sensor may generate a data: (type = seismic, id = 12, location = NE, time stamp = 01.01.01, and footprint = vehicle/wheeled/over 40 t). A sink may send an interest of the form: (type = seismic, location = NE). The intermediate nodes may send an interest for data for vehicle data in the NE quadrant toward the approximate direction. The strength of the gradient may be different toward different neighbors, resulting in different amounts of information flow.

Minimum Cost Forwarding Algorithm for Large Sensor Networks

The minimum cost forwarding approach proposed by Ye et al. [24] exploits the fact that the data flow in sensor networks is in a single direction and is always toward the fixed base station. Their method neither requires sensor nodes to have a unique identity nor maintain routing tables to forward the messages. Each node maintains the least-cost estimate from itself to the base station. Each message to be forwarded is broadcasted by the node. On receiving a message, the node verifies if it is on the least cost path between the source sensor node and the base station. If so, it would forward the message by broadcasting.

In principle, the concept behind minimum cost forwarding is similar to the gravity field that drives waterfalls from top of mountain to the ground. At each point, water flows from a high post to a low post along the shortest path. For this algorithm to work, each node needs to have the least-cost estimate from itself to the base station. The base station broadcasts an advertisement message with the cost set to zero. Every node initially has the estimate set to infinity. On receiving an advertisement message, every node verifies if the estimate in the message plus the cost of link on which it is received is less than the current estimate. If so, the current estimate and the estimate in the advertisement message are updated. If the received advertisement message is updated with a new cost estimate, it is forwarded; else, it is purged. As a result of forwarding advertisement message immediately after updating, it was noticed by the authors that some nodes receive multiple updates and do multiple forwards as lesser cost estimates flow in. Furthermore, the nodes far away from the base station receive more updates than those close to the base station. To avoid this instability during the setup phase, a back-off algorithm was proposed. According to this back-off algorithm, on updating the current cost estimate, the advertisement message is not forwarded until $A \star C_{node}$ units of time, where A is a constant determined through simulations and C_{node} is the cost of link on which the advertisement message was received.

Flow-Based Routing Protocol

In [28], the authors proposed to model the sensor network as a flow network and have proposed an Integer Linear Program (ILP)-based routing method. The objective of this ILP-based method is to minimize the maximum energy spent by any sensor node during a period of time. Through simulation results, the authors have shown that our ILP-based routing heuristic increases the lifetime of sensor network significantly.

In the above-mentioned study, the authors observed that the sensor nodes that are one hop away from a base station (sink) drain their energy much earlier than other nodes in the network. As a result, the base station is disconnected from the network. To address this problem, deployment of multiple, intermittently mobile base stations was proposed. The operation time of sensor network was split into equal periods of time referred to as rounds. Modifications were made to the flow network model and the ILP such that solving it gives locations of base stations in addition to the routing information. Apart from increasing the lifetime of the network, the authors argued that multiple, mobile base stations would decrease the average hop length taken by each packet and increase the robustness of the system.

Sensor Protocols for Information via Negotiation

Kaulik et al. [5] proposed a set of protocols to disseminate individual sensor information to all the sensor nodes. Sensor Protocols for Information via Negotiation (SPIN) overcomes information implosion and overlap by using negotiation and information descriptors (meta-data). Classic flooding suffers from the problem of implosion in that the information is sent to all nodes regardless of whether they have already seen that information or not. Another problem is that of overlap of information where two pieces of information might have some components in common; hence, it might be sufficient to just forward the information after removing the common part. SPIN uses three kinds of messages to communicate:

- ADV — When a node has data to send, it advertises this using this message.
- REQ — A node sends this message when it wishes to receive some data.
- DATA — Data message containing the data with a meta-data header.

The details of SPIN are as follows:

1. SPIN-PP: This protocol is designed for point-to-point communication, assuming that two nodes can communicate with each other without interfering with other nodes' communication. This protocol also assumes that energy is not a constraint and packets are never lost. This protocol works on a hop-by-hop basis. A node that has information to send advertises this by sending an ADV to its neighboring nodes. The nodes that are interested in receiving this information express their interest by sending an REQ. The originator of the ADV then sends the data to the nodes that sent an REQ. This process repeats itself.
2. SPIN-EC: This protocol adds an energy heuristic to the previous protocol. A node participates in the process only if it can complete all the stages in the protocol without going below a low energy threshold.
3. SPIN-BC: This protocol was proposed for broadcast channels. The advantage is that all the nodes within hearing range can hear a broadcast, while the disadvantage is that the nodes have to desist from transmitting if the channel is already in use. Another difference from the previous protocols is that nodes do not immediately send out REQ messages on hearing an ADV. Each node sets a random timer and on expiry of that timer sends out the REQ message. The other nodes whose timers have not yet expired cancel it on hearing the request thus preventing redundant copies of the request from being sent again.
4. SPIN-RL: This protocol was designed for lossy broadcast channels by incorporating two adjust ments. First, each node keeps track of the advertisements it receives and rerequests data if a response from the requested node is not received within a specified time interval. Second, nodes limit the frequency with which they will resend data. Every node waits for a predetermined time period before servicing requests for the same piece of data again.

© 2005 by CRC Press LLC

Multihop flat routing can also be subdivided according to the signal processing techniques. There are two types of cooperative signal processing techniques: noncoherent and coherent. For noncoherent processing, raw data are preprocessed at the node itself before forwarding it to the central node (CN) for further processing. For coherent processing, the data are forwarded after minimum processing to the central node. The processing at the node involves operations like time stamping. Thus, for energy efficiency, algorithmic techniques assume importance for coherent processing since the data traffic is low, while path optimality is important for coherent processing.

Cluster-Based Routing Protocols

In cluster-based routing protocols, special nodes, referred to as cluster heads, discover and maintain routes and non-cluster-head nodes join one of the clusters. All the data packets originating in the cluster are forwarded toward the cluster heads. Cluster heads in turn will forward these packets toward the destination using the routing information. Here, we describe some cluster-based routing protocols from the literature.

Low Energy-Adaptive Clustering Hierarchy

Chandrakasan et al. [17] proposed Low Energy-Adaptive Clustering Hierarchy (LEACH) as an energy-efficient communication protocol for wireless sensor networks. Authors of LEACH claim that this protocol will extend the life of wireless sensor networks by a factor of 8, when compared to protocols based on multihop routing and static clustering. In LEACH, self-elected cluster heads collect data from all the sensor nodes in their cluster, aggregate the collected data by data fusion methods and transmit the data directly to the base station. These self-elected cluster heads continue to be cluster heads for a period referred to as a round. At the beginning of each round, every node determines if it can be a cluster head during the current round. If it decides to be a cluster head for the current round, it announces its decision to its neighbors. Other nodes that choose not to be cluster heads opt to join one of the cluster heads on listening to these announcements, based on predetermined parameters like signal-to-noise ratio.

LEACH is proposed for routing data in wireless sensor networks, which have a fixed base station to which the recorded data need to be routed. All the sensor nodes are considered to be static, homogeneous, and energy constrained. The sensor nodes are expected to sense the environment continuously and thus have data to be sent at a fixed rate. Furthermore, radio channels are assumed to be symmetric. The term symmetric means that the energy required to transmit a particular message between two nodes is the same in either direction. A first-order radio model [4] is assumed to describe the transmission characteristics of the sensor nodes. Based on these assumptions, it is clear that having too many intermediate nodes to route the data might consume more energy, on a global perspective, when compared to direct transmission to the base station. The authors use this argument to support the decision to transmit the aggregated data directly from the cluster head to the base station.

The key features of LEACH are localized coordination for cluster setup and operation, randomized rotation of cluster heads, and local fusion of data to reduce global communication costs. LEACH is organized into rounds where each round starts with a setup phase followed by a longer steady-state data transfer phase. Here, we describe various subphases involved in both these phases.

1. *Advertisement phase*: A predetermined fraction of nodes, say p, elect themselves as cluster heads. The optimum value of p can be found from a plot between normalized energy dissipation and the percent of nodes acting as cluster heads. For a detailed description of this procedure, we refer the reader to [4]. The decision to be a cluster head is made by choosing a random number between 0 and 1. If the generated number is less than a threshold $T(n)$, then the node will be a cluster head for the current round. The threshold $T(n)$ is given by the expression $p/[1 - p(rmod(1/p))]$. This would ensure that every node would be a cluster head once in $1/p$ rounds. Once the decision is made, cluster heads advertise their id by using the CSMA MAC protocol.
2. *Cluster setup phase*: On listening to advertisements in the previous phase, non-cluster-head nodes determine which cluster head to join by comparing signal-to-noise ratios from various cluster

© 2005 by CRC Press LLC

heads surrounding it. Each node informs the cluster head of the cluster which it decides to join by using the CSMA MAC protocol.

3. *Schedule creation*: On receiving all the messages, the cluster head creates a TDMA schedule and announces it to all the nodes in the cluster. In order to avoid interference between nodes in adjacent clusters, the cluster head determines the CDMA code to be used by all the nodes in its cluster. This CDMA code to be used in the current round is transmitted along with the TDMA schedule.
4. *Data transmission*: Once the schedule is known, each node will transmit the data during the time slot allocated to it. When the cluster head receives data from all the nodes in its cluster, it will run some data fusion algorithms to aggregate the data. The resulting data are transmitted directly to the base station.

Threshold-sensitive Energy-Efficient sensor Network protocol

In [25], the authors have classified sensor networks into proactive networks and reactive networks. Nodes in proactive networks continuously monitor the environment and thus have the data to be sent at a constant rate. LEACH suits such sensor networks in transmitting data efficiently to the base station. In case of the reactive sensor networks, nodes need to transmit the data only when an event of interest occurs. Hence, all the nodes in the network do not have equal amount of data to be transmitted. Manjeshwar et al. proposed Threshold-sensitive Energy-Efficient sensor Network protocol (TEEN) [25] for routing in reactive sensor networks.

TEEN uses the cluster formation strategy of LEACH, but adopts a different strategy in the data transmission phase. TEEN makes use of two user-defined parameters, hard threshold (Ht) and soft threshold (St), to determine if it needs to transmit the value it sensed currently. When the monitored value exceeds Ht for the first time, it is stored in a variable and is transmitted during the time slot of the node. Subsequently, if the monitored value exceeds the currently stored value by a magnitude of St, then the node will transmit the data. This transmitted value is stored for comparing in future.

Two-Level Clustering Algorithm

Estrin et al. [3] proposed a two-level clustering algorithm that can be extended to build a cluster hierarchy. In this algorithm, every sensor at a particular level is associated with a radius or the number of hops that its advertisements will reach. Sensors at a higher level are associated with higher radii. All sensors start with level 0. Each sensor sends out periodic advertisements to other nodes that are within its radius. The advertisements carry its current level, its parent's identity (if any), and the remaining energy. After transmitting the advertisement, each node will wait for a time proportional to its radius to receive advertisements from other nodes. At the end of the wait time, all level 0 nodes start a promotion timer that is proportional to its remaining energy reserves and the number of level 0 nodes whose advertisements it received. When the promotion timer expires, the node promotes itself to level 1 and starts sending out periodic advertisements. In these new advertisements, it lists its potential children, which are the level 0 nodes that it previously heard. A level 0 node then picks up its parent from one of the level 1 nodes, whose advertisements included its identity. Once a level 0 node picks up its parent, it cancels its promotion timer and drops out of the race. At the end, each level 1 node starts a wait timer and waits for its potential children's acknowledgements. If no level 0 node selected it as its parent or its energy dropped below a certain level, it demotes itself to a level 0 node. All level 0 and level 1 nodes periodically enter the wait stage to take into account any change in network conditions, and reclustering takes place.

78.6 Other Important Issues

In this Section, we will discuss other important issues such as security, location determination, lifetime analysis, power management, and clock synchronization. We describe why these issues are paramount for the functioning of sensor networks and some solutions proposed in the literature.

© 2005 by CRC Press LLC

Security

Security is a very critical issue for the envisioned mass deployment of sensor networks. In particular, a strong security framework is a must in battlefield and border monitoring applications. The security framework in sensor networks should fulfill the following objectives:

- Authentication/nonrepudiation: Each sensor should be able to identify the sender of a message correctly and no node should deny its previous actions.
- Integrity: Messages sent over wireless medium should not be altered by unauthorized entities.
- Confidentiality: Messages should be kept secret from unauthorized entities.
- Freshness: Messages received by sensors should be current.

Sensor Networks Vs *Ad hoc* Networks: Security Perspective

Sensor networks share some similarities with *ad hoc* networks. But security in sensor networks is different from *ad hoc* networks due to the following reasons:

- *Node Power*: Sensor nodes have limited power supply and low computational capabilities as compared to *ad hoc* nodes. *Asymmetric Key* encryption [46] schemes require large computational power as compared to *Symmetric Key* encryption [46]. Thus, sensor networks can only use *Symmetric Key* encryption. To use *Symmetric Key* encryption mechanisms, we need to address the *Key Distribution* problem.
- *Mode of Communication*: As stated earlier, most of the communication in the sensor networks is from sensor nodes to the base station. At times, base station would issue commands to the sensor nodes. In this mode of communication, every node may not need to share keys with every other node in its network. Moreover, it is not practical to store keys, which are shared with every node, at every node.
- *Node Mobility*: In *ad hoc* networks, every node can move. In general, sensor nodes are static and in some architectures they have mobile base stations as in Reference [28].

The above differences make *ad hoc* network's or any other traditional network's security protocols impratical for sensor networks.

Proposed Security Protocols

Recently, there has been some work related to sensor network security. Perrig et al. [34] proposed *Security Protocols for Sensor Networks (SPINS). The SPINS* framework consists of two protocols to satisfy the security objectives. *Secure Network Encryption Protocol (SNEP)* provides data integrity, two-party authentication, data freshness, and *micro Timed Efficient Streaming Loss-tolerent Authentication Protocol (μTESLA)* provides authenticated broadcast. In SNEP, each sensor node and base station share a unique key, which is bootstrapped. This shared key and an incremental message counter, maintained at both sensor nodes and base station, are used to derive new keys using the RC5 [46] algorithm. In μTESLA, a sender generates a chain of keys using one-way function MD5 [46]. The important property of the chain of keys is that if the sender authenticates the initial key, then other keys in the chain are self-authenticated. The sender divides time into equal intervals and each interval is assigned a key from the chain of keys. The sender and receiver agree upon the key disclosure schedule. The first key from the chain is authenticated using unicast authentication. After the first authentication, the receiver authenticates packets after receiving a symmetric key from the sender as per the disclosure shedule. μTESLA uses delayed disclosure of symmetric keys to authenticate packets after the first authentication of one key in the chain.

In [35], the authors proposed a security framework based on broadcast with end-to-end encryption of the data. This scheme avoids traffic analysis and also removes compromised and dead nodes from the network. Sasha et al. [36] divided the messages in sensor networks into three classes depending on the security required. Each class of messages is encrypted using different encryption keys. They showed that this multilevel scheme saves the resources at the nodes.

In general, the base stations will broadcast commands to all the sensor nodes. Hence, secure broadcast is a very important issue in the security framework. In μTESLA, the authentication of the first key in the

© 2005 by CRC Press LLC

chain is done using a unicast mechanism. This unicast authentication mechanism has a scalability problem. Authors in [37] replaced this unicast-based mechanism with a broadcast-based mechanism, which avoids *dental of service* [46] attacks. In [38], the authors proposed a routing-aware broadcast key distribution algorithm. Karlof et al. [39] described possible attacks on different routing protocols in the literature and suggested countermeasures.

The Asymmetric Key mechanism requires large computational power, bandwidth, and memory. Therefore, sensor networks use the Symmetric Key encryption to satisfy security objectives. A key distribution [40–44] in the Symmetric Key encryption mechanism is another important issue in sensor networks. Eschenauer et al. [40] proposed a probabilistic predistribution of keys scheme. In this scheme, every sensor node will be given a small set of m keys out of a large set of available keys such that every two sensor nodes will have one common key with the given probability p. This scheme dramatically reduces the number of keys stored in each sensor as compared to storing separate keys to every node in its network. In [41], the authors proposed three extentions to this basic key distribution scheme. In the first, *q-composite* keys extention, sensor nodes will share q common keys instead of one key with a given probability p. This extention improves the security against small-scale attacks such as eavesdroping on one link. The second extention, *multipath* extention, deals with setting up end-to-end path keys between two communicating nodes. In this extention, a path key is established between two nodes by sending random keys through every available path between them. A receiver uses all received random keys along all the paths to establish a path key. This improves the security against large-scale attacks such as eavesdropping many links. The third extention, *random pair-wise* keys scheme, provides the node-to-node authentication. In this scheme, unique node identities are generated randomly. Every node is randomly paired with m other nodes and m corresponding keys. Every node is aware of other node's ID in the pair and the corresponding key. This node ID information is used for node-to-node authentication.

Location Determination

Sensor nodes monitor surrounding phenomena like temperature, light, seismic currents, chemical leaks, radiation, and other parameters of interest. After detecting an event, sensor nodes forward the sensed data toward the nearest base station. In order to process any message reported by the sensor network, the base station is required to know the sender's location. For example, if the sensor network is deployed to detect forest fires, the base station should know the reporting sensor's location. Hence, the base station needs to be aware of the location of every sensor node deployed in the network. In this Section, we will explain different solutions proposed in the literature for location determination in sensor networks. Locationing algorithm's performance can be measured [47] by the following parameters:

- Resolution: The smallest distance between nodes that can be distinguished by the locationing system.
- Accuracy: Probability of locationing system finding the correct location.
- Robustness: Ability of the locationing system to find the correct location when subjected to node failures and link failures.

Global Positioning System (GPS) [48] has been used to locate outdoor nodes. Due to reflection and multipath fading, GPS is not a viable option for indoor locationing. Since sensor nodes can be deployed at indoor locations or on other planets, the GPS-based locationing system is not suggestable. Many non-GPS-based locationing solutions are proposed by the research community. Most of these solutions are either *proximity-* or *beacons*-based. In *proximity*-based solutions, some nodes will act as special nodes, whose locations are known. We can divide proximity-based solutions into two types. In the first type [50], beacons are sent by special nodes, from which other nodes can approximate their location. In the second type of proximity-based solutions [49], beacons are sent by nonspecial nodes, from which special nodes can approximate the locations of nonspecial nodes. *Cricket* [50] uses the difference in arrival times from known beacons as the basis for finding the location. In *RADAR* [51], authors used SNR as the basis for finding the location of nodes. The *SpotON* [52] system finds the location of nodes in the three-dimensional space. These solutions can be adopted for the location detection in sensor networks. In [23], the

© 2005 by CRC Press LLC

authors proposed a location detection scheme, which consists of *local positioning* and *global positioning.* In *local positioning,* nodes will approximate their relative location from anchor nodes, whose locations are assumed, by using *triangulation* method, *Global positioning* finds global location by using *cooperative ranging* approach, in which nodes iteratively converge to the global position by interacting with each other.

Saikat et al. [47] proposed a robust location detection algorithm for emergency applications. None of the above-explained solutions dealt with robustness. Robustness is an important issue in emergency scenarios such as building collapses. This location detection improves robustness by finding *identifying codes.* Estrin et al. [3] gave an interesting application of their clustering algorithm to pinpoint the location of an illegimate object. This algorithm is robust to link or node failures and the overhead is proportional to the local population density and a sublinear function of the total number of nodes.

Lifetime Analysis

Lifetime refers to the time period for which a sensor network is capable of sensing and transmitting the sensed data to the base station(s). In sensor networks, thousands of nodes are powered with very limited supply of battery power. As a result, lifetime analysis becomes an important tool to efficiently use the available energy. In sensor networks using rechargable energy such as solar energy, lifetime analysis helps the nodes to use the enery efficiently before recharging. Lifetime analysis may include an upper bound on the lifetime and factors influencing this upper bound.

Theoretical upper bound on the lifetime of a sensor network helps to understand the other protocol's efficiency. Bhardwaj et al. [27] proposed a theoretical upper bound on the lifetime of a sensor network deployed for tracking the movement of external objects. In [55], authors found the lifetime of a sensor network with *Hybrid Automata* modeling. Hybrid Automata is a mathematical method to analyze the systems with both discrete and continous behaviors. The authors used the trace data to analyze the power consumption and to estimate the lifetime of a sensor network.

Power Management

Sensor networks should operate with the minimum possible energy to increase the life of sensor nodes. This requires power-aware computation/communication component technology, low-energy signaling, and networking and power-aware software infrastructure.

Design challenges encountered in the building of wireless sensor networks can be broadly classified into hardware, wireless networking, and OS/applications. All three categories should minimize the power usage to increase the life of a sensor node. Hardware includes the design activities related to all hardware platforms that make up sensor networks. MEMS, digital circuit design, system integration, and RF are important categories in the design of hardware. The second aspect includes design of power-efficient algorithms and protocols. In the previous sections, we described a few energy-efficient protocols for MAC and routing. Next, we present a few OS/application-level strategies related to power management in sensor nodes.

Once the system is designed, additional power savings can be obtained by using the *Dynamic Power Management (DPM)* [13]. The basic idea behind DPM is to shut down (sleep mode) the devices when not needed and get them back when required. This requires an embedded operating system [14] that is able to support the DPM. The switching of a node from the sleep state to the active state takes some finite time and resource. Each sensor node could be equipped with multiple devices. The number of devices switched off determines the level of the sleep state. Each sleep state is characterized by the latency and the power consumption. The deeper the sleep state, the lesser the power consumption, and the more the latency. This requires a careful use of DPM to maximize the life of a sensor node. But in many cases, it is not known beforehand when a particular device is required. Hence, a stochastic analysis should be applied to predict the future events.

Energy can be conserved by using *Dynamic Voltage Scheduling (DVS)* [13, 19]. DVS minimizes the idle processor cycles by using a feedback control system. Energy savings can be obtained by optimizing the sensor nodes performance in active state. DVS is an effective tool to achieve this goal. The main idea

© 2005 by CRC Press LLC

behind DVS is to change the power supply to match the workload. This needs tuning of the processor to deliver the required throughput to avoid idle cycles. The crux of the problem lies in the fact that future workloads are nondeterministic. Thus, the efficiency depends on predicting the future workload.

Efficient Link-Layer strategies can be used to conserve energy at each sensor node. In [18], the authors propose to conserve energy by compromising on the quality of the link layer established. This is possible by maintaining the bit error rate (BER) just below the user requirements. Different error-controlling algorithms like Bose–Chaudhuri–Hocquen (BCH) coding, convolution coding, and turbo-coding can be used for error control. The algorithm with the lowest power consumption to support the predetermined BER and latency should be chosen.

Local computation and processing [14, 17] of sensor data in wireless networks can be made highly energy efficient. *Partitioning* the computation among multiple sensor nodes and performing the computation in parallel permit a greater control on latency and results in energy conservation through frequency scaling and voltage scaling.

Biomedical wireless sensor networks could use *Power-Efficient Topologies* [16] to save the energy spent in communication. Biomedical sensor nodes include monitors and implantable devices intended for long-term placement in the human body. Topology is predetermined in these sensor networks. Ayad et al. proposed *Directional Source-Aware routing Protocol* (DSAP) for this class of sensor networks. DSAP incorporates power considerations into routing tables. The authors explored various topologies to determine the most energy-efficient topology for biomedical sensor networks.

Clock Synchronization

Some of the communication algorithms for wireless sensor networks that are proposed in the literature make an inherent assumption that there exists some mechanism through which local clocks of all the sensor nodes are synchronized. Although this assumption is valid, we need to have an explicit way of synchronizing local clocks of all sensor nodes. Apart from the implementation of the communication algorithms, clock synchronization is required for accurate time stamps in cryptographic schemes, for recognizing duplicate detection of the same event from different sensor nodes, for data aggregation algorithms like beam forming, for ordering of logged events, and many other similar applications. In this Section, a *post facto* clock synchronization algorithm proposed by Elson and Estrin [26] is described.

The *post facto* clock synchronization algorithm discussed here is suitable for applications like beam forming, duplicate event detection, and other similar localized methods. This algorithm is expected to be implemented on systems similar to the Wireless Integrated Network Sensors (WINS) platform where a processor has various sleep modes and has the capability of powering down high-energy peripherals. Because of the capability of the sensor node processor to power down a device and power up when there is a requirement to sense data and transmit, existing clock synchronization methods for distributed systems are not applicable.

The basic idea behind *post facto* clock synchronization algorithm is that for certain applications like data fusion and beam forming, it is sufficient to order the events in a localized manner. In this scheme, node's clocks are normally unsynchronized. When a stimulus arrives (time to sense and transmit data), each node records the stimulus with respect to its local clock. Immediately following this event, a third party will broadcast a synchronization pulse. Every node receiving this pulse normalizes their stimulus time stamp with respect to the broadcasted synchronizing pulse. It is essential to note that the time elapsed between recording the stimulus and arrival of synchronized pulse needs to be measured accurately. For this reason, the algorithm is inappropriate for systems that need to communicate a time stamp over a long distance.

78.7 Conclusions

In this chapter, we made an attempt to present an overview of the wireless sensor networks and describe some design issues. We discussed various solutions proposed to prolong the lifetime of sensor networks.

© 2005 by CRC Press LLC

Proposed solutions to issues like MAC layer, routing data from sensor node to the base station, power management, location determination, and clock synchronization were discussed.

79.4 Summary

79.1 Introduction

The increasing miniaturization of electronic components and advances in modern communication technologies enable the development of high-performance spontaneously networked and mobile systems. Wireless microsensor networks promise novel applications in several domains. Forest fire detection, battlefield surveillance, or telemonitoring of human physiological data are only in the vanguard of plenty of improvements encouraged by the deployment of microsensor networks. Hundreds or thousands of collaborating sensor nodes form a microsensor network. Sensor data is collected from the observed area, locally processed or aggregated, and transmitted to one or more base stations.

Sensor nodes can be spread out in dangerous or remote environments whereby new application fields can be opened. A sensor node combines the abilities to compute, communicate, and sense. Figure 79.1 shows the structure of a typical sensor node consisting of processing unit, communication module (radio interface), and sensing and/or actuator device.

Figure 79.2 shows a scenario taken from the environmental application domain: leakage detection of dykes. During floods, sandbags are used to reinforce dykes. Piled along hundreds of kilometers around lakes or rivers, sandbag dykes keep waters at bay and bring relief to residents. Sandbags are stacked against sluice gates and parts of broken dams to block off the tide. To find out spots of leakage each

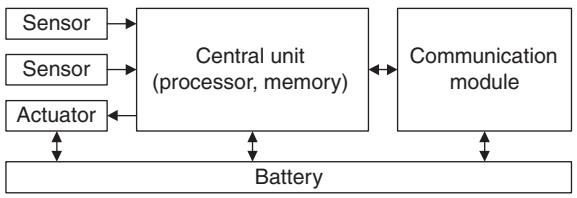

FIGURE 79.1 Structure of a sensor node.

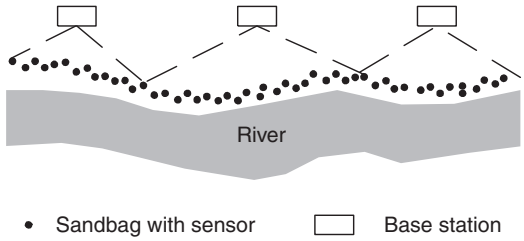

FIGURE 79.2 Example sensor network application: leakage detection.

sandbag is equipped with a moisture sensor and transmits sensor data to a base station next to the dyke. Thus, leakages can be detected earlier and reinforcement actions can be coordinated more efficiently.

Well-known research activities in the field of sensor networks are UCLA's WINS [3], Berkeley's Smart Dust [1], WEBS [2], and PicoRadio [4]. An example of European research activities is the EYES-Project [5]. Detailed surveys on sensor networks can be found in [6] and [7].

This chapter focuses on innovative architectures and basic concepts of current software development solutions for wireless sensor networks.

79.2 Preliminaries

Central unit of a sensor node is a low-power microcontroller that controls all functional parts of the node. Software for such a microcontroller has to be resource-aware on the one hand. On the other hand, several Quality-of-Service (QoS) aspects have to be met by sensor node software, such as latency, processing time for data fusion or compression, or flexibility regarding routing algorithms or MAC techniques.

Conventional software development for microcontrollers usually covers Hardware Abstraction Layer (HAL), operating system and protocols, and application layer. Often, software for microcontrollers is limited to an application-specific monolithic software block that is optimized for performance and resource usage. Abstracting layers such as HAL or operating system are often omitted due to resource constraints and low-power aspects.

Microcontrollers are often developed and programmed for a specific, well-defined task. This limitation of the application domain leads to high-performance embedded systems even with strict resource constraints. Development and programming of such systems is much effort. Furthermore, an application developed for one microcontroller is in most cases not portable to any other one, so that it has to be reimplemented from scratch. Microcontroller and application form an inseparable unit. If the application domain of an embedded system changes, often the whole microcontroller is replaced instead of writing and downloading a new program.

For sensor nodes, application-specific microcontrollers are preferred instead of general-purpose microprocessors. This is because of the small size and the low energy consumption of those controllers. However, requirements concerning a sensor node exceed the main characteristics of a conventional microcontroller and its software. The main reason for this is the dynamic character of a sensor node's task. Sensor nodes can adopt different tasks, such as sensor data acquisition, data forwarding, or information processing. The task assigned to a node with its deployment is not fixed until the end of its life cycle. Depending on, for instance, location, energy level, or neighborhood of a sensor node, a task change can become advantageous or even necessary.

Additionally, software for sensor nodes should be reusable. An application running on a certain sensor node should not be tied to a specific microcontroller but to some extent be portable onto different platforms to enhance interoperability of sensor nodes with different hardware platforms. Not limited to software development for wireless sensor networks is the general requirement for a straightforward programmability and, as a consequence, a short development time.

It is quite hard or even impossible to meet the requirements mentioned above with a monolithic application. Hence, at present there is much research effort in the areas of middleware and service architectures for

© 2005 by CRC Press LLC

wireless sensor networks. A middleware for wireless sensor networks should encapsulate required functionality in a layer between operating system and application. Incorporating a middleware layer has the advantage that applications get smaller and are not tied to a specific microcontroller. At the same time, development effort for sensor node applications reduces since a significant part of the functionality moves from application to middleware. Another research domain tends to service architectures for wireless sensor networks. A service layer is based on mechanisms of a middleware layer and makes its functionality more usable.

Architectural Layer Model

Like in other networking systems, the architecture of a sensor network can be divided into different layers (see Figure 79.3). The lower layers are hardware and HAL. The operating system layer and protocols are above the hardware-related layers. The operating system provides basic primitives like multithreading, resource management, and resource allocation that are needed by higher layers. Also, access to radio interface and input/output operations to sensing devices are supported by basic operating system primitives. Usually in node-level operating systems these primitives are rudimentary and there is no separation between user and kernel mode. On top of the operating system layer reside middleware, services, and application layer.

In recent years, much work has been done to develop sensor network node devices (e.g., Berkeley motes [9]), operating systems and algorithms, for example, for location awareness, power reduction, data aggregation, and routing. Today researchers are working on extended software solutions including middleware and service issues for sensor networks. The main focus of these activities is to simplify application development process and to support dynamic programming of sensor networks.

The overall development process of sensor node software usually ends with a manual download of an executable image over direct wired connections or over-the-air interface to target node.

After deployment of nodes, it is nearly impossible to improve or adapt new programs to the target nodes. But this feature is necessary in future wireless sensor networks to adapt the behavior of sensor networks dynamically by new injected programs. The task assigned to a node with its deployment is not fixed until the end of its life cycle. Depending on, for instance, location, energy level, or neighborhood of a sensor node, a task change can become advantageous or even necessary.

Middleware and Services for Sensor Networks

In sensor networks, design and development of solutions for higher-level middleware functionality and creation of service architectures are an open research issue. Middleware for sensor networks has two primary goals:

- Support of acceptable middleware Application Programming Interfaces (APIs), which abstract and simplify low-level APIs to ease application software development and to increase portability, and
- Distributed resource management and allocation.

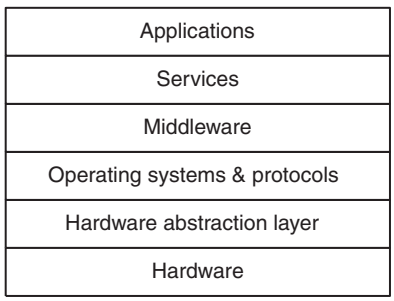

FIGURE 79.3 Layered software model.

© 2005 by CRC Press LLC

Besides the native network functions, such as routing and packet forwarding, future software architectures are required to enable location and utilization of services. A service is a program which can be accessed through standardized functions over a network. Services allow a cascading without previous knowledge of each other, and thus enable the solution of complex tasks.

A typical service used during the initialization of a node is the localization of a data sink for sensor data. Gateways or neighboring nodes can provide this service. To find services, nodes use a service discovery protocol.

Programming Aspect vs. Behavioral Aspect

Wireless sensor networks do not have to consist of homogeneous nodes. In reality, a network composed of several groups of different sensor nodes is imaginable. This fact changes the software development approach and points out new challenges as they are well-known from the distributed systems domain. In an inhomogeneous wireless sensor network, nodes contain different low-level system APIs, however, with similar functions. From a developers point of view it is hard to create programs, since APIs are mostly incompatible. To overcome the mentioned problems in heterogeneity and complexity, new software programming techniques are required. One attempt to accomplish this aspect is the definition of an additional API or an additional class library on top of each system API. But they are all limited by some means or other, for example, platform independency, flexibility, quantity, programming language. All approaches to achieve an identical API on different systems are covered by the *Programming Aspect* (Figure 79.4).

The programming aspect enables the developer to easily create programs on different hardware and software platforms. But an identical API on all platforms does not necessarily take the dynamics of the distributed system into account. Ideally, the application does not notice any dynamic system changes. This decoupling is termed as *Behavioral Aspect* and covers:

- Access to remote resources without previous knowledge, for example, Remote Procedure Calls (RPC) and discovered services
- Adaptations within the middleware layer to dynamic changes in the behavior of a distributed system, caused by incoming or leaving resources, mobility of nodes, or changes of the environment, and
- The ability of the network to evolve over time including modifications of the system's task, exchange or adaptation of running software parts, and mobile agents.

79.3 Current Software Solutions

This chapter presents five important software solutions for sensor networks. It starts with the most mature development TinyOS and depending software packages. It continues with SensorWare followed by two promising concepts, MiLAN and EnviroTrack. The Section finalizes with an introduction to SeNeTs.

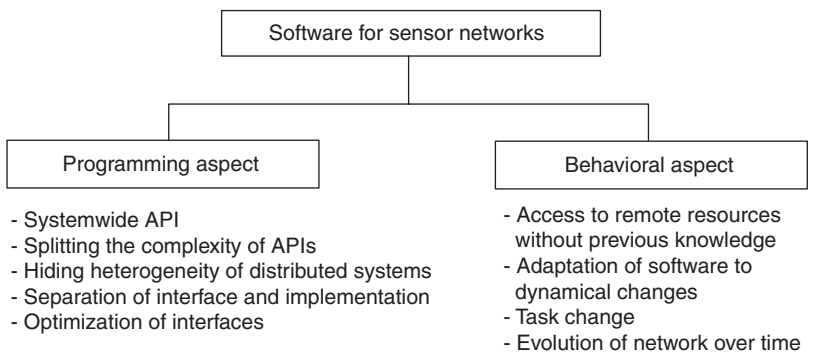

FIGURE 79.4 Two aspects of software for wireless sensor networks.

TinyOS

TinyOS is a component-based operating system for sensor networks developed at UC Berkeley. TinyOS can be seen as an advanced software framework [9] which has a large user community due to its open source character and its promising design. The framework contains numerous prebuilt sensor applications and algorithms, for example, multi-hop *ad hoc* routing and supports different sensor node platforms. Originally it was developed for Berkeley's Mica Motes. Programmers experienced with the C programming language can easily develop TinyOS applications written in a proprietary language called NesC [10].

The design of TinyOS is based on the specific sensor network characteristics: small physical size, low power consumption, concurrency-intensive operation, multiple flows, limited physical parallelism and controller hierarchy, diversity in design and usage, and robust operation to facilitate the development of reliable distributed applications. The main intention of the TinyOS developers was "retaining energy, computational and storage constraints of sensor nodes by managing the hardware capabilities effectively, while supporting concurrency-intensive operation in a manner that achieves efficient modularity and robustness"[16]. Therefore, TinyOS is optimized in terms of memory usage and energy efficiency. It provides defined interfaces between the components which reside in neighboring layers. A layered model is shown in Figure 79.5.

Elemental Properties

TinyOS utilizes an *event model* instead of a stack-based threaded approach, which would require more stack space and multitasking support for context switching, to handle high levels of concurrency in a very small amount of memory space. Event-based approaches are the favorite solution to achieve high performance in concurrency intensive applications. Additionally, the event-based approach uses CPU resources more efficiently and therefore takes care of the most precious resource, the energy.

An event is serviced by an event handler. More complex event handling can be done by a task. The event handler is responsible for posting the task to the task scheduler. Event and task scheduling is performed by a *two-level scheduling structure*. This kind of scheduling provides that *events,* associated with a small amount of processing, can be performed immediately, while longer running *tasks* can be interrupted by events. *Tasks* are handled rapidly, however no blocking or polling is permitted.

The TinyOS system is designed to *scale with the technology trends* supporting both, smaller designs and crossover of software components into hardware. The latter provides a straightforward integration of software components into hardware.

TinyOS Design

The architecture of a TinyOS system configuration is shown in Figure 79.6. It consists of the tiny scheduler and a graph of components. Components satisfy the demand for modular software architectures. Every component consists of four interrelated parts: a command handler, an event handler, an encapsulated fixed-size and statically allocated frame, and a bundle of simple tasks. The frame represents the internal state of the component. Tasks, commands and handlers execute in the context of the frame and operate on its state. In addition, the component declares the commands it uses and the events it signals. Through this declaration, modular component graphs can be composed. The composition process creates layers of components. Higher layer components issue commands to lower level components and these signal events to higher level components. To provide an abstract definition of the interaction of two components via commands and events, the bi-directional interface is introduced in TinyOS.

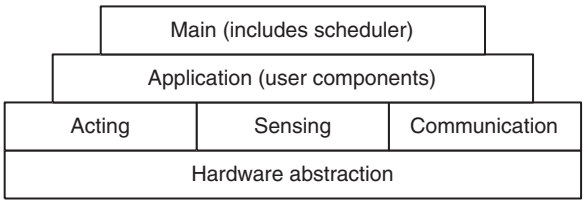

FIGURE 79.5 Software architecture of TinyOS.

© 2005 by CRC Press LLC

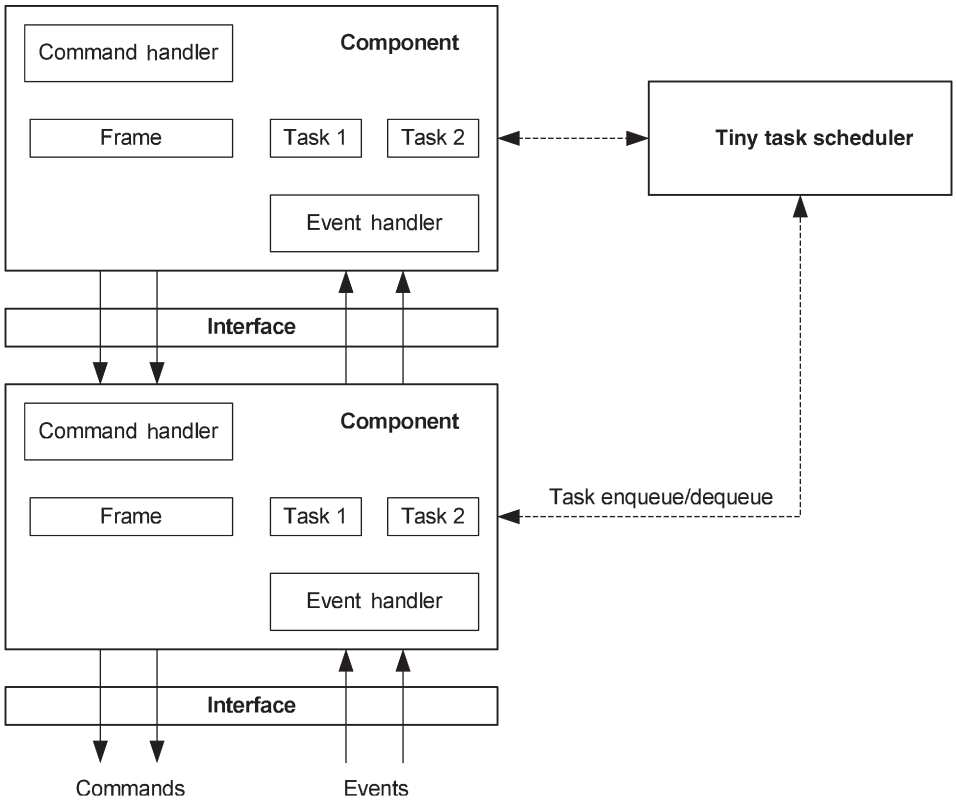

FIGURE 79.6 TinyOS architecture in detail.

Commands are nonblocking requests made to lower layer components. A command provides feedback to its caller by returning status information. Typically, the *command handler* puts the command parameters into the frame and posts a task into the task queue for execution. An event can signal the successful execution of a command.

Event handlers are invoked by *events* of lower layer components, or when directly connected to the hardware, by interrupts. Similar to commands, the frame will be modified and tasks are posted. Both, commands and tasks, perform a small fixed amount of work similar to interrupt service routines.

Tasks perform the primary work. They are atomic, run to completion, and can only be pre-empted by events. Tasks are queued in a FIFO *task scheduler* to perform an immediate return of event or command handling routines. Due to the FIFO scheduling, tasks are executed sequentially and should be short. Alternatively to the FIFO task scheduler, priority-based or deadline-based schedulers can be implemented into the TinyOS framework.

TinyOS distinguishes three categories of components. Hardware *abstraction components* map physical hardware into the component model. Mostly, these components export commands to the underlying hardware and handle hardware interrupts. *Synthetic hardware components* extend the functionality of hardware abstraction components by simulating the behavior of advanced hardware functions, for example, bit-to-byte transformation functions. For future hardware releases, these components can directly cast into hardware. *High-level software components* perform application specific tasks, for example, control, routing, data transmission, calculation on data, and data aggregation.

An interesting aspect of the TinyOS framework is the similarity of the component description to the description of hardware modules in hardware description languages, for example, VHDL or Verilog. A hardware module, for example, in VHDL is defined by an entity with input and output declarations, status registers to hold the internal state, and a finite state machine controlling the behavior of the module.

© 2005 by CRC Press LLC

In comparison, a TinyOS component contains commands and events, the frame and a behavioral description. These similarities simplify the cast of TinyOS components to hardware modules. Future sensor nodes generations can benefit from this similarity in describing hardware and software components.

TinyOS Application

A TinyOS application consists of one or more components. These components are separated into modules and configurations. Modules implement application specific code, whereas configurations wire different components together. By using a top-level configuration, wired components can be compiled and linked to form an executable.

The interfaces between the components declare a set of commands and events which provide an abstract description of components. The application developer has to implement the appropriate handling routine into the component.

Figure 79.7 shows the component graph of a simple TinyOS application, that turns a LED on and off depending on the clock. The top-level configuration contains the application specific components (ClockC, LedsC, BlinkM) and a operating system specific component providing the tiny task scheduler and initialization functions. The Main component encapsulates the TinyOS specific components from the application. StdControl, Clock, and Leds are the interfaces used in this application. While BlinkM contains the application code, ClockC and LedsC are again configurations encapsulating further component graphs controlling the hardware clock and the LED's connected to the controller.

TinyOS provides a variety of additional extensions like the virtual machine MATÉ and the database TinyDB for cooperative data acquisition.

MATÉ

MATÉ [8] is a byte-code interpreter for TinyOS. It is a tiny communication-centric virtual machine designed as a component for the system architecture of TinyOS. MATÉ is located in the component graph on top of several system components, represented by sensor components, network component, timer component, and nonvolatile storage component.

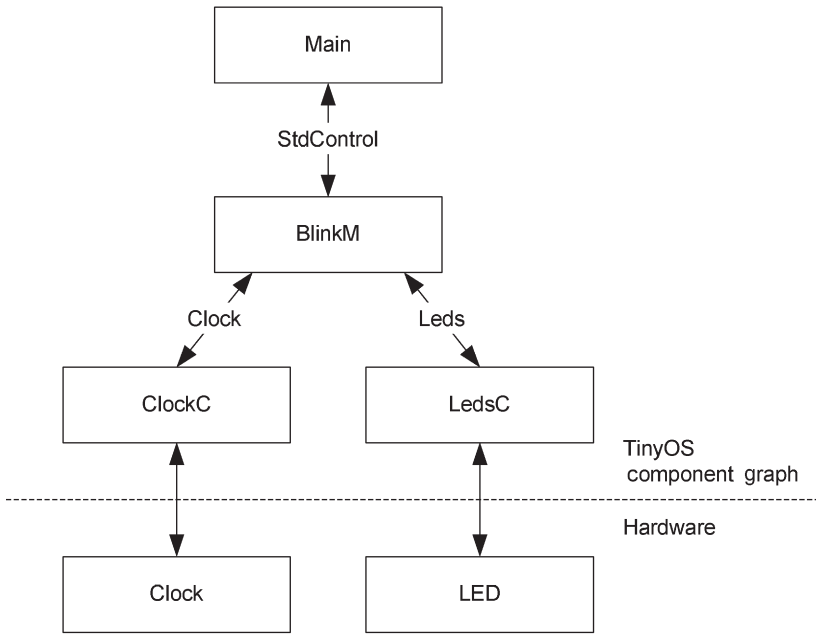

FIGURE 79.7 Simple TinyOS application.

© 2005 by CRC Press LLC

The developer motivation for MATÉ was to solve novel problems in sensor network management and programming, in response to changing tasks, for example, exchange of the data aggregation function or routing algorithm. However, the associated inevitable reprogramming of hundreds or thousands of nodes is restricted to energy and storage resources of sensor nodes. Furthermore, the network is limited in bandwidth and network activity as a large energy draw. MATÉ attempts to overcome these problems, by propagating so-called code capsules through the sensor network.

The MATÉ virtual machine provides the possibility to compose a wide range of sensor network applications by the use of a small set of higher level primitives. In MATÉ, these primitives are one-byte instructions and they are stored into capsules of 24 instructions together with identifying and versioning information.

Architecture

MATÉ is a stack-based architecture which allows a concise instruction set. The use of instructions hides the asynchronous character of native TinyOS programming; because instructions are executed successively as several TinyOS tasks.

The MATÉ virtual machine shown in Figure 79.8 has three execution contexts: *Clock, Send*, and *Receive*, that can run concurrently at instruction granularity. *Clock* corresponds to timer events and *Receive* to message receive events, signaled from the underlying TinyOS components. *Send* can only be invoked from the *Clock* or *Receive* context. Each context holds an operand stack for handling data and a

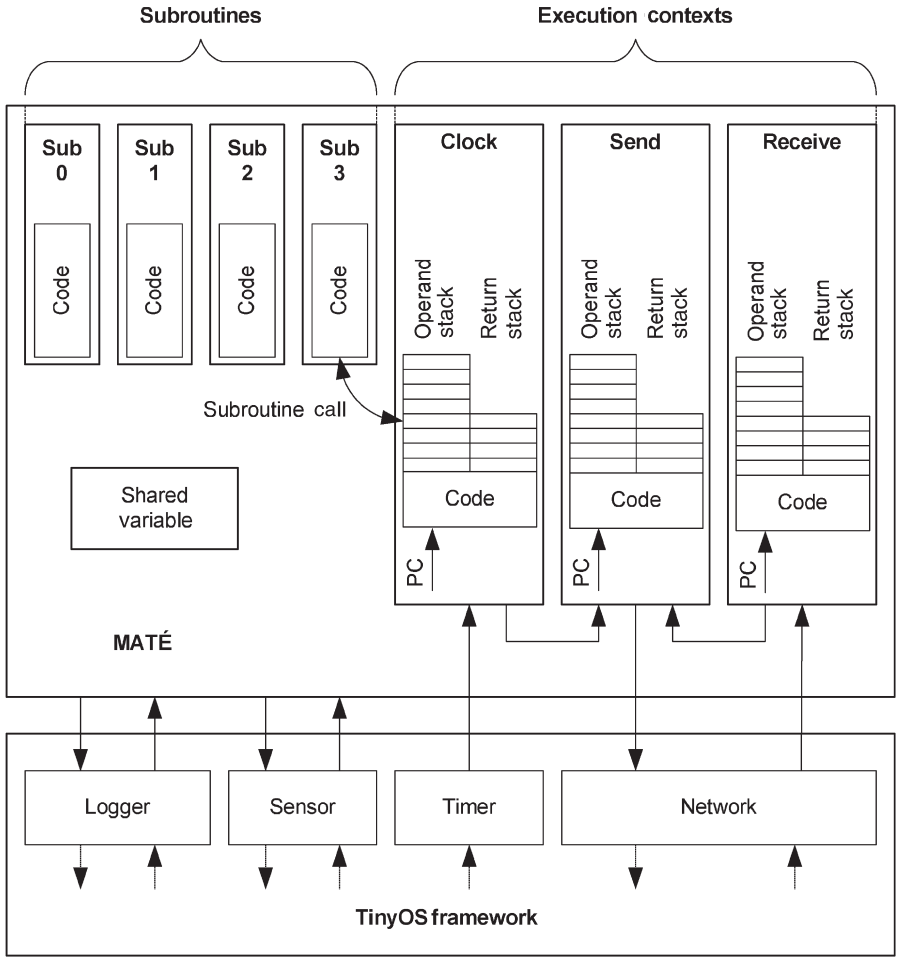

FIGURE 79.8 MATÉ architecture.

© 2005 by CRC Press LLC

return stack for subroutines calls. Subroutines allow programs to be more complex as a single capsule can provide. Therefore, MATÉ has four spaces for subroutine code.

The code for the contexts and the subroutines is installed dynamically at runtime by code capsules. One capsule fits into the code space of a context or subroutine. The capsule installation process supports self-forwarding of capsules to reprogram a whole sensor network with new capsules. It is the task of the sensor network operator to inject code capsules in order to change the behavior of the network.

The program execution in MATÉ starts with a timer event or a packet receive event. The program counter jumps to the first instruction of the corresponding context (*Clock* or *Receive*) and executes until it reaches the *Halt* instruction. Each context can call subroutines for expanding functionality. The *Send* context is invoked from the other contexts to send a message in response to a sensor reading or to route an incoming message.

The MATÉ architecture provides separation of contexts. One context cannot access the state of another context. There is only one single shared variable among the three contexts that can be accessed by special instructions. The context separation qualifies MATÉ to fulfill the traditional role of an operating system. Compared to native TinyOS applications, the source code of MATÉ applications is much shorter.

TinyDB

TinyDB is a query processing system for extracting information from a network of TinyOS sensor nodes [11]. TinyDB provides a simple, SQL-like interface to specify the kind of data to be extracted from the network along with additional parameters, for example, the data refresh rate. The primary goal of TinyDB is to prevent the user from writing embedded C programs for sensor nodes or composing capsules of instructions regarding to MATÉ. The TinyDB framework allows data-driven applications to be developed and deployed much more quickly as developing, compiling, and deploying a TinyOS application.

Given a query specifying the data interests, TinyDB collects the data from sensor nodes in the environment, filters and aggregates the data, and routes it to the user autonomously. The network topology in TinyDB is a routing tree. Query messages flood down the tree and data messages flow back up the tree participating in more complex data query processing algorithms.

The TinyDB system is divided into two subsystems: sensor node software and a JAVA-based client interface on a PC. The sensor node software is the heart of TinyDB running on each sensor node. It consists of:

- sensor catalog and schema manager responsible for tracking the set of attributes, or types of readings and properties available on each sensor,
- query processor, utilizing the catalog to fetch the values of local attributes, to receive sensor readings from neighboring nodes, to combine and aggregate the values together, to filter, and to output the values to parents,
- small, handle-based dynamic memory manager,
- network topology manager to deal with the connectivity of nodes and to effectively route data and query subresults through the network.

The sensor node part of TinyDB is installed on top of TinyOS on each sensor node as an application. The JAVA-based client interface is used to access the network of TinyDB nodes from a PC physically connected to a bridging sensor node. It provides a simple graphical query-builder and a result display. The JAVA API simplifies writing PC applications that query and extract data from the network.

SensorWare

SensorWare is a software framework for wireless sensor networks that provides querying, dissemination, and fusion of sensor data as well as coordination of actuators [12]. A SensorWare platform has less stringent resource restrictions. The initial implementation runs on iPAQ handhelds (1 Mbyte ROM/128 kbyte RAM). The authors intended to develop a software framework regardless of present sensor node limitations.

SensorWare developed at the University of California, Los Angeles, aims at the programmability of an existing sensor network after its deployment. The functionality of sensor nodes can be dynamically modified

© 2005 by CRC Press LLC

through autonomous mobile agent scripts. SensorWare scripts can be injected into the network nodes as queries and tasks. After injection, scripts can replicate and migrate within the network.

Motivation for the SensorWare development was the observation that the distribution of updates and the download of complete images to sensor nodes is impractical for the following reasons. First, in a sensor network, a special sensor node may be not addressable because of missing node identifiers. Second, the distribution of complete images through a sensor network is highly energy consuming. Besides that, other nodes are affected by a download when multi-hop connections are necessary.

Updating complete images does not correspond to the low power requirements of sensor networks. As a consequence, it is more practicable to distribute only small scripts. In the following paragraphs, the basic architecture and concepts of SensorWare are described in detail.

Basic Architecture and Concepts

SensorWare consists of a scripting *language* and a *run-time environment*. The *language* contains various basic commands which control and execute specific tasks of sensor nodes. These tasks include, for example, communication with other nodes, collaboration of sensor data, sensor data filtering, or moving scripts to other nodes. The language comprises necessary constructs to generate appropriate control flows.

SensorWare utilizes Tcl as scripting language. However, SensorWare extends Tcl's core commands. These core extension commands are joined in several API groups, like Networking-API, Sensor-API, Mobility-API (see Figure 79.9).

SensorWare is event-based. Events are connected to special event handlers. If an event is signaled, an event handler serves the event according to its inherent state. Furthermore, an event handler is able to generate new events and to alter its current state by itself.

The *run-time environment* shown in Figure 79.10 contains fixed and platform-specific tasks. Fixed tasks are part of each SensorWare application. It is possible to add platform-specific tasks depending on specific application needs. The script manager task receives new scripts and forwards requests to the admission control task. The admission control task is responsible for script admission decisions and checks the overall energy consumption. Resource handlers manage different resources of the network.

Figure 79.11 shows the architecture of sensor nodes with included SensorWare software. The SensorWare layer uses operating system functions to provide the run-time environment and control scripts. Static node applications coexist with mobile scripts. To realize dynamic programmability of a deployed sensor network, a transient user can inject scripts into the network. After injection scripts are replicated within the network. The script code migrates between different nodes. SensorWare ensures that no script is loaded twice onto a node during the migration process.

MiLAN

Middleware Linking Applications and Networks (MiLAN) is a middleware concept introduced by Mark Perillo and Wendi B. Heinzelman from the University of Rochester [13, 14]. The main idea is to exploit the redundancy of information provided by sensor nodes. The performance of a cooperative algorithm in a distributed sensor network application depends on the number of involved nodes.

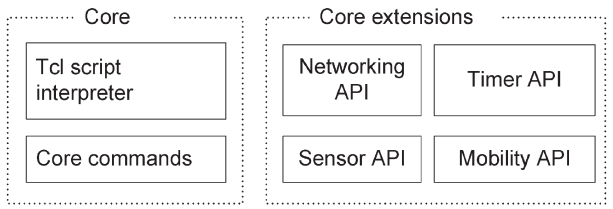

FIGURE 79.9 SensorWare scripting language.

© 2005 by CRC Press LLC

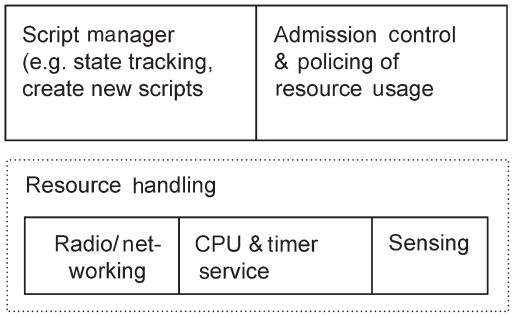

FIGURE 79.10 SensorWare run-time environment.

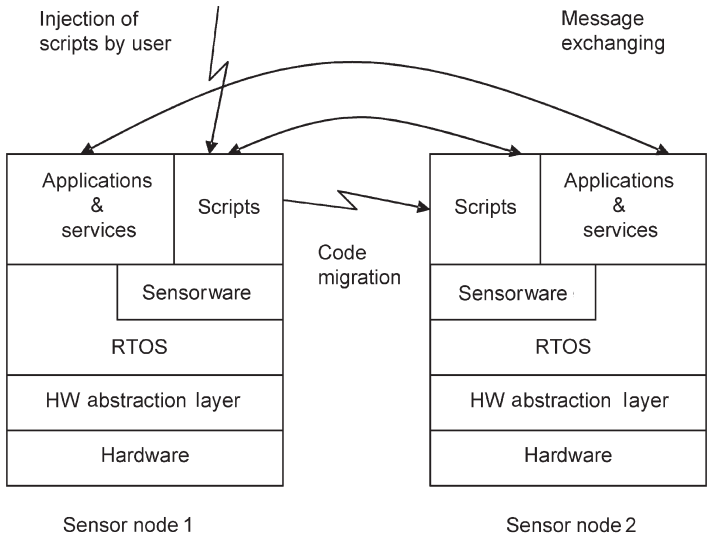

FIGURE 79.11 Sensor node architecture.

Because of the inherent redundancy of a sensor network where several sensor nodes provide similar or even equal information, evaluating all possible sensor nodes leads to high energy and network costs. Therefore, a sensor network application has to choose an appropriate set of sensor nodes to fulfill application demands.

Each application should have the ability to adopt its behavior in respect to the available set of components and bandwidth within the network. This can be achieved by a parameterized sensor node selection process with different cost values. These cost values are described by the following cost equations:

- Application performance: The minimum requirements for network performance are calculated from the needed reliability of monitored data. $F_R = \{S_i: \forall_j \in J \;\; R(S_i,j) \geq r_j\}$, where F_R stands for the *allowable set* of possible sensor node combinations, S_i represents the available sensor nodes, and $R(S_i)$ is their reliability.
- Network costs: Defines a subset of sensor nodes that meet the network n_o constraints. The *network feasible set* $F_N = \{S_i: N(S_i) \leq n_o\}$, where $N(S_i)$ represents the total cost and the maximal data rate the network can support.
- Application performance and network costs are combined to the *overall feasible set*: $F = F_R \cap F_N$.
- Energy: Describes the energy dissipation of the network. $C_P(S_i) \sum_{S_j \in S_i} = C_P(S_j)$, where $C_P(S_j)$ is the power cost to node S_j.

© 2005 by CRC Press LLC

It is up to the application to decide how these equations are weighted. This decision-making process is completely hidden from the application, so the development process is simplified significantly. MiLAN uses two strategies to achieve the objective to balance QoS and energy costs:

- Turning off nodes with redundant information
- Use of energy efficient routing.

The MiLAN middleware is located between network and application layer. It can interface a great variety of underlying network protocols, such as Bluetooth and 802.11. MiLAN uses an API to abstract from network layer but gives the application access to low level network components. A set of commands identifies and configures the network layer.

EnviroTrack

EnviroTrack is a TinyOS-based application developed at the University of Virginia that solves a fundamental distributed computing problem, *environmental tracking of mobile entities* [15]. Therefore, EnviroTrack provides a convenient way to program sensor network applications that track activities in their physical environment. The programming model of EnviroTrack integrates objects living in physical time and space into the computational environment of the application through virtual objects, called *tracking objects.* A tracking object is represented by a group of sensor nodes in its vicinity and is addressed by *context labels*. If an object moves in the physical environment, then the corresponding virtual object moves too because it is not bound to a dedicated sensor node. Regarding the tracking of objects, EnviroTrack does not assume cooperation from the tracked entity.

Before a physical object or phenomenon can be tracked, the programmer has to specify its activities and corresponding actions. This specification enables the system to discover and tag those activities and to instantiate tracking objects. For example, to track an object warmer than 100°C, the programmer specifies a Boolean function, temperature > 100°C, a critical number or mass of sensor nodes, which fulfil the Boolean function within a certain time (a fact that is often referred to as *freshness* of information). These parameters of a tracking object are called aggregate state. All sensor nodes matching this aggregate state join a group. The network abstraction layer assigns a context label to this group. Using this label, different groups can be addressed independent of the set of nodes currently assigned to it. If the tracked object moves, nodes join or leave the group because of the changed aggregate state but the label resides persistent. This group management enables context-specific computation.

The EnviroTrack programming system consists of:

- *EnviroTrack compiler*: In EnviroTrack programs, a list of context declarations is defined. Each definition includes an activation statement, an aggregate state definition, and a list of objects attached to the definitions. The EnviroTrack compiler includes C program templates. The whole project is then built using the TinyOS development tools.
- *Group management protocol*: All sensors associated to a group are maintained by this protocol. A group leader is selected out of the group members when the critical mass of nodes and freshness of the approximate aggregate state is reached. The group management protocol ensures that only a single group leader per group exists. The leader sends a periodical heartbeat to inform its members that the leader is alive. Additionally, the heartbeat signal is used to synchronize the nodes and to inform nodes that are not part of the group, but fulfill the sensing condition.
- *Object naming and directory services*: These services maintain all active objects and their locations. The directory service provides a way to retrieve all objects of a given context type. It also assigns names to groups so they can be accessed easily. It handles dynamical joining and leaving of group members.
- *Communication and transport services*: The Migration Transport Protocol (MTP) is responsible for the transportation of data packets between nodes. All messages are routed via group leader nodes. Group leader nodes identify the context group of the target node and the position of its leader using the directory service. The packet is then forwarded to the leader of the destination group. All

© 2005 by CRC Press LLC

leadership information provided by MTP packets is stored in the leaders on a least-recently-used-basis to keep the leader up-to-date and to reduce directory look-ups.

EnviroTrack enables the construction of an information infrastructure for tracking environmental conditions. It manages dynamic groups of redundant sensor nodes and attaches computation to external events in the environment. Furthermore, EnviroTrack implements noninterrupted communication between dynamically changing physical locales defined by environmental events.

SeNeTs

SeNeTs is a middleware architecture for wireless sensor networks. It is developed at the University of Rostock [17]. The SeNeTs middleware is primarily designed to support the developer of a wireless sensor network during the predeployment phase (programming aspect). SeNeTs supports the creation of small and energy-saving programs for heterogeneous networks. One of the key features of SeNeTs is the optimization of APIs. The required configuration, optimization, and compilation of software components is processed by a development environment. Besides the programming aspect, the middleware supports the behavioral aspect as well, such as task change or evolution over time (see Figure 79.4).

Architecture

SeNeTs is based on the software layer model introduced in Chapter 2. In order to increase flexibility and enhance scalability of sensor node software it separates small functional blocks as shown in Figure 79.12. In addition, the OS-layer is separated into a *Node-specific Operating System* and a *Driver Layer*, which contains at least one *Sensor Driver* and several *Hardware Drivers*, such as timer driver and RF driver. The *Node-specific Operating System* handles device-specific tasks, for example, boot-up, initialization of hardware, memory management, and process management as well as scheduling. *Host Middleware* is the superior software layer. Its main task is to organize the cooperation of distributed nodes in the network. *Middleware Core* handles four optional components, which can be implemented and exchanged according to the node's task. *Modules* are components that increase the functionality of the middleware. Typical modules are routing modules or security modules. *Algorithms* describe the behavior of modules. For example, the behavior of a security module can vary in the case the encryption algorithm changes. The *services* component contains the required software to perform local and cooperative services. This component usually cooperates with service components of other nodes to fulfill its task. *Virtual Machines (VM)* enable an execution of platform independent programs installed at run-time.

Figure 79.13 shows the expansion of the proposed architecture to a whole sensor network from the logical point of view. Nodes can only be contacted through services of the middleware layers. The *Distributed Middleware* coordinates the cooperation of services within the network. It is logically located

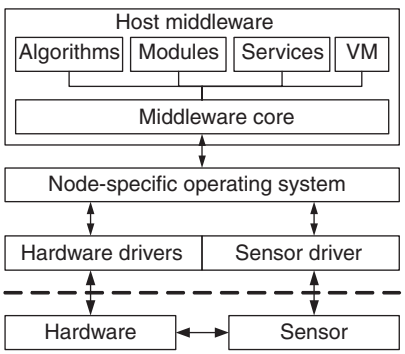

FIGURE 79.12 Structure of a node application.

© 2005 by CRC Press LLC

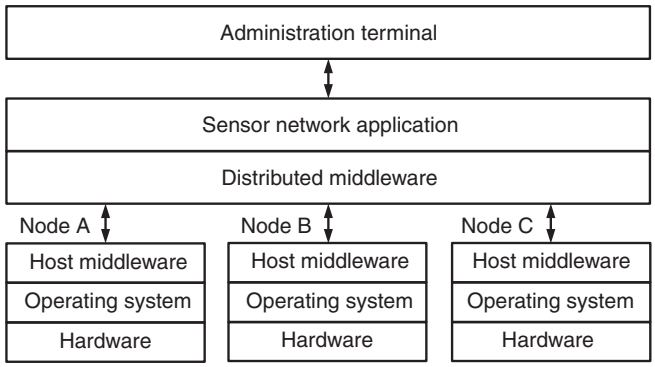

FIGURE 79.13 Structure of a sensor network.

in the network layer but physically exists in the nodes. All layers together in conjunction with their configuration compose the *sensor network application*. Thus, nodes do not perform any individual tasks.

The *Administration Terminal* is an external entity to configure the network and evaluate results. It can be connected to the network at any location.

All functional blocks of the described architecture are represented by *components* containing real source code and a description about dependencies, interfaces, and parameters in XML. One functional block can be rendered by alternative components. All components are predefined in libraries.

Interface Optimization

One of the key features in SeNeTs is interface optimization. Interfaces are the descriptions of functions between two software parts. As illustrated in Figure 79.14, higher level applications using services and middleware technologies require abstract software interfaces. The degree of hardware-dependent interfaces increases in lower software layers. Hardware-dependent interfaces are characterized by parameters to configure hardware components directly in contrast to abstract software interfaces whose parameters describe abstractions of the underlying system.

Software components require a static software interface to the application in order to minimize customization effort for other applications and to support compatibility. The use of identical components in different applications leads to a higher number of complex interfaces in these components. This is caused by component programming focused on supporting most possible use-cases of all possible applications whereby each application uses only a subpart of the functionality of a component. Reducing the remaining overhead is the objective of *generic software* and can be done by *interface optimization* during compile time.

Interface optimizations result in proprietary interfaces within a node (Figure 79.15). Parts of the software cannot be exchanged without sensible effort. In a sensor node, the software is mostly static except programs for virtual machines. Accordingly, static linking is preferred. Statically linked software in conjunction with interface optimization leads to in faster and smaller programs.

In SeNeTs, interfaces are customized to the application in contrast to common approaches used in desktop computer systems. These desktop systems are characterized by writing huge adaptation layers. The interface optimization can be propagated through all software layers and, therefore, saves resources. As an example of an optimization, a function OpenSocket(int name, int mode) identifies the network interface with its first parameter and the opening mode in the second parameter. However, a node that has only one interface opened with constant mode once or twice, does not need these parameters. Consequently, knowledge of this information at compile time can be used for optimizing, for example, by:

- Inlining the function
- Eliminating both parameters from the delivery process.

© 2005 by CRC Press LLC

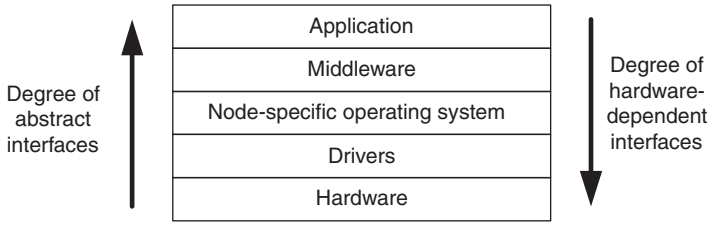

FIGURE 79.14 Interfaces within the software-layer model.

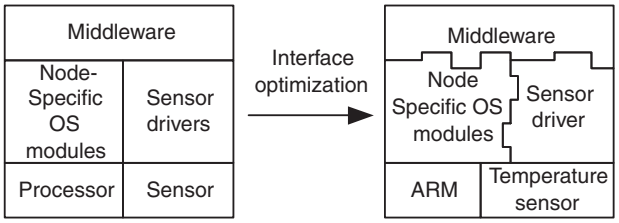

FIGURE 79.15 Interface optimization.

Another possibility is to change the semantics of data types. A potential use case is the definition of accuracy of addresses that results in changing data type's width. In SeNeTs, there are several types of interface optimizations proposed (Table 79.1).

Some optimizations such as "static parameters" are sometimes counterproductive in particular, if register-oriented parameter delivery is used. This is caused by the use of offset addresses once at parameter delivery instead of absolute addresses embedded in the "optimized" function. Consequently, the introduced optimizations strongly depend on:

- Processor and processor architecture
- Type of parameter delivery (stack or register-oriented)
- Memory management (small, huge, size of pointers)
- Objective of optimization (memory consumption, energy consumption, or compact code etc.), and
- Sensor network application.

Development Process

Figure 79.16 shows the development process of sensor node software in SeNeTs. First, for each functional block the components have to be identified and included into the project. During design phase, the chosen components are interconnected and configured depending on developer's settings. Then, interface as well as parameter optimization is performed. The final source codes are generated and logging

TABLE 79.1 Types of Interface Optimization

Optimization	Description
Parameter elimination	Parameters which are not used in one of the called subfunctions can be removed.
Static parameters	If a function is still called with same parameters, these parameters can be defined as constants or static variables in the global namespace. Thus, the parameter delivery to the function can be removed.
Parameter ordering	The sequence order of parameters is optimized in order to pass parameters through cascading functions with same or similar parameters. It is particular favorable in systems using processor registers instead of the system stack to deliver parameters to sub-functions.
Parameter aggregation	In embedded systems, many data types are not byte-aligned, for example, bits to configure hardware settings. If a function has several non byte-aligned parameters, these parameters may be combined.

© 2005 by CRC Press LLC

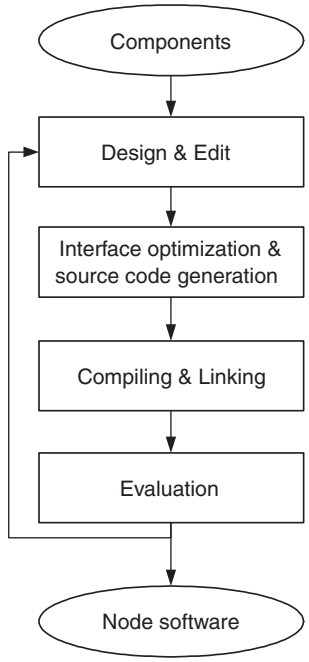

FIGURE 79.16 Development process of node software.

components can be included to monitor run-time behavior. The generated source codes are compiled and the executable is linked together. During evaluation phase, the created node application can be downloaded to the node and executed. Considering the monitoring results, a new design cycle can be started to improve project settings. As a result of the design flow, optimized node application software is generated. The node application now consists of special tailored parts only needed by the specific application of the node.

Optionally, software components in a node can be linked together statically or dynamically. Statically linking facilitates an optimization of interfaces between several components within a node. A dynamic link process is used for components exchanged during run-time, for example, algorithms downloaded from other nodes. This procedure results in system-wide interfaces with significant overhead and prevents interface optimization.

Currently, SeNeTs is in design state. Due to its initial design, the implementation of SeNeTs and proof of concept remain to be seen.

79.4 Summary

At the present time, TinyOS is the most mature operating system framework for sensor nodes. The component-based architecture of TinyOS allows an easy composition of sensor node applications. New components can be added easily to TinyOS to support novel sensing or transmission technologies or to support upcoming sensor node platforms.

MATÉ addresses the requirement to change a sensor node's behavior at run-time by introducing a VM on top of TinyOS. Via transmitting capsules containing high-level instructions, a wide range of sensor node applications can be installed dynamically into a deployed sensor network.

TinyDB was developed to simplify data querying from sensor networks. On top of TinyOS it provides an easy-to-use SQL interface to express data queries and addresses the group of users nonexperienced with writing embedded C code for sensor nodes.

EnviroTrack is an object-based programming model to develop sensor network applications for tracking activities in the physical environment. Its main feature is dynamical grouping of nodes depending on environmental changes described by predefined aggregate functions, critical mass, and freshness horizon.

© 2005 by CRC Press LLC

SensorWare is a software framework for sensor networks employing lightweight and mobile control scripts that allow the dynamic deployment of distributed algorithms into a sensor network. In comparison to the MATÉ framework, the SensorWare run-time environment supports multiple applications to run concurrently on one SensorWare node.

The MiLAN middleware provides a framework to optimize network performance, needed sensing probability and energy costs based on equations. It is the programmer's decision to weight these equations.

SeNeTs is a new approach to optimize the interfaces of sensor network middleware. SeNeTs aims at the development of energy-saving applications and the resolving of component dependencies at compile-time.

80.1 Introduction
80.2 Methods of Fusion
Data Fusion in Probability Theory • Data Fusion in Evidence Theory • Data Fusion in Possibility Theory • Discussion
80.3 Conclusion

80.1 Introduction

Humans use multi-sensor data fusion largely and naturally in order to perceive the environment. We can give, for example, the testing of wine to estimate its vintage and to appreciate it (fusion of taste, smell, and vision). Another example is medical diagnosis where many parameters (temperature, context, tiredness, ...) must be taken into account. Artificial processes (robots, manufacturing process, vehicles, ...) work like natural ones, and they often need several parameters. By multiplying information origin, the goal is to increase accuracy, robustness, and reduce eventual conflicts and ambiguity. Wald, in [22], uses "increasing the quality" to define the main goal of data fusion.

B.V. Dasarathy, says: "*When you use information from one source, it's plagiarism; When you use information from many, it's information fusion*" to qualify fusion in [7]. There are other, more technical, definitions that emanated from working groups. Here is an example: "*Data fusion is a formal framework in which are expressed the means and tools for the alliance of data originating from different sources. Data fusion aims at obtaining information of greater quality; the exact definition of 'greater quality' well depend upon the application*" [22].

Here are two web sites where readers can find many references and some generalities about the subject: http://www.infofusion.org./isif/publications.html and http://www.data-fusion.org/. Multi-sensor data fusion has originally been used for military applications such as target recognition, battlefield surveillance, or guidance and control of autonomous vehicles. Current applications include monitoring of complex machinery or medical diagnosis [11].

Fusion in image processing could be used on one image to increase the potentialities of treatment and extraction of primitives [2,6,17,23]. But it can also be used to combine many homogenous or heterogeneous images, to increase the robustness and the accuracy.

For an autonomous system, it is essential to be able to sense its own enviornment. The sensor measurements usually contains noisy information with less than the expected accuracy. Thus, different types of sensors are often used to give a set of information allowing to extract parameters with a better accuracy. Robotics is a good application field for sensor fusion [4,5]. One can easily demonstrate the pertinence of using redundancy and complementarity of sensors [19]. Indeed, navigation in real enviornment requires a very large and complete perceptoin of the surroundings of the robot. For example, odometry and more generally the proprioceptives sensors are not sufficient because they systematically imply a bias

© 2005 by CRC Press LLC

in the estimation [14]. The exteroceptive perception (telemetry, vision) allows to solve this problem by performing absolute localization. However, sometimes, it is impossible to use these sensors. Hence, the fusion of odometry and exteroceptive sensors allows to estimate the state of the robot even if one is unable to give correct information.

In general, three types of multi-sensors data fusion are distinguished:

1. A complementary fusion: fusion of several disparate sensors that individually only give partial information of the environment. The multiplicity of ultrasonic or infrared range sensors can give multidirectional information.
2. A competitive fusion: in which information about the same parameter is collected through observations of several sensors, and the best estimate is evaluated. Stereovision and range sensors are often used in competitive fusion to estimate the distance from obstacles.
3. A cooperative fusion: fusion of different sensors of which one sensor relies on the observations of another to make its own observations.

A number of classifications have been proposed; most of them can be summarized in a three-level model:

Signal (or pixel)[1]-level fusion refers to the combination of the signals of a group of sensors in order to provide a signal that is usually of the same form as the original signals but of greater quality. The signals from sensors can be modeled as random variables corrupted by uncorrelated noise, and the fusion process can be considered as an estimation procedure. At this level, temporal or special concordance between signals to fuse is very important. When this concordance is not possible, a prediction process is used to synchronize all data. In this case, fusion reduces variance and increases image-processing tasks. The most common techniques for signal-level fusion consist in weighted averaging and Kalman filtering.

Feature extraction level: this stage increases the robustness of the features extracted from raw signals, or increases the variety of information provided about a target and the accuracy. Typical features are extracted from an image and are used for fusion include edges and regions of similar intensity.

Symbolic level or classification level: this level uses symbolic (linguistic, logical, semantical) techniques to infer more information on the state of the world or for object recognition tasks. Symbolic-level fusion can effectively integrate the information from multiple sensors at the highest level of abstraction. Symbol-level fusion is commonly used in the applications where multiple sensors are of different nature or refer to different regions of the environment. The symbols used for fusion can be derived from the processing of the individual sensory information, or through symbolic reasoning processes that may make use of prior knowledge from a world model or sources external to the system. This level increases the certitude of the decision.

In Section 80.2, we present some of the most relevant computational methods capable of performing the data fusion efficiently. With each one, we propose some examples of data fusion application to show how these methods can be implemented and their advantages. They have been chosen according to their relevance to the previously mentioned methods and because they correspond to very different experimental conditions. These applications are, respectively, mobile robotics and image processing. But the readers can find other applications, for example, in [12,15].

80.2 Methods of Fusion

These methods respectively belong to the probability theory, the evidence theory, and the possibility theory [10,24]. However, we can also mention other methods such as the AND operator, the weighted average, the voting, the information theory, or the geometric methods. Among this large set of methods, we will show that the choice can be made according to the learning stage, the mode of fusion, and the type of final decision.

[1] We use signal concept for signals and images, even if many authors treat these differently.

© 2005 by CRC Press LLC

In order to provide the description of the methods in a homogeneous framework, we define the data fusion problem as follows: we first consider a centralized point of view in which all the information is available simultaneously. This restriction allows to avoid the problems linked to the synchronization or the datation of data, for example. We then suppose n heterogeneous sensors or sources S_j, which provide information about an observed phenomenon, and $D=\{D_1,..,D_l\}$, the set of hypotheses or decision space in which each D_i represents a decision on an element e. Numerically, for each element e, each source S_j will provide for each decision D_i a value M_{ij} currently called a mesaure but that can take another particular signification according to the selected data fusion method. The final aim then consists in taking the most appropriate decision for each element by fusing the different measures.

Data Fusion in Probability Theory

The probabilistic framework is undoubtedly the most widely used in signal or image fusion. The probability theory was developed during the 18th century and allows to model some random phenomena and also to integrate the deviations between the true and the observed values. Probability theory is a huge domain and we will restrict our presentation to the Bayesian approach and the Kalman filter.

The Bayesian Approach

Bayesian data fusion has been the object of numerous works and is probably the most currently used method in probabilistic data fusion. This method defines the membership of a class for an element with the minimum error and estimates the risk of a decision. The combination of information is performed thanks to the generalization of the Bayes theorem. Consider an event E that may depend on N causes C_i that are different and mutually incompatible. The aim is to estimate the probability that C_i is the cause of E. We can deduce that $E = \bigcup_{i=1}^{N} E \cap C_i$ since $\{C_i\}$ is a complete system. From the total probability theorem, we obtain $P(E) = \sum_{i=1}^{N} P(E \cap C_i)$ and by the application of the conditional probability theorem, we have $P(C_i/E) = P(E)\, P(C_i/E) = P(C_i)\, P(E/C_i)$ and then finally:

$$P(C_i/E) = \frac{P(C_i)\, P(E/C_i)}{\sum_{k=1}^{N} P(C_k)\, P(E/C_k)}$$

The expression $P(C_i/E)$ is called *the a posteriori probability*. $P(C_i)$ is the *a priori probability* of meeting this cause and $P(E/C_i)$ is the likelihood probability or the conditional probability. The denominator of the previous equation is a normalization factor (the sum of all a *posteriori probabilities* is equal to 1).

Fusion uses this theorem where E is a set of events. For example, we consider two events (E_1, E_2). In order to obtain more reliable information about the events, we can fuse by taking the product of the two probability density functions:

$$P(C_1/E_1, E_2) = \frac{P(C_1/E_2)\, P(C_1/E_1)}{P(C_1)}$$

Proof 1. Demonstration of the probabilities fusion.

Numerical example: We consider two doctors who respectively provide diagnosis M_1 and M_2 for the common decisions D_1 and D_2 about two sicknesses. $P(D_1/M_1)$ is the conditional probability density function and this corresponds to the likelihood of the disease D_1 after the diagnosis M_1.

In order to obtain more reliable information about the sickness, we can fuse the diagnosis of both doctors by taking the product of the two probability density functions:

$$P(D_1/M_1, M_2) = \frac{P(D_1/M_2)\, P(D_1/M_1)}{P(D_1)}$$

Decisions (likelihood that the patient has the sickness) of the two doctors are shown in Table 80.1.

© 2005 by CRC Press LLC

To evaluate $P(D_1/M_1M_2)$, we need the *a priori probabaility* value $P(D_1)$. It could be estimated as the frequency of the apparition of the sickness D_1. In our case, we consider that $P(D_1)=P(D_2)=1$. Thus, we can only compute the numerator of the previous equation:

$$P(D_1/M_1,M_2)=0.6 \text{ and } P(D_2/M_1,M_2)=0.9$$

This means that the patient probably has the sickness D_2. To decide this, we choose the maximum *a posteriori* rule. They are many criteria to build decision rule: maximum likelihood, maximum entropy,… But the most used one is the maximum *a posteriori.*

The reader can find other implementations of Bayes rule with some examples in [12].

The Kalman Filter

The Kalman filter is usually used in automatic and systems control. It uses the system modeling by state variables and is particularly well adapted for the modelization of dynamic systems. From an observation, the aim consists in finding the value of the state vector according to the statistics of the additional noise of the system. An optimal estimation of the state vector is then obtained iteratively according to a least squares criterion. In the case of data fusion with Kalman filter, we consider measures from the different sensors as observations of the same state vector. As previously, the uncertainty of a measure can be modeled by the integration of the additional noise, contrary to the imprecision, which cannot be evaluated.

Assume that the state of the system obeys the linear dynamic model

$$x_k=Ax_{k-1}+Bu_k+w_{k-1}$$

and the measure is equal to

$$z_k=Hx_k+v_k$$

The random variables w_k and v_k, respectively, represent process noise and measurement noises. They are assumed to be independent, white, and with normal probabilty distributions

$$P(w)=N(0, Q) \text{ and } P(v)=N(0, R)$$

Q and R, respectively, represent the process and the measurement noise covariance matrices. The matrix A relates the state at the previous time step $k-1$ to the state at current step k. The matrix B relates the optional control input u to the state x. The matrix H relates the state x_k to the measurement z_k.

Figure 80.1 shows the different steps for the evaluation of the parameters of the system. There are two steps: the time update (prior or prediction) and the measurement update (posterior or correction). The system parameters are first estimated from the values of the previous step and are then corrected by the measures of the correction step.

This model is relatively general, and the solution gives the optimal way to utilize the measurements for reconstructing the system state. Still wider generality is offered by the *extended Kalman filter* (EKF): the model can be nonlinear (the solution in that case, however, is only approximative).

The interested readers can find more details in [9].

Example of application: In [1], the robot is equipped with an odometer, an omnidirectional laser rangefinder, and a camera in order to detect vertical lines. An EKF is used for the data fusion and the estimation of the robot position (*on-the-fly localization*). First, the position (state vector) is predicted from

TABLE 80.1 Likelihood Proposed by Two Doctors

$P(D/M)$	M_1	M_2
D_1	0.3	0.2
D_2	0.2	0.45

© 2005 by CRC Press LLC

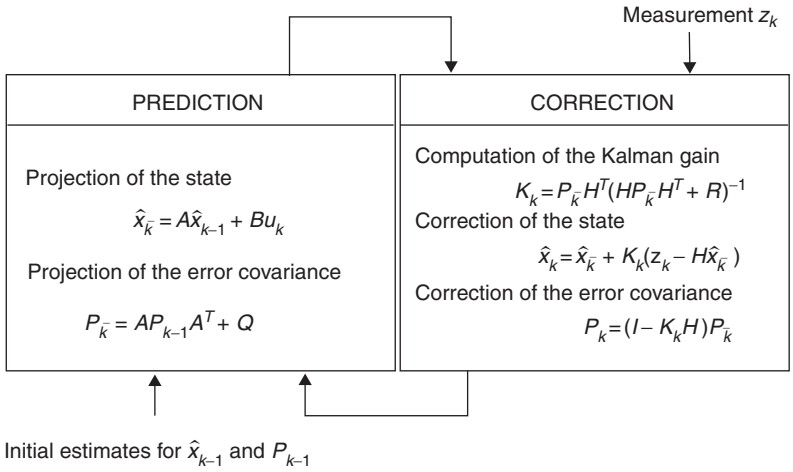

FIGURE 80.1 Scheme of fusion by using Kalman filter.

the odometry. Next, the vector of observations is created from the exteroceptives data: two parameters for the line segments (ρ, θ) and the azimuth angle for the vertical lines. After the prediction of the measures and their matching with the real measures, the next step consists in estimating the pose of the robot and updating the covariance matrices. The covariance matrices linked to the state vector and the observations represent, respectively, the uncertainties of the robot position and of the sensor measures. This robot has been successfully tested for several days and for more than 140,000 localizations.

Data Fusion in Evidence Theory

Evidence theory, initially introduced by Dempster [8], has been reformulated with a more complete formalism by Shafer [18]. This theory is described as a generalization of the Bayesian inference to the uncertainty treatment. In this way, it allows to manipulate unnecessary exclusive events. This capacity provides the advantage to explicitly represent the uncertainty for an event. Moreover, it takes into account the ignorance about an event and perfectly represents what is already known. The evidence theory allows to evaluate the best decision(s) according to the belief that describes the uncertainty for each decision. It is worth noting that the belief evaluation is performed in a subjective way in accordance with our knowledge.

Dempster–Shafer theory begins by the construction of a frame of discernment Θ, which is a set of mutually exclusive decisions. This frame can represent the possible values for any element. For example, if a medical diagnosis for a disease has to be performed, the frame of discernment will be composed of the possible diseases. We then define the mass function that represents the belief measure assigned to an element A of Θ. This function is also called basic probability assignment. Then, if Θ is a frame of discernment, a function $m : 2^{\Theta} \rightarrow [0,1]$ is called mass function or basic probability assignment if:

$$m(\phi)=0$$

and

$$\sum_{A \subset \Theta} m(A) = 1.$$

In this way, the belief for the empty set must be null and a total belief for a decision is equal to 1. This quantity measures the belief that we exactly assign to A and not the total belief assigned to A. In order to obtain the total belief to A, it is necessary to add to $m(A)$ the quantities $m(B)$ for all proper subsets B of A:

$$Bel(A) = \sum_{B \subset A} m(B)$$

© 2005 by CRC Press LLC

If Θ is a frame of discernment, then a function $Bel:2^{\Theta} \rightarrow [0,1]$ is a credibility function if and only if it satisfies the following conditions:

$$Bel(\phi)=0$$

$$Bel(\Theta)=1$$

$\forall n>0$ and for any collection $A_1, A_2, \ldots, A_n$ of Θ:

$$Bel(A_1 \cup \ldots \cup A_n) \geq \sum_{\substack{1 \subset \{1,\ldots,n\} \\ 1 \neq \phi}} (-1)^{|I|+1} Bel\left(\bigcap_{i \in I} A_i\right)$$

In the same way, the plausibility function is defined as:

$$Pl(A)=\sum_{B \cap A=\phi} m(B)=1-Bel(\bar{A})$$

Thus, $1-Pl(A)$ represents a measure of the doubt in A, noted $Dou(A)=Bel(\bar{A})$. A subset A of a frame Θ is called a focal element of a belief function over Θ if $m(A)>0$. If we suppose that $\Theta=\{D_1,D_2,D_3\}$ and $m(\{D_1\})=0.3$, $m(\{D_1,D_2\})=0.2$ and $m(\{D_1,D_2,D_3\})=0.5$ then we obtain the belief and the plausibility of Table 80.2.

Belief functions are well adapted to the representation of evidence because they admit a genuine combination rule. Given several belief functions over a common frame of discernment but based on different bodies of evidence, Dempster's combination rule permits the computation of their orthogonal sum, which is a new belief function based on the combined evidence. The combination rule is the following:

If $k=\sum_{\substack{B,C \\ B \cap C=\phi}} m_1(B)m_2(C)<1$ then

$$(m_1 \oplus m_2)(A)=\frac{\sum_{B,C/A=B \cap C} m_1(B)m_2(C)}{1-\sum_{B,C/B \cap C=\phi} m_1(B)m_2(C)}$$

k can obviously be used as a measure of conflict.

For example, if $\Theta=\{D,D'\}$, where D means "There is an obstacle in front of the robot" and D' means, "There is no obstacle in front of the robot." We suppose that m_1 is the mass function that assigns a belief that there is an obstacle from an acoustic sensor and m_2 the same measure from an infrared sensor with the values of Table 80.3, for example:

we obtain Table 80.4:

thus,

$$m_1+m_2(\{D\})=0.72+0.08+0.18=0.98$$

TABLE 80.2 Results of the Belief and Plausibility Computation

$Bel(\{D_1\})=0.3$	$Pl(\{D_1\})=1.0$
$Bel(\{D_1\ D_2\})=0.5$	$Pl\{(D_1,D_2\})=1.0$
$Bel(\{D_1,D_3\})=0.3$	$Pl(\{D_1,D_3\})=1.0$
$Bel(\{D_1,D_2,D_3\})=1.0$	$Pl(\{D_1,D_2,D_3\})=1.0$

TABLE 80.3 Mass Distribution

$m_1(\{D\})=0.8$	$m_1(\{D'\})=0$	$m_1(\{D,D'\})=0.2$
$m_2(\{D\})=0.9$	$m_2(\{D'\})=0$	$m_2(\{D,D'\})=0.1$

© 2005 by CRC Press LLC

Table 80.4 Results of the Fusion

m_1		m_2		
		0.9 $\{D\}$	0 $\{D'\}$	0.1 $\{D,D'\}$
0.8	$\{D\}$	0.72	0	0.08
0	$\{D'\}$	0	0	0
0.2	$\{D,D'\}$	0.18	0	0.02

$$m_1 + m_2(\{D'\}) = 0$$

$$m_1 + m_2(\{D,D'\}) = 0.02$$

In order to combine a collection of belief functions, one can form the pairwise orthogonal sums:

$$((\ldots(m_1 \oplus m_2)\ldots) \oplus m_{n-1}) \oplus m_n$$

Finally, several criteria may be applied in order to make a decision among the frame of discernment [19]. Nonexhaustively, we can distinguish: maximum credibility, maximum plausibility, maximum credibility, and plausibility.

Application [21] proposes to use the perceptual organization combined with the Dempster–Shafer theory. The goal of the perceptual organization phase is to build global order in visual information with elementary information from one image. In our case, this means that we have to use some characteristics about straight lines to group the similar ones. The principal idea is to consider these characteristics as different sensory information and to perform data fusion on this information. The paper presents two parts, which, respectively, rectify the segmentation mistakes by restoring the coherence of the segments, and detects objects in the scene by forming groups of primitives. The authors show that without any prior knowledge and any threshold, their bottom-up algorithm efficiently detects the different objects even in a cluttered environment. Moreover, it is demonstrated that robustness and flexibility in indoor and outdoor scenes without any modification of parameters are more important.

Murphy [16] deals with mobile robot navigation by using the Dempster–Shafer theory.

Data Fusion in Possibility Theory

Another possibilistic approach, which received considerable attention, is fuzzy logic [25,26]. In possibility theory, the information available, relative to the value of parameter *x,* is represented by a possibility distribution π. A possibility distribution corresponds to an interval (or a set) representing imprecise information. Such a set is generally fuzzy. The union and the intersection of sets are both important ways, from others, to fuse the sets.

Let Ω be the referential. Let us then assume we have two sources of information, noted 1 and 2, which inform us about the value of parameter *x* as follows:

Source 1: $x \in E_1 \subseteq \Omega$
Source 2: $x \in E_2 \subseteq \Omega$

The decision about *x* then depends on whether sets E_1 and E_2 intersect more or less, or not at all, and whether the sources are reliable or not. In each case, the knowledge context of the situation will allow a conclusion to be reached. There is no method to fuse these two elements that is able to deal with all possible cases. But there exist different combinatory modes suiting each case.

It is possible to find a large range of schemes suiting each case. Among the ensemblist methods of data fusion, we can essentially remark:

© 2005 by CRC Press LLC

The conjunctive fusion that corresponds to the fuzzy sets intersection. This approach assumes that the sources are totally reliable. The resulting set of this fusion, which concerns the value of the parameter x must largely tally with each other.

The disjunctive fusion that corresponds to the fuzzy sets union. This method is adequate if the sources are in conflict and if one of them is reliable contrary to the other. This approach allows to fuse sources that present nonintersecting sets.

The adaptive fusion that allows to take advantage of the conjunctive and the disjunctive fusions (after normalization, if necessary). For example, it is possible to apply the disjunctive fusion in order to complete information resulting from a conjunctive fusion in which a conflict appeared. If no agreement can be found between the sources, the conjunctive fusion is discarded in favor of the consideration of the disjunctive fusion.

A decision is usually taken from the largest of membership values after the combination step.

We propose a simple example in which two sensors $S1$ and $S2$ provide information about the shape of an object among the following propositions {cube, cylinder, sphere, prism}. We choose to use a conjunctive fusion as an intersection of the fuzzy sets. This kind of fusion assumes that the information sources are in full agreement and we particularly define the minimum function as:

$$\forall w \in \Omega,\ \pi_{conj}(w) = \min(\pi_1(w), \pi_2(w))$$

π_1 and π_2 are the possibility distributions that represent the opinion of the two sensors on the shape of the object x. Figure 80.2 describes the different cases that may be encountered according to the agreement of the sources.

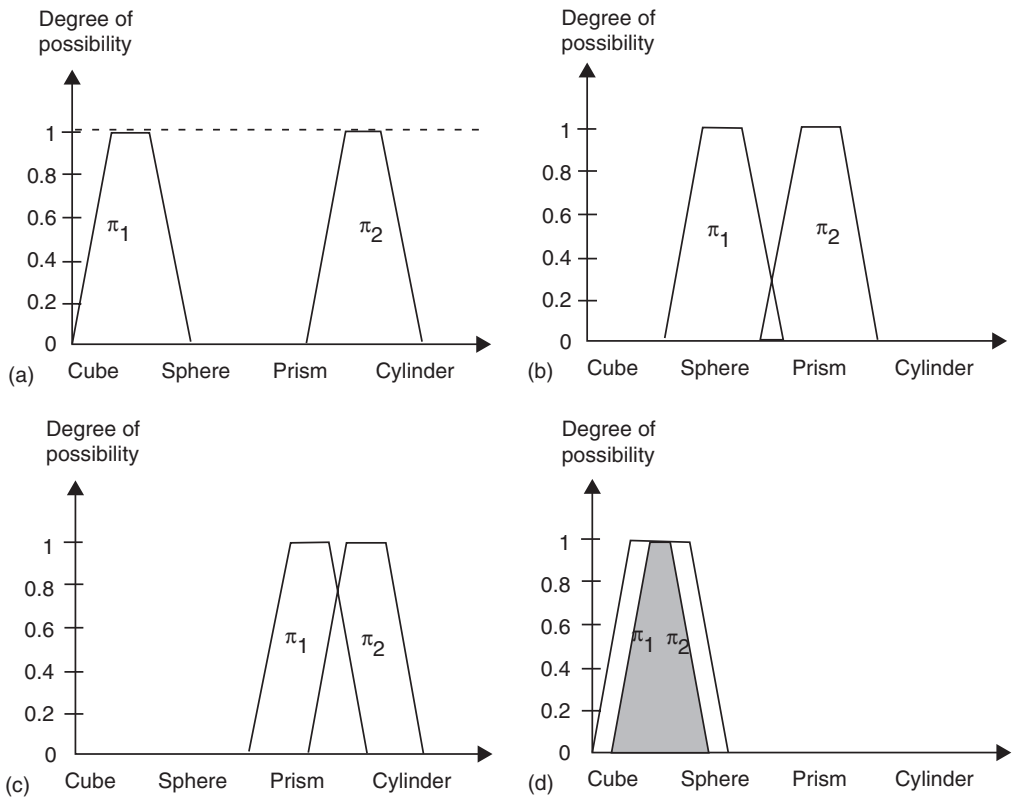

FIGURE 80.2 Illustration of the conjunctive fusion.

© 2005 by CRC Press LLC

TABLE 80.5 Management of Imprecision and Uncertainty in Different Approaches

Approach	*Imprecision*	*Uncertainty*
Bayesian	Implicit	Explicit
Possibilistic	Explicit	Implicit
Evidential	Explicit	Explicit

We can see that the results of the fusion are, respectively, in total conflict (a), in strong conflict (b), in weak conflict (c), and in agreement (d). In fact, the last case is only appropriate for the conjunctive fusion and another kind of function must be used for the other situations.

Bloch [3] gives a very good statement and review of the fusion problem. Three approaches (Bayesian, Dempster–Shafer, and fuzzy set framework) to deal with imprecision and uncertainty in data fusion are described. These methods were applied and illustrated with medical images (dual echo MRI of the brain) in order to estimate the three classes (brain, ventricles, and pathology). Here, four stages are considered: modeling, estimation, combination, and decision. For each stage, a brief discussion about the three approaches is proposed.

Sossai et al. [20] presents one application of this approach to localize a mobile robot.

Discussion

Probabilistic approaches represent the category of the most used methods of fusion. This is not only due to its history but also and essentially due to its solid mathematical foundment. This is the large range of tools available for the modelization and the learning that make these methods successful. Moreover it is very easy to introduce information that can be represented as probabilities. However, some disadvantages can be noticeable. First, if the probabilistic methods allow to correctly represent the uncertainty, they do not provide the possibility to treat the inaccuracy. Moreover, the very severe constraints linked to the probabilistic methods can give rise to a very delicate learning phase. This remark is also valid for the combination rule, which often requires some simplifying hypotheses rarely verified.

The restrictions of the probabilistic approach also deal with the reasoning that can be done only on singletons in a closed world. Indeed, contrary to evidential and possibilistic theories, the probabilistic methods do not allow to treat the partial membership. In the same way, these theories allow the management of the ignorance and of the conflicts and offer powerful tools of modelization and management of uncertainty and inaccuracy. However, the decision rules are less formalized and efficient than the probabilistic methods.

We give, in Table 80.5, an abstract of the management of imprecision and uncertainty for the three approaches.

There is no real global solution in order to select a method of fusion rather than another one. Nevertheless, the nature of the data and of the sensors, the learning facility, and the system itself can direct the choice.

80.3 Conclusion

We have presented the multi-sensor data fusion problem, the principal classes of computational data fusion methods, and some examples of applications. Obviously, this presentation is not exhaustive and the methods have been proposed in a general framework. The aim was just to provide an overview of the different possibilities and to explain basically the functioning of these methods. Applications were chosen to show how these methods are implemented and their advantage; they give an idea about the variety of areas in which data fusion concepts can be applied. The contribution of data and sensor fusion was demonstrated through the increasing accuracy and robustness of developed systems. More generally, it is important to remark that the nonprobabilistic methods are becoming more and more popular and that they are better exploited.

81.1 Introduction

Consider the *airbag* in the steering wheel of your car. It should, after the detection of a crash (and only then), inflate just in time to softly catch your head to prevent it from hitting the steering wheel; not too early — since this would make the airbag deflate before it can catch you, nor too late — since the exploding airbag could then injure you by blowing up in your face and/or catch you too late to prevent your head from banging into the steering wheel.

The computer-controlled airbag system is an example of a real-time system (RTS). But RTSs are of many different types, including vehicles, telecommunication systems, industrial automation systems, household appliances, etc.

There is no commonly agreed upon definition of what an RTS is, but the following characterization is (almost) universally accepted:

- RTSs are computer systems that physically interact with the real world.
- RTSs have requirements on the timing of these interactions.

Typically, the real-world interactions occur via sensors and actuators, rather than the keyboard and screen of your standard PC.

Real-time requirements typically express that an interaction should occur within a specified timing bound. It should be noted that this is quite different from requiring the interaction to be as fast as possible.

© 2005 by CRC Press LLC

Essentially all RTSs are embedded in products, and the vast majority of *embedded computer systems* are RTSs. RTS is the dominating application of computer technology, as more than 99% of the manufactured processors (more than 8 billion in 2000 [Hal00]) are used in embedded systems.

Returning to the airbag system, we note that it in addition to being an RTS, it is a safety-critical system, that is, a system that, due to severe risks of damage, has strict *Quality of Service* (QoS) requirements, including requirements of functional behavior, robustness, reliability, and timeliness.

A typical strict timing property could be that a certain response to an interaction must always occur within some prescribed time, for example, that the charge in the airbag must detonate between 10 and 20 msec from the detection of a crash; violation of this must be avoided at any cost, since it would lead to something unacceptable, like you having to spend a couple of months in hospital. A system that is designed to meet strict timing requirements is often referred to as a *hard real-time system.* In contrast, systems for which occasional timing failures are acceptable — possibly because this will not lead to something terrible — are termed *soft real-time systems.*

An illustrative comparison between hard and soft RTSs, which highlights the difference between the extremes, is shown in Table 81.1. A typical hard RTS could in this context be an engine control system, which must operate with μs-precision, and that will severely damage the engine if timing requirements fail by more than a few *msec.* A typical soft RTS could be a banking system, for which timing is important, but where there are no strict deadlines and some variations in timing are acceptable.

Unfortunately, it is impossible to construct real systems that satisfy hard real-time requirements, since due to the imperfection of hardware (and designers), any system may break. The best that can be achieved is a system that with very high probability provides the intended behavior during a finite interval of time.

However, on the conceptual level, hard real-time makes sense, since it implies a certain amount of rigor in the way the system is designed, for example, it implies an obligation to prove that the strict timing requirements are met, at least under some simplifying, but realistic, assumptions.

Since the early 1980s, a substantial research effort has provided a sound theoretical foundation (e.g., [RTS, Klu]) and many practically useful results for the design of hard real-time systems. Most notably, hard RTS scheduling has evolved into a mature discipline, using abstract, but realistic, models of tasks executing on single CPU, multiprocessor, or distributed computer systems, together with associated methods for timing analysis. Such *schedulability analysis,* for example, the well-known rate-monotonic analysis [LL73, KRP$^+$98, ABD$^+$95], have also found significant use in some industrial segments.

However, hard real-time scheduling is not the cure for all RTSs. Its main weakness is that it is based on analysis of the worst possible scenario. For safety-critical systems, this is of course a must, but for other systems, where general customer satisfaction is the main criterion, it may be too costly to design the system for a worst-case scenario that may not occur during the system's lifetime.

If we look at the other end of the spectrum, we find the *best-effort approach,*which is still the dominating approach in industry. The essence of this approach is to implement the system using some best practice, and then use measurements, testing, and tuning to make sure that the system is of sufficient quality. Such a system will hopefully satisfy some soft real-time requirement, the weakness being that we do not know which. On the other hand, compared to the hard real-time approach, the system can be better

TABLE 81.1 Typical Characteristics of Hard and Soft RTSs [Kop03]

Characteristic	Hard Real-Time	Soft Real-Time
Timing requirements	Hard	Soft
Pacing	Environment	Computer
Peak-load performance	Predictable	Degraded
Error detection	System	User
Safety	Critical	Noncritical
Redundancy	Active	Standby
Time granularity	Millisecond	Second
Data files	Small	Large
Data integrity	Short term	Long term

© 2005 by CRC Press LLC

optimized for the available resources. A further difference is that hard real-time system methods essentially are applicable to static configurations only, whereas it is less problematic to handle dynamic task creation, etc., in best-effort systems.

Having identified the weaknesses of the hard real-time and best-effort approaches, major efforts are now being put into more flexible techniques for soft RTSs. These techniques provide analyzability (like hard real-time), together with flexibility and resource efficiency (like best-effort). The bases for the flexible techniques are often quantified *Quality-of-Service* (QoS) characteristics. These are typically related to nonfunctional aspects, such as timeliness, robustness, dependability, and performance. To provide a specified QoS, some kind of resource management is needed. Such a QoS-management is either handled by the application, by the operating system, by some middleware, or by a mix of the above. The QoS-management is often a flexible on-line mechanism that dynamically adapts the resource allocation to balance between conflicting QoS-requirements.

81.2 Design of RTSs

The distinguishing factor for RTS design is the need to always have *timing predictability* in mind. Ignoring timing issues in the design phase, and hope to be able to understand, analyze, and modify the timing behavior of the completed system is a sure recipe for failure.

In this section, we describe the general structure of embedded RTSs and their major design structures. We also outline some commercial tools that are available for the design of RTSs.

Reference Architecture

A generic system architecture for an RTS is depicted in Figure 81.1. This architecture is a model of any computer-based system interacting with an external environment via sensors and actuators.

Since our focus is on the RTS, we will look more into different organizations of that part of the generic architecture in Figure 81.1. The simplest RTS is a single processor; but in many cases, the RTS is a distributed computer system consisting of a set of processors interconnected by a communications network. There could be several reasons for making an RTS distributed, including

- the physical distribution of the application,
- the computational requirements, which may not be conveniently provided by a single CPU,
- the need for redundancy to meet availability, reliability, or other safety requirements, or
- to reduce the cabling in the system.

Figure 81.2 shows an example of a distributed RTS. In a modern car, like the one depicted in the figure, there are some 20 to 100 computer nodes (which in the automotive industry are called Electronic Control Units; ECUs) interconnected with one or more communication networks. The initial

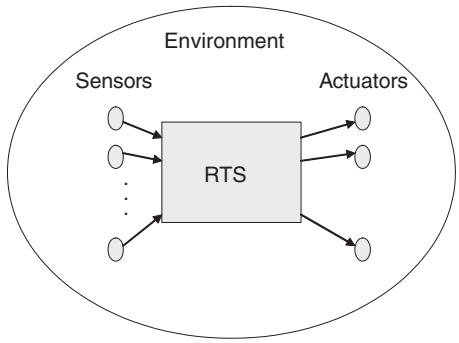

FIGURE 81.1 A generic RTS architecture.

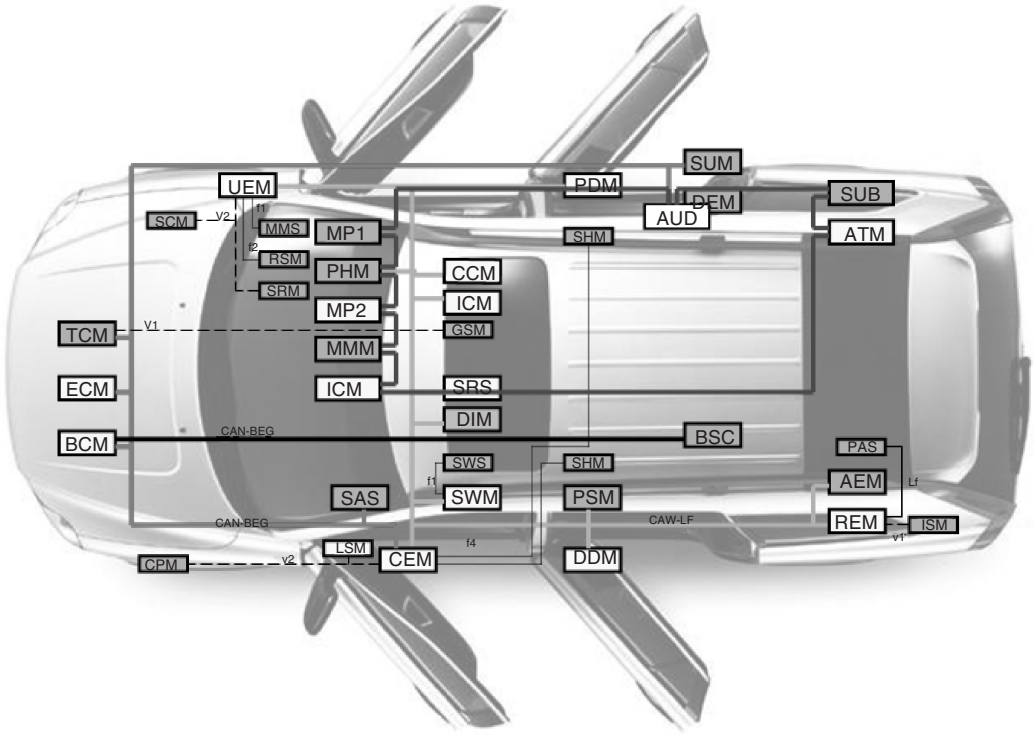

FIGURE 81.2 Network infrastructure of Volvo XC90.

motivation for this type of electronic architecture in cars was the need to reduce the amount of cabling. However, the electronic architecture has also led to other significant improvements, including substantial pollution reduction and new safety mechanisms, such as computer-controlled Electronic Stabilization Programs (ESPs). The current development is toward making the most safety-critical vehicle functions, like braking and steering, completely computer controlled. This is done by removing the mechanical connections (e.g., between steering wheel and front wheels, and between brake pedal and brakes), replacing them with computers and computer networks. Meeting the stringent safety requirements for such functions will require careful introduction of redundancy mechanisms in hardware and communication, as well as software, that is, a safety-critical system architecture is needed (an example of such an architecture is TTA [KB03]).

Models of Interaction

Above, we presented the physical organization of an RTS; but for an application programmer, this is not the most important aspect of the system architecture. Actually, from an application programmer's perspective, the system architecture is more given by the *execution paradigm* (execution strategy) and the *interaction model* used in the system. In this section, we describe what an interaction model is and how it affects the real-time properties of a system, and in the next section we discuss the execution strategies used in RTSs.

A model of interaction describes the rules by which components interact with each other (in this section, we will use the term component to denote any type of software unit, such as a task or a module). The interaction model can govern both control flow and data flow between system components. One of the most important design decisions, for all types of systems, is which interaction models to use (sadly, however, this decision is often implicit, and hidden in the system's architectural description).

© 2005 by CRC Press LLC

When designing RTSs, attention should be paid to what are the timing properties of the interaction models chosen. Some models have a more predictable and robust behavior with respect to timing than other models. Examples of some of the more predictable models that are also commonly used in RTSs design are given below.

Pipes-and-filters. In this model, both data and control flow is specified using input and output ports of components. A component becomes eligible for execution when data have arrived on its input ports and when the component finishes execution it produces output on its output ports.

This model fits for many types of control programs very well, and control laws are easily mapped to this interaction model. Hence, it has gained widespread use in the real-time community. The real-time properties of this model are also quite good. Since both data and control flow unidirectionally through a series of components, the order of execution and end-to-end timing delay usually become highly predictable. The model also provides a high degree of decoupling in time; that is, components can often execute without having to worry about timing delays caused by other components. Hence, it is usually straightforward to specify the compound timing behavior of a set of components.

Publisher–subscriber. The publisher–subscriber model is similar to the pipes-and-filters model but it usually decouples data and control flow. That is, a subscriber can usually choose different forms for triggering its execution. If the subscriber chooses to be triggered on each new published value, the publisher–subscriber model takes on the form of the pipes-and-filters model. However, in addition, a subscriber could choose to ignore the timing of the published values and decide to use the latest published value. Also, for the publisher–subscriber model, the publisher is not necessarily aware of the identity, or even the existence, of its subscribers. This provides a higher degree of decoupling of components.

Similar to the pipes-and-filters model, the publisher–subscriber model provides good timing properties. However, a prerequisite for analysis of systems using this model is that subscriber components make explicit as to which values they will subscribe to (this is not mandated by the model itself). However, when using the publisher–subscriber model for embedded systems, it is the norm that subscription information is available (this information is used, for instance, to decide which values have to be published over a communications network, and to decide the receiving nodes of those values).

Blackboard. The blackboard model allows variables to be published on a globally available blackboard area. Thus, it resembles the use of global variables. The model allows any component to read or write values to variables in the blackboard. Hence, the software engineering qualities of the blackboard model are questionable. Nevertheless, it is a model that is commonly used, and in some situations it provides a pragmatic solution to problems that are difficult to address with more stringent interaction models.

Software engineering aspects aside, the blackboard model does not introduce any extra elements of unpredictable timing. On the other hand, the flexibility of the model does not help engineers to achieve predictable systems. Since the model does not address the control flow, components can execute relatively undisturbed and decoupled form other components.

On the other end of the spectrum of interaction models, there are models that increase the (timing) unpredictability of the system. These models should, if possible, be avoided when designing RTSs. The two most notable, and commonly used, are:

Client–server. In the client–server model, a client asynchronously invokes a service of a server. The service invocation passes the control flow (plus any input data) to the server, and control stays at the server until it has completed the service. When the server is done, the control flow (and any return data) is returned to the client, which in turn resumes execution.

The client–server model has an inherently unpredictable timing. Since services are invoked asynchronously, it is very difficult to a priori assess the load on the server for a certain service invocation. Thus, it is difficult to estimate the delay of the service invocation and, in turn, it is difficult to estimate the response-time of the client. This matter is furthermore complicated by the fact that most components often behave both as clients and servers (a server often uses other servers to implement its own services), leading to very complex and unanalyzable control flow paths.

Message-boxes. A component can have a set of message-boxes, and components communicate by posting messages in each other's message-boxes. Messages are typically handled in FIFO order, or in priority order

© 2005 by CRC Press LLC

(where the sender specifies a priority). Message passing does not change the flow of control for the sender. A component that tries to receive a message from an empty message-box, however, blocks on that message-box until a message arrives (often, the receiver can specify a timeout to prevent indefinite blocking).

From a sender's point of view, the message-box model has problems similar to the client–server model. The data sent by the sender (and the action that the sender expects the receiver to perform) may be delayed in an unpredictable way when the receiver is highly loaded. Also, the asynchronous nature of the message passing makes it difficult to foresee the load of a receiver at any particular moment.

Furthermore, from the receiver's point of view, the reading of message-boxes is unpredictable in the sense that the receiver may or may not block on the message-box. Also, since message boxes are often of limited size, a highly loaded receiver risks to lose some messages. Which messages that are lost is another source of unpredictability.

Execution Strategies

There are two main execution paradigms for RTSs: *time triggered* and *event triggered*. When using timed-triggered execution, activities occur at predefined instances of time, for example, a specific sensor value is read exactly every 10 msec and exactly 2 msec later the corresponding actuator receives an updated control parameter. In an event-triggered execution, on the other hand, actions are triggered by event occurrences, for example, when the level of toxic fluid in a tank reaches a certain level an alarm will go off. It should be noted that the same functionality typically can be implemented in both paradigms, for example, a time-triggered implementation of the above alarm would be to periodically read the level-measuring sensor and set off the alarm when the read level exceeds the maximum allowed. If alarms are rare, the time-triggered version will have a much higher computational overhead than the event-triggered one. On the other hand, the periodic sensor readings will facilitate detection of a malfunctioning sensor.

Time-triggered executions are used in many safety-critical systems with high dependability requirements (such as avionic control systems), whereas the majority of other systems are event triggered. Dependability can also be guaranteed in the event-triggered paradigm, but due to the observability provided by the exact timing of time-triggered executions, most experts argue for using time-triggered in ultradependable systems. The main argument against time-triggered systems is its lack of flexibility and the requirement of preruntime schedule generation (which is a nontrivial and possibly time-consuming task).

Time-triggered systems are mostly implemented by simple proprietary table-driven dispatchers [XP90] (see the section Off-line schedulers for a discussion on table-driven execution); but complete commercial systems including design tools are also available [TTT, KG94]. For the event-triggered paradigm, a large number of commercial tools and operating systems are available (examples are given in the section Commercial RTOSes). There are also examples of systems integrating the two execution paradigms, thereby aiming at getting the best of two worlds: time-triggered dependability and event-triggered flexibility. One example is the Basement system [HLS96] and its associated real-time kernel Rubus [Arc].

Since computations in time-triggered systems are statically allocated both in space (to a specific processor) and time, some kind of configuration tool is often used. This tool assumes that the computations are packaged into schedulable units (corresponding to tasks or threads in an event-triggered system). Typically, for example in Basement, computations are control-flow based, in the sense that they are defined by sequences of schedulable units, each unit performing a computation based on its inputs and producing outputs to the next unit in sequence. The system is configured by defining the sequences and their timing requirements. The configuration tool will then automatically (if possible[1]) generate a schedule, which guarantees that all timing requirements are met.

[1] This scheduling problem is theoretically intractable; thus, the configuration tool will have to rely on some heuristics that works well in practice, but that does not guarantee finding a solution in all cases when there is a solution.

© 2005 by CRC Press LLC

Event-triggered systems typically have a richer and more complex APIs (Application Programmer Interfaces), defined by the used operating system and middleware, which will be elaborated on in Section 81.3.

Component-Based Design of Real-Time Systems

Component-Based Design (CBD) of software systems is an interesting idea for software engineering in general, and for engineering of RTSs in particular. In CBD, a *software component* is used to encapsulate some functionality. This functionality is only accessed through the *interface* of the component. A system is composed by assembling a set of components and connecting their interfaces.

The reason CBD could prove extra useful for RTSs is the possibility to extend components with *introspective interfaces.* An introspective interface does not provide any functionality *per se*, rather the interface can be used to retrieve information about *extrafunctional* properties of the component. Extrafunctional properties can include attributes such as memory consumption, execution-times, task periods, etc. For RTS, timing properties are of course of particular interest.

Unlike the functional interfaces of components, the introspective interfaces can be available off-line, that is, during the component assembly phase. This way, the timing attributes of the system components can be obtained at design time and tools to analyze the timing behavior of the system could be used. If the introspective interfaces are also available on-line they could be used in, for instance, admission control algorithms. An admission control could query new components for their timing behavior and resource consumption before deciding to accept a new component to the system.

Unfortunately, many industry standard software techniques are based on the client–server or the message-box models of interaction, which we deemed, in the section Models of Interaction, unfit for RTSs. This is especially true for the most commonly used component models. For instance, the Corba Component Model (CCM) [OMG02], Microsoft's COM [Mica] and .NET [Micb] models, and Java Beans [SUN] all have the client–server model as their core model. Also, none of these component technologies allow the specification of extrafunctional properties through introspective interfaces. Hence, from the real-time perspective, the biggest advantage of CBD is void for these technologies.

However, there are numerous research projects addressing CBD for real-time and embedded systems (e.g., [Sta01, vO02, MSZ02, SVK97]). These projects are addressing the issues left behind by the existing commercial technologies, such as timing predictability (using suitable computational models), support for off-line analysis of component assemblies, and better support for resource-constrained systems. Often, these projects strive to remove the considerable run-time flexibility provided by existing technologies. This run-time flexibility is judged to be the foremost contributor to unpredictability (the flexibility is also adding to the run-time complexity and prevents CBD for resource-constrained systems).

Tools for Design of RTSs

In industry, the term *RTS* is highly overloaded, and can mean anything from interactive systems to superfast systems, or embedded systems. Consequently, it is not easy to judge what tools are suitable for developing RTSs (as we define real-time in this chapter).

For instance, UML [OMG03b] is commonly used for software design. However, UML's focus is mainly on client–server solutions, and it has proven inept for RTSs' design. As a consequence, UML-based tools that extend UML with constructs suitable for real-time programs have emerged. The two most well-known of such products are Rational's Rose RealTime [Rat] and i-Logix' Rhapsody [IL]. These tools provide UML-support with the extension *of real-time profiles.* While giving real-time engineers access to suitable abstractions and computational models, these tools do not provide means to describe timing properties or requirements in a formal way; thus, they do not allow automatic verification of timing requirements.

TeleLogic provides programming and design support using the language SDL [Tel]. SDL was originally developed as a specification language for the telecom industry, and is as such highly suitable for describing complex reactive systems. However, the fundamental model of computation is the

© 2005 by CRC Press LLC

message-box model, which has an inherently unpredictable timing behavior. However, for soft embedded RTSs, SDL can give very time- and space-efficient implementations.

For more resource-constrained hard RTSs, design tools are provided by, for example, Arcticus System [Arc], TTTech [TTT], and Vector [Veca]. These tools are instrumental during both system design and implementation, and also provide some timing analysis techniques that allow timing verification of the system (or parts of the system). However, these tools are based on proprietary formats and processes, and have as such reached a limited customer base (mainly within the automotive industry).

Within the near future, UML2 will become an adopted standard [OMG03c]. UML2 has support for computational models suitable for RTSs. This support comes mainly in the form of *ports* that can have *protocols* associated to them. Ports are either *provided* or *required,* hence allowing type-matching of connections between components. UML2 also includes much of the concepts from Rose RealTime, Rhapsody, and SDL. Other, future design techniques that are expected to have an impact on the design of RTSs include the EAST/EEA *Architecture Description Language* (EAST-ADL) [ITE]. The EAST-ADL is developed by the automotive industry and is a description language that will cover the complete development cycle of distributed, resource-constrained, safety-critical, RTSs. Tools to support development with EAST-ADL (which is a UML2-compliant language) are expected to be provided by automotive tool vendors such as ETAS [ETA], Vector [Vecb], and Siemens [Sie].

81.3 Real-Time Operating Systems

When building real-time computer systems, it is often beneficial to use a *Real-Time Operating System* (RTOS). An RTOS provides services for resource access and resource sharing, very much similar to a general-purpose operating system. The main reasons for not using a general-purpose operating system when developing RTSs are:

- High resource utilization, for example, large RAM and ROM footprints, and high internal CPU-demand.
- Difficult to access hardware and devices in a timely manner, for example, no application-level control over interrupts.
- Lack of services to allow timing-sensitive interactions between different processes.

Typical Properties of RTOSes

The state of practice in RTOS is reflected in [FAQ]. Not all operating systems are RTOSes. An RTOS is typically multithreaded and preemptible; there has to be a notion of thread priority, predictable thread synchronization has to be supported, priority inheritance should be supported, and the OS behavior should be known [Art03]. This means that the interrupt latency, worst-case execution time of system calls, and maximum time during which interrupts are masked must be known. A commercial RTOS is usually marketed as the run-time component of an embedded development platform.

As a general rule of thumb, one can say that RTOSes are:

- Being apt for the resource constrained environments where most RTSs operate.
  Most RTOSes can be configured preruntime (e.g., at compile time) to only include a subset of the total functionality. Thus, the application developer can choose to leave out unused portions of the RTOS in order to save resources.
  RTOSes typically store much of their configuration in ROM. This is done for mainly two purposes: (1) minimize the use of expensive RAM memory and (2) minimize the risk that critical data is overwritten by an erroneous application.
- Giving the application programmer easy access to hardware features such as interrupts and devices.
  Most often, the RTOSes give the application programmer means to install Interrupt Service Routines (ISRs) during compile time and/or during runtime. This means that the RTOS leaves all

© 2005 by CRC Press LLC

interrupt handing to the application programmer, allowing fast, efficient, and predictable handling of interrupts.

In general-purpose operating systems, memory-mapped devices are usually protected from direct access using the Memory Management Unit (MMU) of the CPU, thus forcing all device accesses to go through the operating system. RTOSes typically do not protect such devices and allow the application to directly manipulate the devices. This gives faster and more efficient access to the devices. (However, this efficiency comes at the price of an increased risk of erroneous use of the device.)

- Providing services that allow implementation of timing-sensitive code.

  An RTOS typically has many mechanisms to control the relative timing between different processes in the system. Most notably, the RTOS has a real-time process scheduler whose function is to make sure that the processes execute in the way the application programmer intended them to. We will elaborate more on the issues of scheduling in Section 81.4.

  An RTOS also provides mechanisms to control the process's relative performance when accessing shared resources. This can, for instance, be done by priority queues, instead of plain FIFO-queues as is used in general-purpose operating systems. Typically an RTOS supports one or more real-time resource locking protocols, such as priority inheritance, or priority ceiling (the next section discusses resource locking protocols further).
- Being tailored to fit the development process that is typical when developing embedded systems (recall; most RTSs are also embedded systems).
- RTSs are usually constructed in a *host environment* that is different from the *target environment,* so-called *cross-platform* development. Also, it is typical that the whole memory image, including both RTOS and one or more applications, is created at the host platform and downloaded to the target platform. Hence, most RTOSes are delivered as source code modules or precompiled libraries that are statically linked with the applications at compile time.

Mechanisms for Real-Time

One of the most important functions of an RTOS is to arbitrate access to shared resources in such a way that the timing behavior of the system becomes predictable. The two most obvious resources that the RTOS manages to access are:

- The CPU — That is, the RTOS should allow processes to execute in a predictable manner.
- Shared memory areas — That is, the RTOS should resolve contention to shared memory in a way that gives predictable timing.

The CPU access is arbitrated with a *real-time scheduling policy.* Section 81.4 will describe real-time scheduling policies in more depth. Examples of scheduling policies that can be used in RTSs are priority scheduling, deadline scheduling, or rate scheduling. Some of these policies directly use timing attributes (like deadline) of the tasks to perform scheduling decisions, whereas other policies use scheduling parameters (like priority, rate, or bandwidth) that indirectly affect the timing of the tasks.

A special form of scheduling, which is also very useful for RTSs, is table-driven (static) scheduling. Table-driven scheduling is described further in the section Off-line schedulers on page **81**-11. To summarize, in table-driven scheduling all arbitration decisions have been made off-line and the RTOS scheduler just follows a simple table. This gives very good timing predictability, albeit at the expense of system flexibility.

The most important aspect of a real-time scheduling policy is that it should provide means to *a priori* analyze the timing behavior of the system, thus giving a predictable timing behavior of the system. Scheduling in general-purpose operating systems normally emphasizes properties like fairness, throughput, and guaranteed progress; these properties may all be adequate in their own respect; however, they are usually in conflict with the requirement that an RTOS should provide timing predictability.

Shared resources (such as memory areas, semaphores, and mutexes) are also arbitrated by the RTOS. When a task locks a shared resource, it will *block* all other tasks that subsequently tries to lock the

© 2005 by CRC Press LLC

resource. In order to achieve predictable blocking times, special real-time resource locking protocols have been proposed ([But97, BW96] provides more details about the protocols).

Priority Inheritance Protocol (PIP). PIP makes a low-priority task inherit the priority of any higher priority task that becomes blocked on a resource locked by the lower priority task.

This is a simple and straightforward method to lower the blocking time. However, it is computationally intractable to calculate the worst-case blocking (which may be infinite since the protocol does not prevent deadlocks). Hence, for hard RTSs or when timing performance needs to be calculated *a priori*, the PIP is not adequate.

Priority Ceiling inheritance Protocol (PCP). PCP associates to each resource a *ceiling value* that is equal to the highest priority of any task that may lock the resource. By clever use of the ceiling values of each resource, the RTOS scheduler will manipulate task priorities to avoid the problems of PIP.

PCP guarantees freedom from deadlocks, and the worst-case blocking is relatively easy to calculate. However, the computational complexity of keeping track of ceiling values and task priorities gives PCP high run-time overhead.

Immediate ceiling priority Inheritance Protocol (IIP). IIP also associates to each resource a *ceiling value,* which is equal to the highest priority of and task that may lock the resource. However, different from PCP, in IIP a task is immediately assigned the ceiling priority of the resource it is locking.

IIP has the same real-time properties as the PCP (including the same worst-case blocking time[2]). However, IIP is significantly more easy to implement. It is, in fact, for single node systems easier to implement than any other resource locking protocol (including non-real-time protocols). In IIP, no actual locks need to be implemented; it is enough for the RTOS to adjust the priority of the task that locks or releases a resource. IIP has other operational benefits, notably it paves the way for letting multiple tasks use the same stack area. Operating systems based on IIP can be used to build systems with footprints that are extremely small [Ast, Liv99].

Commercial RTOSes

There is an abundance of commercial RTOSes. Most of them provide adequate mechanisms to enable development of RTSs. Some examples are Tornado/VxWorks [Win], LYNX [LYN], OSE [Sys], QNX [QNX], RT-Linux [RTL], and ThreadX [Log]. However, the major problem with these tools is the rich set of primitives provided. These systems provide both primitives that are suitable for RTSs and primitives that are unfit for real-time systems (or that should be used with great care). For instance, they usually provide multiple resource locking protocols, some of which are suitable and some of which are not suitable for real-time.

This richness becomes a problem when these tools are used by inexperienced engineers and/or when projects are large and project management does not provide clear design guidelines/rules. In these situations, it is very easy to use primitives that will contribute to timing unpredictability of the developed system. Rather, an RTOS should help the engineers and project managers by providing only mechanisms that help in designing predictable systems. However, there is an obvious conflict between the desire/need of RTOS manufacturers to provide rich interfaces and stringency needed by designers of RTSs.

There is a smaller set of RTOSes that have been designed to resolve these problems, and at the same time also allow extreme lightweight implementations of predictable RTSs. The driving idea is to provide a small set of primitives that guide the engineers toward good design of their system. Typical examples are the research RTOS Asterix [Ast] and the commercial RTOS SSX5 [Liv99]. These systems provide a simplified task model, in which tasks cannot suspend themselves (e.g., there is no `sleep()` primitive) and tasks are restarted from their entry point on each invocation. The only resource locking protocol that is supported is IIP, and the scheduling policy is fixed priority scheduling. These limitations make it possible to build an RTOS that is able to run, for example, 10 tasks using less than 200 bytes of RAM, and at the same time giving predictable timing behavior [App98].Other commercial systems that follow a similar principle of reducing the degrees of freedom and hence promote stringent design of predictable RTSs include Arcticus Systems' Rubus OS [Arc].

[2]However, the average blocking time will be higher in IIP than in PCP.

© 2005 by CRC Press LLC

Many of the commercial RTOSes provide standard APIs. The most important RTOS-standards are RT-POSIX [IEE98], OSEK [Gro], and APEX [Air96]. Here, we will only deal with POSIX since it is the most widely adopted RTOS standard, but those interested in automotive and avionic systems should take a closer look at OSEK and APEX, respectively.

The POSIX standard is based on Unix, and its goal is portability of applications at the source code level. The basic POSIX services include task and thread management, file system management, input and output, and event notification via signals. The POSIX real-time interface defines services facilitating concurrent programming and providing predictable timing behavior. Concurrent programming is supported by synchronization and communication mechanisms that allow predictability. Predictable timing behavior is supported by preemptive fixed priority scheduling, time management with high resolution, and virtual memory management. Several restricted subsets of the standard intended for different types of systems have been defined, as well as specific language bindings, for example, for Ada [ISO95].

81.4 Real-Time Scheduling

In this section, we will give an overview of the more common types of schedulers used in RTSs.

Traditionally, real-time schedulers are divided into *off-line* and *on-line* schedulers. Off-line schedulers are making all scheduling decisions before the system is executed. At runtime, a simple dispatcher is used to activate tasks according to off-line generated schedule. On-line schedulers, on the other hand, decide during execution, based on various parameters, which task should execute at any given time.

As there are several different schedulers developed in the research community, in this section we have focused on highlighting the main categories of schedulers that are readily available in existing RTOSes.

Introduction to Scheduling

An RTS consists of a set of real-time programs, which in turn consist of a set of *tasks.* These tasks are sequential pieces of code, executing on a platform with limited resources. The tasks have different timing properties, for example, *execution times, periods,* and *deadlines.* Several tasks can be allocated to a single processor. The scheduler decides, at each moment, which task to execute.

An RTS can be *preemptive* or *nonpreemptive.* In a preemptive system, tasks can preempt each other, letting the task with the highest priority execute. In a nonpreemptive system, a task that has been allowed to start will execute until its completion.

Tasks can be categorized into either being *periodic, sporadic,* or *aperiodic.* Periodic tasks are executing with a specified time (period) between task releases. Aperiodic tasks have no information stating when the task is to be released. Usually, aperiodics are triggered by interrupts. Similarly, sporadic tasks have no period, but in contrast with aperiodics, sporadic tasks have a known minimum time between releases. Typically, tasks that perform measurements are periodic, collecting some value(s) every *n*th time unit. A sporadic task is typically reacting to an event/interrupt that we know has a minimum inter arrival time, for example, an alarm or the emergency shutdown of a production robot. The minimum interarrival time can be constrained by physical laws, or it can be enforced by some hardware mechanism. If we do not know the minimum time between two consecutive events, we must classify the event-handling task to be aperiodic.

A real-time *scheduler* schedules the real-time tasks sharing the same resource (e.g., a CPU or a network link). The goal of the scheduler is to make sure that the timing requirements of these tasks are satisfied. The scheduler decides, based on the task timing properties, which task is to execute or to use the resource.

Off-line Schedulers

Off-line schedulers, or table-driven schedulers, work the following way: the schedulers create a schedule (the table) before the system is started (off-line). At runtime, a *dispatcher* follows the schedule, and makes sure that tasks are only executing at their predetermined time slots (according to the schedule). Off-line schedules are commonly used to implement the time-triggered execution paradigm (described in the section Execution strategies).

By creating a schedule off-line, complex timing constraints can be handled in a way that would be difficult to do on-line. The schedule that is created is the schedule that will be used at runtime. Therefore, the online behavior of table-driven schedulers is very deterministic. Because of this determinism, table-driven schedulers are the more commonly used schedulers in applications that have very high safety-critical demands. However, since the schedule is created off-line, the flexibility is very limited, in the sense that as soon as the system will change (due to, e.g., adding of functionality or change of hardware), a new schedule has to be created and given to the dispatcher. To create new schedules is nontrivial and sometimes very time consuming.

There also exist combinations of the predictable table-driven scheduling and the more flexible priority-based schedulers, and there exist methods to convert one policy to another [FLD03, Arc, MTS02].

On-line Schedulers

Scheduling policies that make their scheduling decisions during runtime are classified as *on-line schedulers.* These schedulers make their scheduling decisions based on some task properties, for example, task priority. Schedulers that make their scheduling decisions based on task priorities are called *priority-based schedulers.*
