INDUSTRIAL ELECTRONICS SERIES

Series Editor
J. David Irwin, *Auburn University*

TITLES INCLUDED IN THE SERIES

Supervised and Unsupervised Pattern Recognition: Feature Extraction and Computational Intelligence
Evangelia Micheli-Tzanakou, *Rutgers University*

Switched Reluctance Motor Drives: Modeling, Simulation, Analysis, Design, and Applications
R. Krishnan, *Virginia Tech*

The Power Electronics Handbook
Timothy L. Skvarenina, *Purdue University*

The Handbook of Applied Computational Intelligence
Mary Lou Padgett, *Auburn University*
Nicolaos B. Karayiannis, *University of Houston*
Lofti A. Zadeh, *University of California, Berkeley*

The Handbook of Applied Neurocontrols
Mary Lou Padgett, *Auburn University*
Charles C. Jorgensen, *NASA Ames Research Center*
Paul Werbos, *National Science Foundation*

The Industrial Information Technology Handbook
Richard Zurawski, *ISA Corporation*

Foreword

Extending the Reach of Automation to Achieve Continuous Productivity Improvements

Automation is largely about productivity improvements, and distributed control systems have been deployed extensively around the world to this end. While the systems were installed to reduce process variability, increase plant availability and automate tasks, the improvements were achieved by focusing primarily on process control. In the 1990s, the open control systems (OCS) were introduced. These had been developed to "open up" the control system environment, making information from the plant floor available to other applications and facilitating interfacing with applications assigned principally to keep the process running smoothly. They were the first such systems to feature major incorporations of "off-the-shelf" technology. However, the focus was still primarily on controlling the process.

All that has now changed. Today, to deliver additional productivity gains, it is necessary to extend the reach of the automation system beyond the world of process control.

Utilizing Data More Intelligently

As mentioned, consistent and predictable process control was achieved in the past with traditional DCS/OCS functionality — operations, engineering, and logic. The operations functions were focused on the needs of the production operator. Interfaces to applications and devices external to the control system with their own data storage typically were collected and duplicated in the control system database to provide accessibility for reporting and operational needs. This approach was found to be difficult to engineer and maintain. The practice of having information stored in multiple locations made it difficult to ensure data integrity as the individual software applications were advanced at asynchronous paces and the customized interfaces between them required frequent maintenance. The increasing deployment of peripheral applications related to productivity improvement, such as quality systems, advanced control, production management, information management, and maintenance management, resulted in different user interfaces for different types of information sources. More recently, the availability of "smart" field devices has vastly increased the amount of data available to improve productivity in a plant. However, each device has its own data collection and communication environment, adding to the complexity of the integration task.

Hence, the data are there, but can an enterprise be sure that they are made available to the right individual, at the appropriate time and in a format that is relevant? The data must be analyzed, and action must be taken to ensure maximum production asset availability, optimal quality, and predictable and appropriate performance — ever-increasing productivity. One of the most consistent demands voiced by end-users is the need to get the right information to the right person to facilitate sound business decisions and appropriate action.

Time for Automation Systems that Can Provide Extended Automation

The systems of today and the future have to have an architecture moving the automation to a new level. From an information access and integration perspective, such systems incorporate functionality far beyond process control.

© 2005 by CRC Press LLC

Specifically, systems have to incorporate process control, production management, safety, discrete logic and sequence control, advanced control, information management, smart instrumentation, smart drives, asset management, and document management capabilities in a singular virtual database environment. Such an integrated system environment allows incorporation of any application solution from any vendor. Consequently, it will be possible to access data directly from its source in the context of the production asset without needing to know where the data come from, and without concern about data integrity and concordance. This elegant solution addresses the engineering and maintenance issues of past solutions mentioned above.

Putting Operations within Reach of Different Stakeholders

From an operations perspective, the modern Human–Machine Interface (HMI) system shall provide a single, consistent HMI intuitive to access and interact with information from all the applications encompassed within an extended automation environment. It allows users of all disciplines who impact production to organize information and navigate throughout the system in the context of their job function. The HMI shall be designed to provide a work environment that helps users to identify events occurring in the process that are relevant to their job function in real-time, while they are happening. This is achieved by customizing the information that is displayed — and, just as importantly, the information that is *not* displayed — as well as the way it is presented for a given process area, according to the job function of the person using the system. As a consequence, the root cause of events can be quickly and intuitively analyzed, and the best course of action can be determined, by virtue of the system's integration and its ability to link to the process object all aspects of information provided by the various system applications.

How Modern Automation Systems Can Improve Productivity

A good example of how a modern automation system will positively affect productivity can be found in the area of plant asset availability and performance. Two methods of instrument maintenance are prevalent today in the industry: *preventive* and *corrective* maintenance. Preventive maintenance is a scheduled activity, based on experience or recommendations designed to reduce or eliminate the possibility of a failure that could cause a production stoppage. Corrective maintenance is carried out "after the fact," that is, when a device has failed in operation and requires immediate repair.

Failures are rare today, since most of the field instruments operating within their design range have a Mean Time Between Failure (MTBF) of 5 years and more. Rearranging and drift require manual intervention, but this need is also greatly reduced when fieldbus and digital transmitters are used. Pressure transmitters, for example, are essentially trouble-free devices. Nevertheless, there is always the possibility of unstable process conditions and unexpected process events significantly affecting device performance. Extended operation in stress conditions will, over time, affect the measurement accuracy. If these events go undetected, the device could continue to send wrong readings to the control system until the next scheduled maintenance, which might be months away.

To prevent this from happening, all pressure transmitters are checked on a regular basis. However, this exercise is wasteful as well as costly; in more than 60% of the scheduled interventions, the result is "negative — no failure found!" That this has an adverse effect on productivity hardly needs mentioning.

Smart Field Devices and their Maintenance

By tying together smart field devices with documentation, asset optimization, and maintenance management functions, a modern automation system ensures that events leading to performance degradation and failures are detected, and that the time between detection and notification, decision, and action is reduced to a minimum.

© 2005 by CRC Press LLC

Today's smart field devices store a wealth of data that can be used to assess their health and performance. The emergence of fieldbus, Fieldbus Device Tools (FDT), and Device Type Manager (DTM) standards has meanwhile made these data available to control systems and other asset management applications.

A modern automation system provides all the capabilities needed for continuous condition monitoring and for streamlining the maintenance process. Continuous monitoring of asset conditions allows preventive maintenance strategies to be replaced by predictive maintenance in response to warnings of degraded asset performance before the asset can fail, and focuses maintenance activity on those devices requiring it. This significantly reduces the number of unnecessary device checks in the field.

Most of these issues and developments are covered in *The Industrial Information Technology Handbook.*

Preface

Aim

The purpose of *The Industrial Information Technology Handbook* is to provide a reference useful for a broad range of professionals and researchers from industry and academia involved or interested in the use of information technology (IT) in industrial applications ranging from industrial automation to industrial enterprise integration. This is the first publication to cover this field in a cohesive and comprehensive way. The focus of this book is on existing technologies used by the industry, as well as newly emerging technologies and trends, evolution of which has been driven by the actual needs and by the industry-led consortia and organizations.

Field of Industrial IT

Over the last decade, IT has had a profound impact on the evolution of industrial enterprises toward fully integrated entities. Nowadays, we witness major efforts led by some of the largest multinationals to harness IT to achieve integration of I/O control, device configuration, and data collection across multiple networks and plant units; seamless integration between automation and business logistic levels to exchange jobs and production data; transparent data interfaces for all stages of the plant life cycle; the Internet- and Web-enabled remote diagnostics and maintenance, as well as electronic orders and transactions. Some of the IT technologies used in the office and enterprise operation have been adopted and/or transformed to suit and advance industrial controls and automation, and industrial enterprise integration. OPC, Real-Time Corba, Real-Time Linux, Windows CE, real-time specifications for Java (RTSJ, RTCE), and Real-Time UML are good examples, to mention some. The Internet technologies extended the boundaries of the operation of industrial enterprises to their customers and suppliers, as well as the management and technical staff through electronic commerce, B2B, remote data access, and monitoring and control. The industrial IT field spans a number of technological areas such as software and hardware technologies, as well as Web and networking technologies. Those technologies, when used in an integrative way, offer a potential for horizontal and vertical integration of functional layers of industrial units and enterprises, thus transforming traditional islands of automation and enterprise operations into more integrated enterprises better adjusted to cope with the demands of competitive markets.

Contributors

The book contains 112 contributions on topics related to industrial IT, written by experts from industry and academia. One third of the contributions are from industry and industrial research establishments; from the leading multinational corporations at the forefront of the development of IT and industrial automation technologies, to mention ABB (Germany, Norway, Sweden, and Switzerland), Alcatel (Belgium), Cadence Systems, Microsoft Corporation, NEC Labs (U.S.), Rockwell Automation, Schneider Electric (France and Germany), Siemens (Austria and Germany), Volvo Truck Corp. (Sweden), and

© 2005 by CRC Press LLC

Yokogawa America. Most of the multinationals mentioned play a leading role in the formulation of long-term policies for technology development, and are key members of the industry–academe consortia implementing those policies.

The contributions from academia and governmental research organizations are represented by some of the most renowned and reputable institutions such as Columbia University, Cornell University, Frauenhofer FOKUS (Germany), Georgia Institute of Technology, Monash University (Australia), National Institute of Standards and Technology (U.S.), Princeton University, Politecnico di Torino (Italy), UC Berkeley, UC Irvine, UC San Diego, University of Texas at Austin and Dallas, University of Tokyo, Stanford University, Technical University of Berlin, Vienna University of Technology, and many others.

How Written

The material is presented in the form of tutorials, surveys, and technology overviews combining fundamentals with advanced issues, making this publication relevant to the beginner as well as seasoned professional from industry and academia. Particular emphasis is on the industrial perspective, illustrated by actual implementations and technology deployments. The contributions are grouped into sections for cohesive and comprehensive presentation of the areas treated. Some of these sections can be used as a reference material for study (including a formal coursework) at the intermediate through advanced levels. The reports on recent technology developments, deployments, and trends frequently cover material released to the profession for the first time.

Audience

The handbook is designed to cover a very wide range of topics that comprise the field of industrial IT. The material covered in this volume will be of interest to a wide spectrum of professionals and researchers from industry and academia, as well as graduate students, from the fields of industrial and mechatronic engineering, production engineering, electrical and computer engineering, computer science, and IT.

Organization

The book is organized into two parts. Part 1, *Fundamentals of Information Technology*, presents material to cover new and fast evolving aspects of IT. Part 2, *Industrial Information Technology*, introduces cutting-edge and newly emerging areas of industrial IT.

The focus of the book is on fast evolving areas with a major impact on the evolution of industrial automation and industrial enterprise integration. Some of those areas have received limited coverage in other publications due to the fast evolution of the technologies involved, or material confidentiality, or limited circulation in the case of industry-driven developments. The areas covered in the book include industrial communication technology, sensor technology, embedded systems, the Internet, Web and IT technologies in industrial automation, and industrial enterprise integration. To complement this material, it was felt appropriate to include background reading material on some of the fastest evolving areas of IT and IP networking. This has been done primarily to assist readers with little or no background in IT and networking technologies, both essential to understand most of the chapters in Part 2 of the book.

Part 1 has two sections: *Computer Software and Web Technologies* and *The Internet and IP Networks*. The section on *Computer Software and Web Technologies* introduces some of the recent software technologies, platforms, and solutions that have had a profound impact on industrial control and automation, and

© 2005 by CRC Press LLC

industrial enterprise integration. It covers material in subsections: *Development Platforms and Frameworks, The Unified Modeling Language, Middleware, Web Technologies, Web Programming,* and *Multidimensional Databases.* Specifically, this section introduces J2EE platform and .Net framework in the *Development Platforms and Frameworks* subsection. J2EE is used extensively at the enterprise business level. The .Net is studied and experimented with by the industry for applications ranging from control to enterprise integration. An overview of UML and its extensions, variants, and implementations is provided in the subsection *The Unified Modeling Language*. The UML language has become a *de facto* standard for modeling real-time and embedded systems, industrial control and automation, as well as business systems. The contribution on UML also introduces selected applications of the language in control and automation. The *Middleware* subsection, on network connectivity software, gives a roundup of Microsoft's distributed components technologies, and Object Management Group Corba standard for object-oriented distributed computing, both of central importance to industrial control and automation. The Web servers, clients, and browsers, as well as languages used for Web and the Internet programming are introduced in the *Web Technologies* subsection. The client–server model is dominant in legacy automation systems. Web services, which allow for platform and language independence in the client–server model, are discussed in the *Web Programming* subsection. The *Multidimensional Databases* subsection gives an overview of multidimensional databases, which is the key technology for the analysis of data, and is essential for effective operation of automated industrial enterprises.

The section *The Internet and IP Networks* provides a comprehensive overview of the Internet and IP network technologies. These technologies have had a major impact on the vertical integration of functional levels of industrial enterprises and the operation of the business level through a variety of e-technologies. This section provides a handy reference material useful for the study of the remaining sections.

The topics covered are organized in the following subsections: *Introduction to the Internet, Internet Core Protocols, Quality of Service in IP Networks, Internet Applications and Application Services, Management of IP Networks, Network Security,* and *Ad Hoc Networking*. Over the last decade, the Internet and IP network technologies have become the basis and catalyst for the transformation of industrial enterprises from so-called "islands of automation" into relatively well-integrated, both horizontally and vertically, modern industrial entities. The section offers a comprehensive overview of the Internet technologies. The contributions introduce fundamentals, as well as present new developments, making the material attractive to both novices and advanced users of those technologies.

A general overview of the Internet is given in the *Introduction to the Internet* subsection. Core protocols and IP routing are covered in the *Internet Core Protocols* subsection. This subsection also includes contributions on multicast, congestion control and Quality of Service (QoS), mobile IP routing, and IP-mobility for cellular and wireless systems. The subsection *QoS in IP Networks* gives an overview of QoS in IP networks and introduces the main features of Multiprotocol Label Switching architecture that integrates label swapping forwarding with network layer routing. It also presents material on the Internet Integrated Services (IntServ) architecture and Reservation Protocol (RSVP), and Internet protocols for real-time Applications (RTP, RTCP, RTSP). Mail transfer protocols (SMTP, POP, IMAP), file transfer protocol (FTP), and hypertext transfer protocol (HTTP) are covered in the *Internet Applications and Applications Services* subsection. Selected aspects of IP networks management are presented in the *Management of IP Networks* subsection. This includes Simple Network Management Protocol (SNMP) and Dynamic Host Configuration Protocol (DHCP). Network security and firewalls are introduced in the *Network Security* subsection. The contribution on *Ad hoc* networking concludes the section on *The Internet and IP Networking*.

Part 2 of the book begins with a section on *Industrial Communication Systems*. Industrial data networks play a pivotal role in the automation and integration of the factory floor by collecting process data and distributing control decisions. This is a very fast evolving area of technology with Ethernet

© 2005 by CRC Press LLC

becoming a *de facto* industry standard for communication in factories and plants at the fieldbus level. The random and native CSMA/CD arbitration mechanism is being replaced by other solutions allowing for deterministic behavior required in real-time communication to support soft and hard real-time deadlines. The wireless and mobile communication technologies have already been recognized as a viable alternative for data communication on the factory floor, with the number of reported actual deployments on the rise. This necessitates the development of new solutions for the integration of wireline and wireless fieldbuses. The requirement for the process data availability via remote access prompted research and creation of new solutions for linking factory floor with the Internet.

The material in this section is organized in the following subsections: *Introduction to Data Communication Networks, Field Area Networks, Ethernet and Wireless/Mobile Network Technologies, Linking Factory Floor with the Internet* and *Wireless Fieldbusses, Security and Safety Technologies in Industrial Networks,* and *Automotive and Industrial Applications*. The first section begins with an introduction to data communication networks to cover principles of lower-layer protocols for data communication to be followed by material on wireless local area networks (WLAN) and wireless personal area networks (WPAN) is presented. The next subsection, *Field Area Networks*, contains a comprehensive technical overview of some of the most widely used fieldbuses in the industry. The contributions describe and evaluate Profibus, WorldFIP, Fundation Fieldbus, CAN, EIA-709, time-triggered communication networks, and IEEE 1394. The choice of networks and selected issues related to networked control systems are also covered. Ethernet is fast becoming a *de facto* industry standard for communication in factories and plants at the fieldbus level. The random and native CSMA/CD arbitration mechanism is being replaced by other solutions allowing for deterministic behavior required in real-time communication to support soft and hard real-time deadlines. These issues and various solutions, including those proposed and already adopted by the industry, are discussed in the *Ethernet and Wireless/Mobile Network Technologies* subsection. The subsection also provides a comprehensive overview of the issues involved in using wireless communication on the factory floor, ranging from the reliability and timeliness of lower-layer wireless protocols to suggestions for new MAC protocols. Bluetooth is also covered. The need for remote access to factory floor data calls for connecting factory floor with the Internet. The solutions are discussed in the *Linking Factory Floor with the Internet and Wireless Fieldbuses* subsection. The subsection also presents architectures and solutions for linking wireline and wireless fieldbuses, a new trend resulting from the presence on the factory floor of devices using wireless communications such as wireless sensors, for instance. The security and safety issues in industrial communication networks are presented in the *Security and Safety Technologies in Industrial Networks* subsection. An implementation of safety technologies is presented in a case study describing Profisafe technology used with Profibus. The *Automotive and Industrial Applications* subsection presents a case study introducing and evaluating the use of different networks in automotive applications, specifically in the range of Volvo commercial automotive products. This subsection also introduces and illustrates the use of the Manufacturing Message Specification (MMS) protocol, an OSI application layer messaging protocol designed for the remote control and monitoring of devices such as Remote Terminal Units (RTU), Programmable Logic Controllers (PLC), Numerical Controllers (NC), or Robot Controllers (RC).

The use of the Internet, Web, and IT technologies in industrial control, automation, and design is presented in the section *The Internet, Web, and IT Technologies in Industrial Automation and Design*. This is a vast area and reporting has had to be limited to selected topics where the impact of these technologies was most notably felt. This section also includes a contribution on IT security in automation systems.

The contributions are organized into the following subsections: *Internet and Web-Based Technologies in Industrial Automation, Component Technologies in Industrial Automation, Java Technology in Industrial Automation, Standards for Programmable Logic Controllers and System Design, Virtual Reality in Design*

© 2005 by CRC Press LLC

and Manufacturing, and *Security for Automation Systems*. The issues, solutions, and technologies involved in remote monitoring and control, as well as maintenance, an aim for industrial enterprises and urban automation, are presented in the *Internet and Web-Based Technologies in Industrial Automation* subsection. This subsection also covers material on telemanipulation over the Internet, and material on the use of IT technologies. OLE for Process Control (OPC), the standard interface for access to Microsoft`s Windows-based applications in automation, is one of the most popular industrial standards among users and developers of Human Machine Interface (HMI), Supervisory Control and Data Acquisition (SCADA), and Distributed Control System (DCS) for PC-based automation, as well as Soft PLCs. OPC is discussed in detail in the subsection on *Component Technologies in Industrial Automation*. (A comprehensive evaluation of Corba technology, and implementations can be found in a contribution on OCEAN in the section on *Integration Technologies*.) An overview of Java technology, real-time extensions, and prospects for applications in controls and industrial automation are given in the *Java Technology in Industrial Automation* subsection. This contribution provides a roundup of two different real-time extensions for the Java language: Real-Time Specification for Java (RTSJ) developed by the Real-Time for Java Expert Group under the auspices of Sun Microsystems and reference implemented by TimeSys Corp, and Real-Time Core Extensions developed by Real-Time Java Working Group operating within J-Consortium. The contribution also introduces Real-Time Data Access (RTDA) specification developed by the Real-Time Data Access Working Group (RTAWG), also operating within J-Consortium. The RTDA specification focuses on API for accessing I/O-data in typical industrial and embedded applications. The subsection on *Standards for Programmable Logic Controllers and System Design* introduces three standards: IEC 60848 Ed. 2, IEC 61131-3, and IEC 61499. The IEC 61499 standard defines a reference architecture for open and distributed control systems, which provides the means for compatibility between automation systems of different vendors. Virtual reality has become an important tool for the design and prototyping of products and complex systems. The subsection *Virtual Reality in Design and Manufacturing* contains two contributions introducing selected aspects of haptic simulation in design and manufacturing, and the use of virtual reality techniques in the design and validation of factory communication systems. The topic of IT security in automation systems is thoroughly explored at the end of the section. The IT security in automation systems poses a particular challenge given the requirement for remote control and manufacturing.

The current trend in the industry for flexible and distributed control and automation has accelerated the migration of the intelligence and control functions to the field devices, particularly sensors and actuators. The increased processing capabilities of those devices were instrumental in the emergence of a trend for networking of field devices around industrial data networks. The benefits are numerous, including increased flexibility, improved system performance, and ease of system installation, upgrade, and maintenance. The increased functional complexity of those devices, however, has pushed their development into the realm of formal design methods and tools characteristic of embedded systems. Another trend in networking of field devices has emerged recently: the wireless sensor networks. A number of deployments on the factory floor have been reported. In this context, the integration of wireline and wireless technologies becomes an important issue. Recent advances in the research on "intelligent space," which initially targeted an office environment, have helped enhance navigation capabilities of industrial autonomous and mobile robots, which are an integral element of automated factories. Some of those issues and trends are presented in the *Intelligent Sensors and Sensor Networks* section.

The material is structured into the following subsections: *Intelligent Sensor and Device Technology, Intelligent Sensors in Robotics, Sensor Systems and Networks,* and *Multisensor Data Fusion*. The *Intelligent Sensor and Device Technology* subsection provides an in-depth overview of the technologies and standards behind intelligent sensors and actuators. It begins with material on the IEEE 1451 standards for

© 2005 by CRC Press LLC

connecting sensors and actuators to microprocessors, control and field networks, and instrumentation systems. The standards also defined the Transducer Electronic Data Sheet (TEDS), which allows for the self-identification of sensors. The IEEE 1451 standards facilitate sensor networking, a new trend in industrial automation, which, among other benefits, offers strong economic incentives. The networking issues and supporting integration technologies are discussed in the next contribution, which also outlines evolution of the intelligent device (sensors and actuators) networking concepts. Intelligent sensors, in addition to performing measurements and sensory information processing, embed complex functionalities essential for their operation and communications. The use of semi/formal design techniques and supporting tools, essential for a rapid and cost-effective design, is discussed in the subsection along with the introduction to the CAP modeling language, which allows for rapid prototyping of intelligent devices. The robotic technology has become an integral part of industrial automation. An overview of the fundamental sensor technologies in robotics is presented in the *Intelligent Sensors in Robotics* subsection. The material covers vision, tactile sensing, sense of smell, and ultrasonic sensors. The subsection *Sensor Systems and Networks* presents contributions on intelligent space and sensor networks, and development methodologies. The intelligent space concept provides solutions, among others, for location of mobile robots nowadays frequently operating autonomously on the factory floor. Distributed wireless sensor networks is a relatively new and exciting proposition for collecting sensory data in the industrial environment. The design of this kind of network poses a particular challenge due to limited computational power and memory size, bandwidth restrictions, power consumption restriction if battery powered, communication requirements, and unattended mode of operation in case of industrially hostile environments, to mention some. The subsection provides a comprehensive discussion of the design issues related to, in particular, self-organizing networks, to include Medium Access Control (MAC) layer protocols, routing protocols, security, location determination, and power management. It also discusses existing software solutions and systems supporting the development of the dynamic wireless sensor networks. This presentation includes middleware, operating systems and execution environments, languages, and whole software frameworks. The section concludes with a subsection and material on *Multisensor Data Fusion*.

The advances in the embedded systems particularly in design methodology and supporting tools, allowed for cost-effective migration of the intelligence and control functions into field devices. This, coupled with developments in other areas, promoted a shift toward decentralized architectures of industrial automation systems, and whole enterprises. The embedded systems is one of the fastest growing areas of technology, and crucial for the realization of fully automated plants and factories. The *Real-Time Embedded Systems* section gives a comprehensive overview of the field: basics and emerging trends. It covers design aspects, languages and tools, security, real-time and embedded operating systems, and networked embedded systems.

The contributions are organized in the following subsections: *Embedded Systems, Security in Embedded Systems, System-on-Chip and Network-on-Chip Design,* and *Networked Embedded Systems*. The fundamental and advanced aspects of embedded systems and design are presented in the subsection *Embedded Systems*. This subsection contains material introducing comprehensively real-time systems, design of embedded systems, models of computation, languages for embedded systems to include hardware-level design and verification languages, design of software for embedded systems, real-time operating systems, and power-aware embedded computing. The security in embedded systems is presented in the *Security in Embedded Systems* subsection. The material in this subsection gives a roundup of the security issues and solutions adopted by the industry. The *System-on-Chip and Network-on-Chip Design* subsection provides a comprehensive overview of the issues involved in the design of systems and networks on chip. The material in this subsection covers system-on-chip and network-on-chip design, platform-based and

© 2005 by CRC Press LLC

derivative design, hardware/software interfaces design for systems-on-chip, and on-chip networks. Networked embedded systems are introduced in the *Networked Embedded Systems* subsection.

The last decade has witnessed an accelerated evolution of industrial enterprises. This trend has been driven by financial factors, and availability of practically proven and affordable technologies and solutions. The advances in the embedded systems design and falling fabrication cost allowed for deployment on the factory floor of a new generation of smart and relatively inexpensive field devices with increased functionality. The trend for networking smart field devices using industrial data networks has transformed control architecture from centralized into distributed and decentralized. This, in turn, allowed for efficient integration of I/O control, device configuration, and data collection across multiple networks and plant units. In this context, the control network, to date largely used to integrate devices at the fieldbus level, attained a new integrative role. Other equally profound changes of an integrative nature include seamless integration between automation and business logistic levels to exchange jobs and production data; transparent data interfaces for all stages of the plant life cycle; the Internet- and Web-enabled remote diagnostics and maintenance, as well as electronic orders and transactions. This integration has been achieved through an interplay of different technologies and solutions. The IT technologies have played some of the most important roles in this process. This section shows a small cross-section of the integration efforts and results, primarily arising from activities of major control and automation vendors and multinational groupings. These efforts have a potential for lasting solutions and new technologies.

The material is organized in the following subsections: *E-Technologies in Enterprise Integration, IT Technologies in Enterprise Integration, Network-Based Integration Technologies, Agent-Based Technologies in Industrial Automation*, and *Industrial Information Technology Solutions for Energy and Power Systems*. An introduction to e-manufacturing is presented in the *E-Technologies in Enterprise Integration* subsection. This material gives an overview of the e-manufacturing strategies, fundamental elements, and requirements to meet the changing needs of the manufacturing industry in transition to an e-business environment. It covers e-manufacturing, e-maintenance, e-factory, and e-business. The subsection *IT Technologies in Enterprise Integration* contains four contributions discussing the use of XML and Web Services, and other IT technologies in enterprise integration. The first contribution deals with replacing paper flow by electronic technologies, and presents the use of XML as a means for information exchange during the design and development of automation systems. The next contribution introduces the World Batch Forum's (WBF) Business To Manufacturing Markup Language (B2MML), which is a set of XML schemas that are based upon the ISA-95 Enterprise-Control System Integration Standards. The material demonstrates how B2MML can be used to exchange data between the business/enterprise and manufacturing systems. The contribution also gives a roundup of the ISA-95 standard. The Web Services technology provides the means for the implementation of open and platform-independent integrated automation systems. The challenges for using Web Services in automated systems, solutions, and future trends are discussed in the third contribution. The final contribution in this subsection presents IT-based connectivity solutions for interfacing production and business systems. The presented concepts and architectures are a result of an extensive study and prototyping efforts conducted by ABB in the search for cost-effective approaches leveraging existing mainstream technologies such as enterprise application integration (EAI), Web services and XML, as well as emerging industry standards such as ISA 95 and CIM. The subsection *Network-Based Integration Technologies* presents novel industry approaches to the development of distributed and flexible automation systems centered around control networks. Prominent examples of these approaches discussed in this subsection are the PROFInet standard of the PROFIBUS User Organization, and the Interface for Distributed Automation (IDA) standard of the IDA Group e.V. Both the approaches draw extensively from the use of Ethernet TCP/IP, Web, and network security technologies, and allow for horizontal and vertical integration, and interoperability of devices

© 2005 by CRC Press LLC

from different vendors to mention some features. Another notable development presented in this subsection is the **O**pen **C**ontroller **E**nabled by an **A**dvanced real-time **N**etwork (OCEAN) project with the aim of realizing a real-time-capable platform for distributed control applications for numerical controls based on standardized communication systems and delivered as an open source. The development draws heavily from the results of the Open System Architecture for Controls within Automation (OSACA) Systems project, a precursor of OCEAN. The high degree of complexity of manufacturing systems coupled with the market-dictated requirements for agility lead to a development of new manufacturing architectures and solutions based on distributed, autonomous, and cooperating units, integrated by the plug-and-play approach, called agents. The *Agent-Based Technologies in Industrial Automation* subsection offers a comprehensive treatment of the topic. It begins with an introduction to the concept of agents and technology, cooperation and coordination models, interoperability, and applications to manufacturing systems. Agents dedicated to real-time manufacturing tasks are called holons. The use of holons and related concepts in manufacturing systems is discussed in the next contribution. The material presented in this contribution is largely based on the results of an international project, Holonic Manufacturing Systems, involving some of the leading multinational corporations. FactoryBroker™, a heterogeneous agent-oriented collaborative control system, developed and implemented by Schneider Electric GmbH (Industrial Automation), in cooperation with DaimlerChrysler AG, Research and Technology, Berlin, Germany, is the focus of the next presentation. The last contribution in this subsection introduces PABIS (Plant Automation Based on Distributed Systems), an IMS project under reference IST-1999-60016, which aims at providing a flexible plant automation solution based on the use of agent technologies. The use of IT in energy and power systems is presented in the concluding subsection. The material presented in this subsection introduces the IEC 61850 standard, the JEVis service platform, and the use of ABB IT platform in power network management. The IEC61850, which incorporates technologies such as Ethernet, TCP/IP, MMS (ISO 9506), and XML, aims at seamless information integration across the utility enterprise using off-the-shelf products. The primary target is the electrical substation automation: switchyards and transformers in the medium- and high-voltage transport and distribution. The JEVis system is an Internet-enabled database connected to distributed networks. It collects measurement data and presents it, after processing, to the customers via Web-based graphical front-ends. One of the JEVis application areas is energy management, or Demand Side Management. The use of ABB's Industrial IT Aspect Integrator Platform in power distribution and transmission applications is presented in the last contribution in the section. Some of the key customer benefits provided by Industrial IT include component-based network control system architecture and company-wide migration opportunities with a low investment.

Locating Topics

To assist readers with locating material, a three-tier structure of the table of contents is offered in the book. A complete table of contents is presented at the front of the book. Each of the seven sections is preceded by an individual table of contents. Finally, each chapter begins with its own table of contents.

Two indexes are provided at the end of the book, the index of authors contributing to the book, together with the titles of the contributions, and a detailed subject index.

Acknowledgments

I would like to thank all members of the International Advisory Board for their help with structuring the book, selection of authors, and material evaluation. Thilo Sauter and Andreas Willig provided crucial assistance with Section 2. Luciano Lavango, Grant Martin and Alberto Sangiovanni-Vincentelli provided support for Section 6.

I have received tremendous cooperation from all contributing authors. I would like to thank them for this.

My gratitude goes to David. J. Irwin, Series Editor, The Industrial Electronics Series, to agree to have this book in his series.

I would like to express gratitude to my publisher Nora Konopka, and other CRC Press staff involved in the book production, particularly Jamie Sigal and Jessica Vakili.

My love goes to my wife who tolerated the countless hours I spent preparing this book.

Richard Zurawski

© 2005 by CRC Press LLC

The Editor

Dr. Richard Zurawski received his M.Sc. in Informatics and Automation from University of Mining and Metallurgy, Krakaw, Poland and his Ph.D. in Computer Science from La Trobe University, Melbourne, Australia. He is president and CEO of ISA Corp, South San Francisco and Santa Clara, CA, a company involved in providing solutions for industrial and societal automation. He is also chief scientist with and a partner in Silicon Valley-based start-ups involved in the development of wireless solutions and technology. Dr. Zurawski is a cofounder of The Institute for Societal Automation, Santa Clara, a research and consulting organization.

Dr. Zurawski has over 25 years of academic and industrial experience, including a regular appointment at the Institute of Industrial Sciences, University of Tokyo, and full-time R&D Advisor with Kawasaki Electric, Tokyo, Japan.

Dr. Zurawski provided consulting services to Telecom Research Laboratories, Melbourne, Australia, Kawasaki, Ricoh, and Toshiba Corporations, Japan. He also participated in a number of Japanese Intelligent Manufacturing Systems programs.

His involvement in R&D projects and activities in the past few years includes remote monitoring and control, network-based solutions for factory floor control, network-based demand side management, MEMS (automatic micro-assembly), Java technology, SEMI implementations, development of DSL telco equipment, and wireless applications.

Dr. Zurawski currently serves as an associate editor of the *IEEE Transactions on Industrial Electronics* and *Real-Time Systems — The International Journal of Time-Critical Computing Systems,* Kluwer Academic Publishers.

He was a guest editor of four special sections in *IEEE Transactions on Industrial Electronics:* two sections on Factory Automation, and two on Factory Communication Systems. He was also a Guest Editor of a special issue of the *Proceedings of the IEEE* dedicated to Industrial Communication Systems.

Dr. Zurawski was invited by IEEE Spectrum to contribute material on Java technology to "Technology 1999: Analysis and Forecast Issue."

He is also the series editor for The Industrial Information Technology Series, CRC Press, Florida.

Dr. Zurawski served as vice president of the IEEE Industrial Electronics Society (IES), chairman of the Factory Automation Council, and chairman of the IEEE IES Ad Hoc Committee on IEEE Transactions on Factory Automation. He was an IES representative to the IEEE Neural Network Council and IEEE Intelligent Transportation Systems Council. He was also on a Steering Committee of the *ASME/IEEE Journal of Micromechanical Systems*. In 1996, he received the Anthony J. Hornfeck Service Award from the IEEE Industrial Electronics Society.

Dr. Zurawski established two IEEE events: IEEE Workshop on Factory Communication Systems — the only IEEE event dedicated to industrial communication networks, and IEEE International Conference dedicated to industrial and Emerging Technologies and Factory Automation — the largest

© 2005 by CRC Press LLC

IEEE conference dedicated to industrial and factory automation. He served as a general, program, and track chair for a number of IEEE conferences and workshops.

Dr. Zurawski has published extensively on various aspects of control systems, industrial and factory automation, industrial communication systems, robotics, formal methods in the design of embedded and industrial systems, and parallel and distributed programming and systems. He was Editor of two major handbooks: *The Industrial Communication Technology Handbook* and *The Embedded Systems Handbook* published by CRC Press in 2004 and 2005, respectively.

PART I FUNDAMENTALS OF INFORMATION TECHNOLOGY

SECTION 1 Computer Software and Web Technologies

1.1 Development Platforms and Frameworks

1. Web-based Enterprise Computing Development using J2EE
   Jiang B. Liu
2. Microsoft's .NET
   Martin v. Löwis and Peter Tröger

1.2 The Unified Modeling Language

3. Unified Modeling Language: The Industry Standard for Software Development
   Kleanthis Thramboulidis

1.3 Middleware

4. Middleware
   Andreas Polze
5. Distributed Components in Microsoft Platforms — Technology Overview
   Marcos Ribeiro Pereira Barretto, Paulo Marcelo Porto Alves Blanco and Marco Antonio Poli
6. CORBA in Manufacturing — Technology Overview
   Marcos Ribeiro Pereira Barretto, Paulo Marcelo Porto Alves Blanco and Marco Antonio Poli

1.4 Web Technologies

7. Web Servers, Clients, and Browsers
   Robert Tolksdorf
8. Internet Programming Languages
   Wolfgang Radinger and Martin Jandl
9. Internet Still Image and Video Formats
   Guido Heising and Kai Uwe Barthel

1.5 Web Programming

10. The Fundamentals of Web Services
    Klaus-Peter Eckert
11. Programming Web Services with .net and Java
    Klaus-Peter Eckert

© 2005 by CRC Press LLC

1.6 Multidimensional Database Technology
12. Multidimensional Databases
Torben Bach Pedersen and Christian S. Jensen

SECTION 2 The Internet and IP Networks

2.1 Introduction to the Internet
13. TCP/IP Architecture, Protocols, and Services
Christian Kurz and Helmut Hlavacs
14. The Fundamentals of the Quality of Service
Wolfgang Kampichler

2.2 Internet Core Protocols
15. The Internet Protocol
Jürgen Falb
16. The Transmission Control Protocol
Aleksander Malinowski and Bogdan M. Wilamowski
17. The User Datagram Protocol
Aleksander Malinowski and Bogdan M. Wilamowski
18. ARP — Address Resolution Protocol
Jürgen Falb
19. IPv6, IPSec, and VPNs
Walter Penzhorn and Johann Amsenga
20. Overview and Classification of IP Routing Protocols — IP Routing: Interior and Exterior Routing Protocols
Lucia Lo Bello and Enzo Palumbo
21. Multicast
Tanja Zseby
22. A Survey of Congestion and QoS Control Mechanisms for the Internet
Dorgham Sisalem and Adam Wolisz
23. Mobile IP Routing
Karin A. Hummel and Helmut Hlavacs
24. IP-Mobility for Cellular and Wireless Networks
Andreas Festag and Adam Wolisz

2.3 Quality of Service in IP networks
25. IP-QoS: Scalable and Flexible Quality-of-Service with Differentiated Services
Klaus Wehrle
26. MPLS — Multiprotocol Label Switching
José Ruela and Manuel Ricardo
27. The Integrated Services Architecture and RSVP
Henning Sanneck
28. RTP, RTCP, and RTSP — Internet Protocols for Real-Time Multimedia Communication
Arjan Durresi and Raj Jain

2.4 Internet Applications and Application Services
29. Mail Transfer Protocols and File Transfer Protocol
Suvendi Chinnappen
30. The Hypertext Transfer Protocol and Uniform Resource Identifier
Karl M. Goeschka

2.5 Management of IP Networks
31. Network Management: Basic Notions and Frameworks
Mai Hoang
32. Simple Network Management Protocol SNMP
Michael Kunes
33. The Dynamic Host Configuration Protocol
Michael Eyrich

2.6 Network Security
34. Network Security and Secure Applications
Christopher Kruegel
35. Internet Firewalls
Günter Schäfer

2.7 *Ad Hoc* Networking
36. *Ad Hoc* Networks
Holger Karl

PART II INDUSTRIAL INFORMATION TECHNOLOGY

SECTION 3 Industrial Communication Systems

3.1 Introduction to Data Communication Networks
37. Principles of Lower-Layer Protocols for Data Communications
Andreas Willig and Hagen Woesner
38. Wireless Local Area Networks and Wireless Personal Area Networks (WLANs and WPANs)
Kirsten Matheus

3.2 Field Area Networks
39. PROFIBUS — Open Solutions for the World of Automation
Ulrich Jecht, Wolfgang Stripf and Peter Wenzel
40. The WORLDFIP Fieldbus
Jean-Pierre Thomesse

© 2005 by CRC Press LLC

41. FOUNDATION Fieldbus: History and Features
Salvatore Cavalieri
42. Operating Principles and Features of CAN Networks
Gianluca Cena and Adriano Valenzano
43. LonWorks/EIA-709 Networks *EIA 709 Protocol (LonTalk)*
Dietmar Loy
44. Time-Triggered Communication Networks
Hermann Kopetz and Günther Bauer
45. IEEE 1394 for Factory Automation
Michael Scholles, Uwe Schelinski and Petra Nauber
46. Which Network for Which Application
Jean-Dominique Decotignie
47. Networked Control Systems Overview
Pau Martí, Ricard Villà, Josep M. Fuertes and Gerhard Fohler

3.3 Ethernet and Wireless/Mobile Network Technologies
48. The Quest for Real-Time Behavior in Ethernet
P. Pedreiras, L. Almeida and J. A. Fonseca
49. Switched Ethernet in Automation Networking
Tor Skeie, Svein Johannessen and Øyvind Holmeide
50. Wireless LAN Technology for the Factory Floor
Andreas Willig
51. Bluetooth
Thomas Jatschka and Robert Tschofen

3.4 Linking Factory Floor with the Internet and Wireless Fieldbusses
52. Linking Factory Floor and the Internet
Thilo Sauter
53. LonWorks™ over IP
Dietmar Loy and Stefan Soucek
54. Interconnection of Wireline and Wireless Fieldbusses
Jean-Dominique Decotignie

3.5 Security and Safety Technologies in Industrial Networks
55. Security in Automation Networks
Christian Schwaiger
56. PROFIsafe — Safety Technology with PROFIBUS
Wolfgang Stripf and Herbert Barthel

3.6 Automotive and Industrial Applications
57. A Comparative Case Study of Distributed Network Architectures for Different Automotive Applications
Jakob Axelsson, Joakim Fröberg, Hans Hansson, Christer Norström, Kristian Sandström and Björn Villing

© 2005 by CRC Press LLC

58. The Standard Message Specification for Industrial Automation Systems — ISO 9506 (MMS)
Karlheinz Schwarz

SECTION 4 The Internet, Web, and IT Technologies in Industrial Automation and Design

4.1 Internet and Web-Based Technologies in Industrial Automation
59. Remote Monitoring and Control over the Internet
Hans-Arno Jacobsen
60. Internet-Based Telemanipulation
P. Korondi, P. Szemes and P. Hashimoto
61. Knowledge Connect — An Approach for an Industrial^{IT} Service Tool
Carsten Beuthel, Paul George and Ulrich Topp

4.2 Component Technologies in Industrial Automation
62. OPC — Openness, Productivity, and Connectivity
Jürgen Lange and *Frank Iwanitz*

4.3 Java Technology and Industrial Applications
63. Java Technology and Industrial Applications
Jörn Peschke and Arndt Lüder

4.4 Standards for Programmable Logic Controllers and System Design
64. The GRAFCET Specification Language
Paulo Portugal and Adriano Carvalho
65. Programming with the IEC 61131-3 Languages and the MatPLC
Mário de Sousa and Adriano Carvalho
66. Acheiving Reconfigurability of Automation Systems by Using the New International Standard IEC 61499: A Developer's View
Hans-Michael Hanisch and Valeriy Vyatkin

4.5 Virtual Reality in Design and Manufacturing
67. Applications of Haptics in Design and Manufacturing
T. Kesavadas, Arvind Balijepalli and Cartik Sharma
68. Implementation of a Virtual Factory Communication System using the Manufacturing Message Specification Standard
Dong-Sung Kim, Zygmunt J. Haas and Wook Hyun Kwon

4.6 Security in Automation Systems
69. IT Security for Automation Systems
Martin Naedele

© 2005 by CRC Press LLC

SECTION 5 Intelligent Sensors and Sensor Networks

5.1 Intelligent Sensor and Device Technology

70. A Smart Transducer Interface Standard for Sensors and Actuators
Kang Lee
71. Integration Technologies of Field Devices in Distributed Control and Engineering Systems
Christian Diedrich
72. Intelligent Sensors: Analysis and Design
E. Dekneuvel

5.2 Intelligent Sensors in Robotics

73. Robot Vision
Ray Jarvis
74. Robot Tactile Sensing
R. Andrew Russell
75. Giving Robots a Sense of Smell
R. Andrew Russell
76. Ultrasonic Sensors in Robotics
Lindsay Kleeman

5.3 Sensor Systems and Networks

77. Intelligent Space and Mobile Robots
Joo-Ho Lee, Kazuyuki Morioka and Hideki Hashimoto
78. A Survey on Self-Organizing Wireless Sensor Networks
Shashidhar Gandham, Ravi Musunuri, Praveen Rentala and Udit Saxena
79. Software for Wireless Sensor Networks
Jan Blumenthal, Frank Golatowski, Marc Haase and Matthias Handy

5.4 Multisensor Data Fusion

80. Introduction to Multisensor Data Fusion
Pascal Vasseur, El Mustapha Mouaddib and Claude Pegard

SECTION 6 Real-Time Embedded Systems

6.1 Embedded Systems

81. Real-Time Systems
Hans Hansson, Mikael Nolin and Thomas Nolte
82. Design of Embedded Systems
Luciano Lavagno and Claudio Passerone
83. Models of Computation for Embedded Systems
Luís Gomes and João Paulo Barros

© 2005 by CRC Press LLC

84. Hardware-level Design Languages
Luís Gomes and Anikó Costa
85. Languages for Embedded Systems
Stephen Edwards
86. Verification Languages
Aarti Gupta, Ali Alphan Bayazit and Yogesh Mahajan
87. Embedded Software in the SoC World.
The Concept of HdS in View of the HW and SW Design Challenge
Frank Pospiech
88. Internal Architecture and Features of Real-Time Embedded Operating Systems
Ivan Cibrario Bertolotti

1.8 Conclusion

Jiang B. Liu
Bradley University

Enterprise computing has undergone several changes in development strategies in the last decade. Early development strategies were primarily focused on developing client/server computing platforms within the company to empower the distributed computing. The development technology mainly uses procedural language-based distributed computing infrastructures such as an OSF-distributed computing environment (DCE) [1]. Later, the development was redirected using object-oriented technologies such as distributed object computing using OMG common object request broker architecture (CORBA) [2] or Microsoft-distributed component object model (COM+/DCOM) [3]. The switch was obviously to take advantage of the new emerging object-oriented computing platforms. But all these developments have a huge development cost due to the complexity involved in the underlying computing technologies. DCE requires several online corporate-maintained security servers running in order to maintain communica-

© 2005 by CRC Press LLC

tion between the client and the application servers. It is also very difficult to port to other computing platforms and an in-depth knowledge of the system is required for the development. DCE development to the distributed computing is analogous to the early generation of programming at the assembly language level. The CORBA and COM+ solved some of the DCE problems by implementing the component model using object-oriented languages. But the development cost did not reduce much. It has achieved some success at the departmental-level and application-level computing, but it never reached the matured enterprise operational level as the early mainframe computing did due to problems of complexity in the development, performance, reliability, and security.

Today, the enterprise computing has undergone other significant changes in its development technologies, with a focus on web-based computing. Two promising development platforms have been developed to address the shortcomings of the previous development strategies. One such strategy is based on Java J2EE [4] using SUN Microsystems Java platform-independent technology, and is therefore widely adapted on the UNIX/LINUX platforms. Another strategy is based on Microsoft .Net [5] using the Microsoft Window technologies, and is therefore widely adapted by applications that rely on the Window platform. In this article, we will introduce the enterprise applications using J2EE development strategy.

1.1 J2EE Java Development Platform

Web-based computing provides the best framework for E-commerce and enterprise computing. It is much easier to develop, deploy, and access the computing components on the web. J2EE provides a complete solution for the development of these components, and comprehensive development tools for a variety of web-based enterprise computations. We will discuss the following Java computing components in this article:

- Java language basics and Java program development
  - Java API Packages
  - Java Virtual Machine (JVM) and Java-enabled browsers
  - Java Client-side programs: Applets; Applications
  - Java Development Tools: Borland Jbuilder, IBM Websphere Studio, SUN ONE Studio
  - Java Security
  - Java Network Protocols: TCP/IP; HTTP; HTTPS
- Java Database Connectivity: JDBC
- Java Server-side programs: Servlets; JavaServer Page (JSP); JavaBeans
- Java-Distributed Object-Computing Technologies
  - Java Naming and Directory: JNDI
  - Remote Method Invocation: RMI
  - Enterprise JavaBeans: EJB
- Java Transaction Service: JTS
- J2EE Web Service

1.2 Java Language Basics and Java Program Development

Java language is a key element in implementing the Java technologies. We will briefly review the Java language features here.

Java is a pure object-oriented language. Its syntax is similar to C++, but the methods of programming are very different. Java program is compiled into a virtual machine (VM) code instead of the machine code as C++ does; therefore, it can be distributed on the Internet irrespective of the platforms. Java VM is a stack machine model, which makes it independent from the real machine register architectures. It also includes a security code verifier to verify the integrity of the distributed Java compiled code. The Java program that is distributed on the Internet and executed inside a web browser is called applet. Java-enabled web browsers such as Microsoft Internet Explorer (IE) and Netscape have a built-in VM interpreter to run

Sample Java Applet Program Structure

```
/** Java Doc Comments */
import java.applet.*;
import ...
public class AppletClassName extends
Applet {
      Type variables;
      methodAttribute methodReturnType
methodName(method parameters) {
         Statements; //Internal comments
      }
}
```

Sample Java Application Program Structure

```
/** Java Doc Comments */
import packageName.*;
class ApplicationClassName {
      Type variables;
          public static void main(String[] args) {
        Statements; //Internal comments
        }
     methodAttribute methodReturnType
methodName(method parameters) {
         Statements;
      }
}
```

FIGURE 1.1 Java applet and application sample programs.

Java applets. Java applets are normally executed inside a so-called sandbox (an enclosed memory address space) so that it cannot do harm to the local recourses. Java applets digitally signed with the public-key encryption can have more access to the local resources, and depends on the security model implemented. Java program can also run as a local applications program, same as the C++ if a Java runtime environment is installed locally. Normally, the JVM is built right into one's Java software download.

Figure 1.1 shows the sample Java applet program and application program.

Java API Packages

Java packages provide a set of units of related Java classes and interfaces for rapid software development. The classes and interfaces in the packages can be imported to the user program by the import statement. Java SDK (Software Development toolKit) provides a core set of packages. The companies and organizations also provide the extended packages for the Java developers to access their software products. Java developers can also create their own packages for their distribution. The following are the Java core packages and some of the commonly used extended packages (see Figure 1.2):

- Language (import java.lang.*)
- Applet (import java.applet.*)
- Utilities (import java.util.*)
- I/O (import java.io.*)
- AWT (import java.awt.*)
- Networking (import java.net.*)
- Security (import java.security.*)
- RMI (import java.rmi.*)
- SQL (import java.sql.*)
- Swing (import com.sun.java.swing.*)
- Java beans (import java.beans.*)
- CORBA (import org.omg.CORBA.*)
- SUN Java servlets (import javax.servlets.*)
- Oracle JDBC (import oracle.jdbc.*)
- IBM DB2 JDBC (import COM.ibm.db2.jdbc.*)

Java Language package provides classes that are fundamental to the design of the Java programming language. Some of the classes are Object class (superclass for all Java classes), Data-type wrapper classes (wrapping Java's fundamental data types into classes), Math class (groups math functions and constants), String classes (handle text strings), System and runtime classes (access system and runtime environment resources), Thread classes (create and manage threads), Class classes (query and load runtime class),

© 2005 by CRC Press LLC

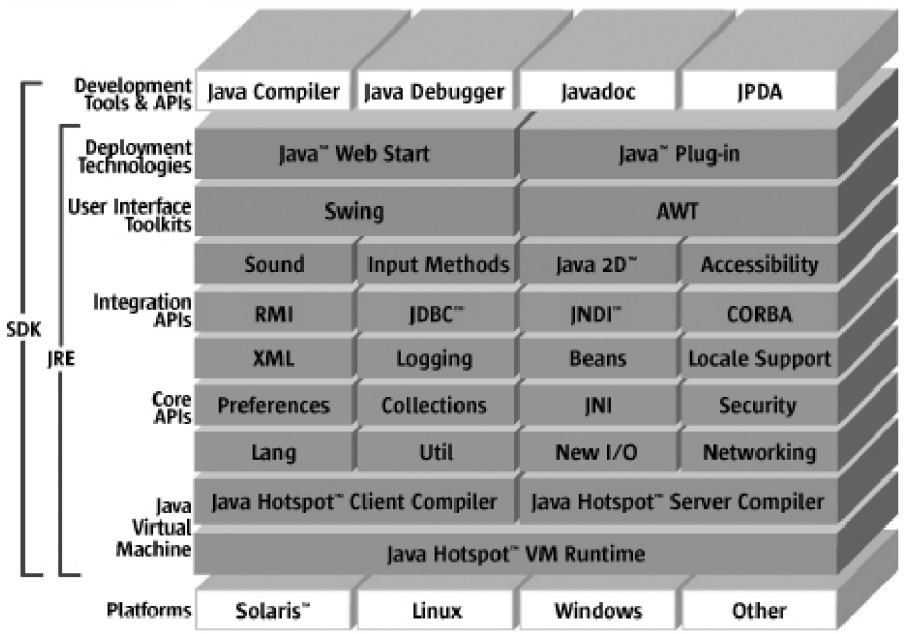

FIGURE 1.2 Java 2 platform. (*Source*: JavaOne conference.)

Exception-handling classes (which deal with runtime error), and Process class (which supports the system process).

Java Applet package provides the classes necessary to create an applet and the classes an applet uses to communicate with its applet context. Some of the classes and interfaces are Applet class (which provides a standard interface between applets and their environment) and AppletContext (which provides the methods for the applet to obtain information about its environment).

Java Utility package provides useful utilities for the Java programmers. Some of the classes are Date class (which represents a calendar date and time based on UTC), Data structure classes and interfaces (which implement popular data structures — BitSet, Dictionary, Hashtable, Properties, Vector, Stack, and Enumeration for storing data), Random class (implements a random-number generator), and StringTokenizer class (which provides a means of converting text string into individual tokens).

Java I/O package provides for system input and output through data streams, serialization, and the file system. Some of the classes are Input stream classes (which handles reading data from an input source such as a file, a string, or memory), Output stream classes (which handles writing data to a output source such as a file, a string, or memory), File classes (which provide methods for file processing), and StreamTokenizer class (which provides methods for converting an input stream of data into a stream of tokens).

Java AWT package provides the simple 2D window implementations. Some of the classes are Graphical classes (which serves as an all-purpose graphical output with all kinds of different drawing functions), Layout manager classes (which provide a framework for controlling the physical layout of GUI elements), Font classes (which provide/specify font information), Dimension class (which represents graphic dimensions such as points, rectangles, and polygons), MediaTracker class (which provides a means to track media when the transmission is completed), and Component/MenuComponent class (an abstract class that defines elements common to all AWT component/menu component classes).

Java Network package provides the classes for implementing TCP/IP networking applications. Some of the classes are InetAddress class (which represents a host name and its IP number), URL classes (which provide access to resources located on the WWW using the HTTP protocol), Socket classes (whcih provide

© 2005 by CRC Press LLC

TCP/IP connection-oriented and connectionless connections), and ContentHandler class (an extension class for new protocols and content types).

Java Security package includes Digital signature classes (which generate a public/private key pair and use them to sign and verifying arbitrary digital data. Digital signatures are used for authentication and integrity assurance of digital data), MessageDigest class (which provides the functionality for a message digest algorithm. Message digests are secure, one-way hash functions that take arbitrary-size data and output a fixed-length hash value. Message digests are useful for producing "digital fingerprints"), and Key management classes (which manage the public and private keys used in the digital signature process).

Java RMI package implements a SUN Microsystems's distributed objects model. Some of the classes are Registry classes (that provide a simple name service that binds a string name to a remote object reference. A server can bind/rebind a name to a remote reference and a client can look up the remote reference for a certain name), RMISecurityManager classes (which manage security issues such as Runtime integrity, Encryption, and Authentication), and UnicastRemoteObject class (which provides support for point-to-point active object references).

Java SQL package provides the JDBC package. JDBC is a standard API for executing SQL statements. It contains classes and interfaces for creating SQL statements and retrieving the results of executing those statements against relational databases. Some of the classes and interfaces are DriverManager (which provides the basic service for managing a set of JDBC drivers), Connection (which makes a connection/session with a specific database), Statement (the object used for executing a static SQL statement and obtaining the results produced by it), PreparedStatement (an object that represents a precompiled SQL statement), CallableStatement (the interface used to execute SQL-stored procedures), and ResultSet (which provides access to a table of returned data).

Java Swing package included a set of "lightweight" (all-Java language) components for all the platforms. It provides a set of 3D graphic components such as JButton, JLabel, JList, JPanel, JTable, and Jtree. Swing has the advantage of a pluggable look and feel and virtual desktop presentation. All the major commercial Java IDEs (Integrated Development Environment) provide virtual programming capabilities for generating the swing component code.

Java Beans package contains classes related to Java Beans development. The graphic components provided by the Java IDEs are an example of Java Beans.

Java CORBA package provides the mapping of the OMG CORBA APIs to the Java programming language and adds CORBA capability to the Java platform. Some of the classes are ORB (providing standards-based interoperability and connectivity), Exception (to throw an exception. Any code using it must have a try/catch block and must handle that exception when it is thrown), and Holder classes (which map the out and inout IDL interface parameters to the Java programming language parameters passing).

Java Servlet package provides the implementation of a server object coded in Java. Server objects coded in Java have the advantage of Java language multithreaded and strong automatic storage management features, which are extremely important for the server executables. Some of the classes and interfaces are ServletRequest (stores information about the client request to the servlet), ServletResponse (sends the server response to the client in the form of Internet MIME-typed message), and ServletContext (which provides information about the server running environment).

Oracle JDBC package provides the JDBC drivers and services to the Oracle databases, and IBM DB2 JDBC package provides the JDBC drivers and services to the IBM DB2 databases.

Java IDE

Java Integrated Development Environment (IDE) provides facilities for constructing high-level objets accessible to HTTP. It usually has extensive editing supports for XML and XSL files and provides facilities for web scripting and lower-level programming, database editing tools, and source code control. It also provides a capable Java and JSP editing environment and EJB template wizards for creating and editing session and entity EJBs.

© 2005 by CRC Press LLC

Some of the popular commercial IDEs are as follows:

- Borland Jbuilder: A leading, cross-platform environment for building industrial-strength enterprise Java applications (EJB, XML), integrated tightly with BEA WebLogic server platform.
- *IBM WebSphere Studio*: An open comprehensive development environment, integrated tightly with IBM Websphere platform. (The IBM VisualAge for Java was withdrawn from the market in 2003. It has a complex visual programming capability. Most of its functionality is incorporated into the Websphere studio.)
- *Sun One Studio (formerly Sun Forte for Java)*: A Java IDE that supports EJB and XML, which paves the way for organization to transform Java objects into Web services.

To illustrate an example, we will briefly describe the IBM Websphere Studio (WS). The IBM WS supports the Java development for the Application Framework for e-business. IBM application framework principles are as follows:

- Server-centric applications
- Managed thin clients
- Scalable architectures
- Java-based techniques
- Platform, Web server independence
- Industry-standard components, services, and interfaces.

IBM WS provides an easy-to-use tool set that helps reduce time and effort when creating, managing, and debugging multiplatform web applications. IBM WS is the first tool in the industry for the visual layout of dynamic Web pages. WS provides tools and wizards support for both individual Web pages development, and large teams advanced Web applications such as servlet, JSP, and EJB development. It has visual layout tools to create dynamic Web sites with Java servlet or JSP components, a built-in XML development environment, and Web services tools for the creation, deployment, and publishing of Web services. Using WS, one can create J2EE applications and make one's application accessible over the Web using the XML Web Services standards such as XML, Simple Object Access Protocol (SOAP), Web Services Description Language (WSDL), and Universal Description Discovery and Integration (UDDI). The major Web development tools provided by WS includes the following:

- *The Web development tools*: The WS web development environment provides the tools necessary to develop applications such as static Web pages with HTML, dynamic Web pages with JSPs or servlets, XML deployment descriptors, and other Web resources, which includes wizards to generate pages driven by databases and Java beans. It automatically updates links when the content changes. It also includes tools for developing images and animated GIFs.
- *Enterprise services toolkit*: The toolkit consists of a set of tools and wizards to facilitate service-oriented development, which provides an additional level of abstraction for developers by providing a consistent view of any service irrespective of implementation.
- *Relational database tools*: The data tools provided allow one to create and manipulate the data design for one's project in terms of relational database schemas. One can create, browse, or import database schemas, and also explore, import, design, and query databases, working with either a local copy of an already deployed design, or by creating an entirely new design to meet one's requirements. The SQL statement wizard and SQL query builder provide a GUI-based interface for creating and executing SQL statements. The relational database tools support connecting to and importing from several database types, such as DB2, Oracle, SQL Server, Sybase, and Informix. The SQL-to-XML wizard can be used to create an XML and related documents that allow one to implement one's query in other applications such as a servlet or JSP.
- *XML tools*: The comprehensive XML tool set includes components for building Document Type Definition (DTDs), XML schemas, and XML files for web service specifications.
- *Java development tools*: The Java tools provide a professional-grade Java development environment.

© 2005 by CRC Press LLC

- *Web services development tools*: The tools help you to discover, create or transform, build, deploy, test, and publish the Web services.
- *Enterprise JavaBeans development tools*: Enterprise JavaBeans (EJB) development tools support the full EJB 1.1 features, includes an updated EJB test client, an enhanced unit test environment for J2EE, and deployment support for Web application archive (WAR) files and enterprise application archive (EAR) files. Entity beans can be mapped to databases, and EJB components can be generated to tie into transaction processing systems. XML provides an extended format for deployment descriptors within EJB.
- *Server tools for testing and deployment*: The Server Tools feature provides a unit-test environment where one can test HTML files, servlets, JSPs, and EJBs. It also provides the capability to configure other local or remote servers for integrated testing and debugging of J2EE applications. The server tools support multiple-server configurations, including WebSphere Application Server and Apache Tomcat web server.

Java Security

Java cryptography architecture uses both symmetric-key and public-key encryption algorithms to generate the encrypted code, and uses the digital signature to authenticate the integrity of the files. The untrusted remote Java code has only a sandbox-restricted access to the local system resources. The trusted signed code can have up to complete access to the local system resources, and depends on the security policy specified. Figure 1.3 shows the Java JDK 1.2 security model.

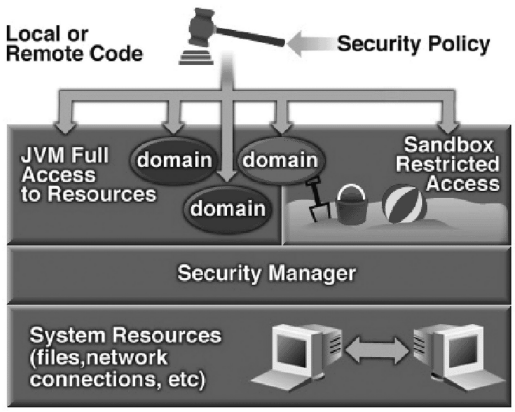

FIGURE 1.3 JDK 1.2 security model. (*Source*: JavaOne conference.)

FIGURE 1.4 A Java Certificate generated using the 512-bit DSA.

© 2005 by CRC Press LLC

Java software provides the tools to generate the encryption keys and certificates for signing the Java code. Figure 1.4 shows an example of a certificate generated using the DSA public-key encryption.

Java Network Protocol

Java application programs can directly communicate with the TCP/IP, similar to C/C++ network programs. Java provides three socket classes for TCP/IP connection-oriented and connectionless services.

- Socket class and ServerSocket class are used for connection-oriented service.
- Socket class provides an incoming/outgoing reliable, ordered stream connection service.
- ServerSocket class provides a server-side socket that listens for incoming connections from clients.
- DatagramSocket class is used for connectionless service.

But web-based Java components such as Applet, Servlet, JSP, and EJB use HTTP and HTTPS as their network protocols. HTTPS is a secure HTTP that runs over the SSL (The Secure Sockets Layer). SSL establishes and uses the secure socket connections with encryption and message authentication.

1.3 Java JDBC

JDBC is a Java Database Connectivity specification. The protocol was jointly developed by SUN JavaSoft, Sybase, Informix, IBM, and others to provide a Java object interface to relational databases. It provides a handy set of lower-level classes to manage database connections, operations, and transaction, and supports common database standards. JDBC is a generic way to query and update relational tables and translate the results into Java data types. It is based on the X\Open SQL CLI (Call Level Interface), which is an SQL wrapper that allows one's application to connect to a database through a local driver. All the major relational database vendors provide the JDBC drivers for their databases.

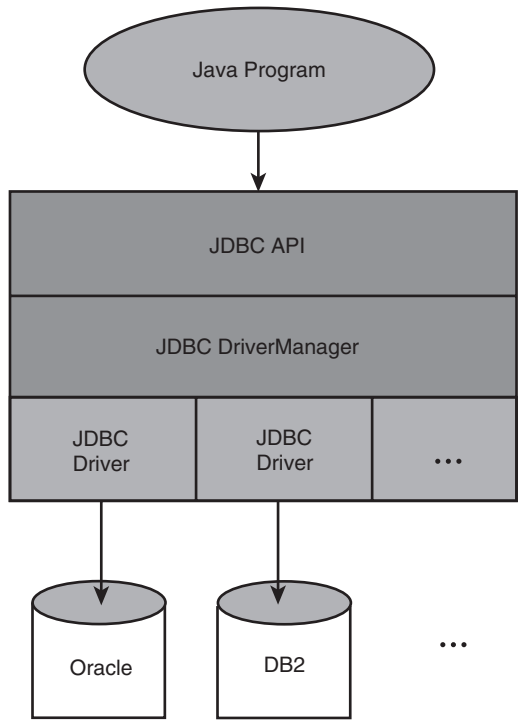

FIGURE 1.5 JDBC architecture.

© 2005 by CRC Press LLC

JDBC consists of a basic set of interfaces (Driver, Connection, Statement, and ResultSet) and a DriverManager class. DriverManager class is a JDBC class that controls the loading of driver-specific classes (Load driver, establish the database connection, etc.). Connection interface is a JDBC interface used by driver developers to create a DBMS-specific implementation of the connection class. Statement and ResultSet classes are JDBC interfaces that are used for executing the SQL statements and processing the return results. The driver provides the functional specifics to a database or database middleware layer.

JDBC Core API locates DBMS drivers, connects to a remote/local database, submits SQL commands, and processes return results. JDBC Java Language Extensions provides new numeric Java data types to meet the precision requirements of SQL. JDBC Java Utilities provide very fine-grained time and date utilities. JDBC Metadata provide the information about the SQL database (see Figure 1.5).

Loading a JDBC Driver

One must select and load a JDBC driver for one's application code. The following show examples of loading three different database drivers.

MS Access: DriverManager.registerDriver(new sun.jdbc.odbc.JdbcOdbcDriver());
Oracle: DriverManager.registerDriver(new oracle.jdbc.driver.OracleDriver());
DB2: DriverManager.registerDriver(new com.ibm.db2.app.DB2Driver()).

Creating a JDBC Connection

A JDBC Connection request can be made on DriverManager class.

```
Connection conn=DriverManager.getConnection(url,userlogin,password)
where URL = jdbc:<subprotocol>:<datasource_name>
```

The following show examples of connecting to a "cs" database on three different database systems.

MS Access:

```
Connection conn = DriverManager.getConnection("jdbc:odbc:cs", user, pass-
word);
```

Oracle:

```
Connection conn = DriverManager.getConnection ("jdbc:oracle:thin:@cs1.
bradley.edu: 1521:cs", user, password);
```

DB2:

```
Connection conn = DriverManager.getConnection ("jdbc:db2:cs", user, pass-
word).
```

Execute the Query

JDBC has three query statements. Statement is used to execute a static SQL statement. Prepared Statement is used to submit a precompiled SQL command so that it can be efficiently executed multiple times with variable parameters. And Callable Statement is used to submit the stored procedure call. Normally, the Callable Statement executes faster than the prepared statements because a block of sql statements is already stored at the database side (see Figure 1.6).

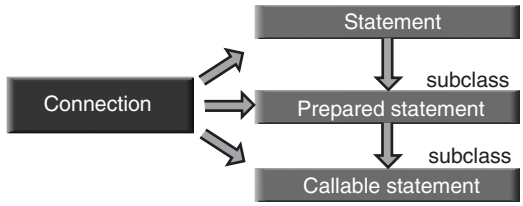

FIGURE 1.6 JDBC query statements. (*Source*: JavaOne conference.)

© 2005 by CRC Press LLC

Example of execution of the SQL SELECT Statement:

```
Statement queryStmt = conn.createStatement();
ResultSet result = queryStmy.executeQuery("SELECT * FROM students").
```

(Similarly, you can execute the delete, insert, and update command using the Statement executeUpdate method.)

Example of execution of the PreparedStatement:

```
PreparedStatement insertStmt = conn.prepareStatement("INSERT INTO students
(firstname, year) VALUES (?,?)");
insertStmt.setString(1, "John"); insertStmt.setInt(2, 3);
insertStmt.executeUpdate().
```

Example of execution of the CallableStatement:

```
CallableStatement cstmt = conn.prepareCall("{call getStudentData(?,?)}");
cstmt.setByte(1, 25); cstmt.setBigDecimal(2, 25.5);
cstmt.registerOutParameter(1, java.sql.Types.TINYINT);
cstmt.registerOutParameter(2, java.sql.Types.NUMERIC);
ResultSet rs = cstmt.executeQuery().
```

Retrieving and Processing Return Data

A ResultSet provides access to a table of data generated by executing a Statement. It maintains a cursor pointing to its current row of data; initially, the cursor is positioned before the first row. The next() method moves the cursor to the next row and it will returns false if there are no more rows left in the table. The table rows are retrieved in sequence and the ResultSet has methods to retrieve column values for the current row.

Example of retrieval and printing of all the first name column of the return records.

```
while (rs.next()) {
  String fname = rs.getString("firstname");
  System.out.println("Name: " + firstname);
}
```

Exception Handling

Most of the methods in Statement and Connection can throw SQLException. Checked exception must be caught. SQLException can be handled in one of two ways: catch and recover locally or catch and "convert" the exception by throwing another exception.

Example of catches and printing of the SQL errors.

```
try {
  Connection conn = DriverManager.getConnection
("jdbc:oracle:thin:@cs1.bradley.edu:1521:cs", user, password);
  Statement stmt = conn.createStatement();
} catch(SQLException e) {
  System.out.println(e+e.getErrorCode()+e.getSQLState()};
}
```

JDBC Efficiency

Database access is the performance bottleneck in most Java applications that use a relational database. The JDBC efficiently depends on a number of factors:

1. Use the right driver.

© 2005 by CRC Press LLC

2. Use only those statements that are necessary.
3. Use JDBC's PreparedStatement and CallableStatement when required.

Sun Java JDBC defines four types of drivers:

Type 1: The JDBC–ODBC bridge — slowest, most portable, requires client software.
Example: sun.jdbc.odbc.JdbcOdbcDriver
Type 2: Native-API partly Java driver: Usually fastest, least portable, requires client software.
Example: oracle.jdbc.driver.OracleDriver
com.ibm.db2.app.DB2Driver
Type 3: Net-protocol all-Java: Requires no client software, internet-capable.
Example: com.ibm.db2.net.DB2Driver
Type 4: Native-protocol all-Java: Requires no client software, suitable for Intranets.

All major commercial database vendors are providing the JDBC drivers on their Web sites. Choosing the right driver would be the first step in improving your JDBC efficiency.
Finally, we will list the development steps of accessing a "cs" database using Oracle JDBC Driver from a remote window client.

1. Oracle database on SUN Solaris server development:
   (a) Create and Test the Database tables.
   (b) Create a Database Source ID (SID) for the database.
   (c) Start the Oracle listener on the Solaris server and log the incoming client connection requests for the debugging.
2. Window 98 JDBC client development (using type 2 driver)
   (a) Download the Oracle JDBC driver from Oracle Web site.
      - Choose the thin driver classes for applet/application: classes12.zip
   (b) Develop the JDBC client to test the JDBC connection.
      - The web server and the Oracle database must be in the same machine for testing the Java applet JDBC; otherwise, the sandbox security model will prevent the JDBC connection.

1.4 Java Server-side Programs

Java server-side programming technologies enable developers to create complete, distributed applications in which the clients can access the server programs through the web pages. Java supports server-side servlet Java program and server-side JSP script (JSP will be dynamically compiled into a servlet at the server side). The developer can choose to build either one or both for their applications.

Servlet

Java Servlet provides a Java-based solution to the server-side programming much as the earlier CGI implementation. Servlets are objects that conform to a specific interface that can be plugged into a Java-enabled server, and thus extends the capabilities of a web server. Servlets are to the server-side as what applets are to the client-side. It runs completely on the server; nothing is ever downloaded to the browser. Servlets serve as platform-independent, dynamically loadable, pluggable bytecode objects on the server-side that can be used to dynamically extend server-side functionality.

Servlets have many advantages for the distributed applications. There is a rich set of platform-neutral Java APIs to connect to most backend assets. It is a reusable object. Web server servlet engine plugin provides a consistent servlet environment. Called within the server context can restrict servlet access within the security architecture. Servlets also have high performance in the server object execution. It runs in the same context as the application server and remains in the memory after the execution. Servlets can be preloaded or loaded on demand and sessions can be maintained across HTTP requests. Servlets are multithreaded and can be scaled with multiprocessors; thus, they are the ideal components for the Enterprise-level applications.

© 2005 by CRC Press LLC

Programming the Servlet

HTTP servlets subclass the javax.servlet.http.HttpServlet class and override one of the following methods depending on which HTTP method is used by the client.

```
doGet(HttpServletRequest req, HttpServletResponse res);
doPost(HttpServletRequest req, HttpServletResponse res).
```

HTTP is a request–response protocol. The Get method will attach the request at the end of the URL. Thus, it is only suitable for short request data pairs, but the servlet can then be directly invoked from the URL. The Post method will send the request through an HTML form. Therefore, it is commonly used for the large request data pairs sent from client (see Figure 1.7).

Servlet Invocations

Servlet is usually invoked from a remote web client. The client makes a request to the hosting web server naming the Servlet as part of the URL. Hosting web server forwards the request to the Servlet engine that locates an instance of the Servlet class. The Servlet engine then calls the Servlet's service method. Servlet can also be invoked by another servlet in the servlet chaining, but not all hosting web servers support this (see Figure 1.8).

Example of Servlet using doGet:

```
import javax.servlet.*;
import javax.servlet.http.*; // servlet using the HTTP protocol.
public class HelloServlet extends HttpServlet {
    public void doGet (HttpServletRequest req, HttpServletResponse res)
        throws ServletException, IOException {
        res.setContentType("text/html"); // MIME type: image/jpeg, ...
        PrintWriter out = res.getWriter();
        out.println("<html><head><title>Hello Servlet</title></head><body>");
        out.println("<h1>Hello, Peoria</h1>");
        out.println("</body></html>"); }
}
```

Example of Servlet using doPost:

```
import javax.servlet.*;
import javax.servlet.http.*; // servlet using the HTTP protocol.
public class HelloPerson extends HttpServlet {
    public void doPost (HttpServletRequest req, HttpServletResponse res) throws
          ServletException, IOException {
          res.setContentType("text/html"); // MIME type: image/jpeg, …
          PrintWriter out = res.getWriter();
          Enumeration enum = req.getParameterNames();
          String fname = (String) enum.nextElement();
          String fvalue = req.getParameter(fname);
          String lname = (String) enum.nextElement();
          String lvalue = req.getParameter(lname);
          out.println("<html><head><title>Hello Person</title></head><body>");
          out.println("<h1>Hello, " + fvalue + ", " + lvalue</h1>");
          out.println("</body></html>"); }
}
```

HTML client form to invoke the HelloPerson servlet:

```
<FORM METHOD="POST" ACTION= "… /servlet/HelloPerson">
<P>Please enter your name:
<P>First name: <INPUT NAME="firstname" TYE="TEXT" SIZE="25">
<P>Last name: <INPUT NAME="lastname" TYE="TEXT" SIZE="25">
<INPUT TYPE="SUBMIT"><INPUT TYPE="RESET">
</FORM>
```

FIGURE 1.7 Servlets using doGet and doPost methods.

© 2005 by CRC Press LLC

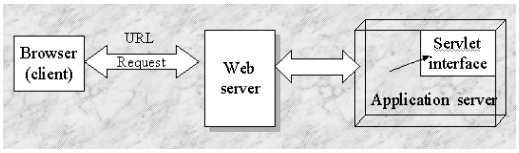

FIGURE 1.8 Servlet Invocation.

Example of a direct invoking of a servlet class name:

```
http:/host_name/servlets/servletClassName  or
<FORM ACTION = http:/host_name/servlets/servletClassName…>
```

```
(Servlet class name can also be converted into a user-friendly registered
name.)
```

Example of invoking of a servlet from an applet:

```
<APPLET NAME = "appletClassName" CODE = "appletName">
<PARAM NAME = "server" VALUE = "http://hostname/servletClassName">
<PARAM NAME = "method" VALUE = "GET">
```

Hosting the Servlets

Some free Java web servers, such as Tomcat, have the simple servlet hosting mechanism. After configuring the server.xml, web.xml, and other xml files, the Tomcat web server hosts the servlets in webapps subdirectory with a default path for html files in webapps/applName/servlets/ and default path for classes files in webapps/applName/WEB-INF/classes.

Other commercial web servers such as IBM WebSphere Application Server (WAS) have a set of utilities and tools to facilitate the servlet hosting. WAS starts the AdminServer to start and keep alive all servers. It runs a Name Service based on the JNDI, a Location Service Daemon, and a Security server. An Admin Console Tasks Configuration tool is used for configuring a web application, creating a web application, and adding Servlets and other server objects.

Servlet Design Issues

Servlets are used to generate the dynamic HTML web pages. Do not use the servlet if the contents of the HTML pages are static. Design of the servlet should follow the object component design principle. Each servlet should have well-organized manageable size. It may call the functions in other classes to minimize its size. Each servlet should not allocate too much memory. Check the request and respond data carefully and make sure there are exceptional handling and security checks for all vital client requests.

JavaServer Page

The HTML web page content delivered to client is composed of static or noncustomized content. Customized or dynamic content of a web page is processed programmatically. Server-side scripting is used to process a composite page on Server prior to delivery to the client — the server executes an embedded code to produce dynamic content. JSPs are an HTML extension for server-side scripting in your web pages. They are called from a browser just like HTML pages, but they have special tags that let you insert Java logic directly into the page. Other server-side scripting technologies include the Microsoft Active Server Pages (ASP) on Microsoft web server and PHP (PHP: Hypertext Preprocessor) on Linux Apache web server. Figure 1.9 shows a sample JSP page and a similar ASP page that dynamically display the current date and time.

JSP Execution Model

JSP (HTML page with an embedded Java code) is first converted into a Java servlet within the web server and is then compiled if the source code is new, loaded, and executed (see Figure 1.10).

© 2005 by CRC Press LLC

```
<!-- A sample JSP Page -->
<HTML>
<HEAD>
<TITLE>Sample.jsp</TITLE>
</HEAD>
<BODY>
    Current Date and Time:
    <%= new java.util.Date()%>
</BODY>
</HTML>
```

```
<!-- A sample JSP Page -->
<%@ LANGUAGE="VBSCRIPT" %>
<SCRIPT RUNAT=SERVER
LANGUAGE=VBSCRIPT>
    Sub WriteDate()
     Response.Write("Current Date and Time: "
& Date & "");
    End Sub
</SCRIPT>
<HTML><HEAD>
<TITLE>Sample.asp</TITLE></HEAD>
<BODY>
    <% Call WriteDate() %>
</BODY></HTML>
```

FIGURE 1.9 Sample JSP and ASP pages.

FIGURE 1.10 JSP compilation.

Figure 1.11 shows the converted sample$jsp.java servlet code from the previous sample.jsp page.

The JSP servlet is a subclass of HttpJspBase created with an overridden service method. The JSP servlet class created defines the _jspService method where the script content is written. pageContext object is created to hold the output page. Output is written to a JspWriter object that supports buffer management.

JSP coding Technologies

The JSP coding in the above example with an embedded Java code in an HTML file is called scriptlets. To separate the detailed Java code with the HTML code, two other technologies can be used to code the JSP. One is to call the JavaBeans object and another is to use the XML tag like custom tag libraries.

(a) *JSP calls JavaBeans*

A JavaBean is a reusable software component. It presents itself through a single object and uses standard "method" naming conventions that exposes three feature sets: Properties (variables), Methods, and Events. The following example shows a JSP page that calls the CounterBean to count how many times the page has been visited.

```
<h2> JavaBeanCount.jsp </h2>
<jsp:useBean id = "CounterBean" class = "jsp.CounterBean" scope = "session" />
<h3>This page has been visited: <jsp:getProperty name = "CounterBean"
property = "counter"/> time(s)</h3>
```

JSP JaveBeans unifying concepts of JSP objects used to encapsulate dynamic content provide interface for computing dynamic content, and manage complex states through client session. JavaBeans can access the business logic in a parameterized manner and encapsulate the result data (dynamic content). JavaBeans hide the detailed Java code so that the web page designer can concentrate on the presentation logic and leave the business logic coding to the JavaBean designers.

(b) *JSP uses Custom Tag Libraries*

JSP1.2 introduced the Custom Tag Libraries to use the XML-like tags to implement the detailed Java coding. These tags will be processed at the server-side and then generate the output for the client. The tags

package org.apache.jsp;
import javax.servlet.*;
import javax.servlet.http.*;
import javax.servlet.jsp.*;
import org.apache.jasper.runtime.*;
public class sample1$jsp extends HttpJspBase {
    static {    }
    public sample1$jsp( ) {    }
    private static boolean _jspx_inited = false;
    public final void _jspx_init() throwsorg.apache.jasper.runtime.JspException {    }
    public void _jspService(HttpServletRequest request, HttpServletResponse  response)
        throws java.io.IOException, ServletException {
        JspFactory _jspxFactory = null;
        PageContext pageContext = null;
        HttpSession session = null;
        ServletContext application = null;
        ServletConfig config = null;
        JspWriter out = null;
        Object page = this;
        String  _value = null;
        try {
            if (_jspx_inited == false) {
                synchronized (this) {
                    if (_jspx_inited == false) {_jspx_init(); _jspx_inited = true;}
                }
            }
            _jspxFactory = JspFactory.getDefaultFactory();
            response.setContentType("text/html;charset=ISO-8859-1");
            pageContext = _jspxFactory.getPageContext(this, request, response,"", true, 8192, true);
            application = pageContext.getServletContext();
            config = pageContext.getServletConfig();
            session = pageContext.getSession();
            out = pageContext.getOut();

            // HTML // begin [file="/jsp/Sample.jsp";from=(0,0);to=(7,0)]
                out.write("<HTML><HEAD><TITLE>Sample.JSP</TITLE></HEAD> \r\n
<BODY>\r\n<H3>Current Date and Time</H3>\r\n");
            // end
            // begin [file="/jsp/Sample.jsp";from=(7,3);to=(7,25)]
                out.print( newjava.util.Date() );
            // end
            // HTML // begin [file="/jsp/Sample.jsp";from=(7,27);to=(9,14)]
                out.write ("\r\n</BODY></HTML>");
            // end
        } catch (Throwable t) {
            if (out != null && out.getBufferSize() != 0)
                out.clearBuffer();
            if (pageContext!= null) pageContext.handlePageException(t);
        } finally {
            if (_jspxFactory != null) _jspxFactory.releasePageContext(pageContext);
        }
    }
}
```

FIGURE 1.11 Generated JSP servlet code.

are defined as Java classes with one class per tag. The tag library is registered with one's web application in the web.xml file. The following is the same example of counting how many times the page has been visited by using tag instead of the Java bean call.

```
<h2> CountTag.jsp </h2>
<%@ taglib uri = "http://brd105nt.bradley.edu:8080/Lib/Jsp" prefix = "ejava" %>
<h3>This page has been visited: <ejava:counter/> time(s)</h3>
```

© 2005 by CRC Press LLC

When the web server JSP container encounters the custom tag, it will create the appropriate tag object. The tag attributes are set using JavaBean style setter methods. The tag object will be executed using doStartTag method. The tag is released at some later time after the run results are returned to the client.

Advantages of using JSP

A JSP processes Java code embedded in an HTML document and returns results to the browser. JSP leverages Java as its language, which is more powerful and flexible than other script languages.

JSP is used to create dynamic contents of the web pages. HTML designers can use a well-defined Java code in JavaBeans or Custom tags inside the HTML pages without necessarily knowing how to write the servlets. Java programmers can use JSP to create dynamic web pages that access server-side business logic and data sources.

JSP vs. Servlets

JSP can generate the dynamic HTML without writing the servlet code (servlet code will be generated by the JSP page compiler.)

Servlet can response to the request from the applet, manage the redirects, and provide a mechanism for more complex dynamic contents creation such as images.

JSP can call the servlet using the normal HTML form action or JSP tags. Servlet can also call the JSP using sendRedirect method in the HttpServletResponse object or forward method in getServletContext().getRequestDispatcher object:

1.5 Java-Distributed Object Computing Technologies

Distributed computing refers to computer applications in which the applications code, the data it works on, and the actual computations performed are spread across multiple computers. Early distributed computing protocols use Remote Procedure Calls (RPC) (such as DCE), which has many disadvantages. The developer is responsible for both the high-level data structures and the tedious data communication details such as data loss and marshaling. The system is difficult to maintain and update.

A distributed object mechanism allows objects implemented on one computer to send messages to objects running in another computer. Objects hide the implementation details, thus providing better solutions than the RPC. Typical distributed object computing system components have a data communication protocol such as TCP/IP for peer-to-peer computing and HTTP/HTTPS for web-based computing, a scheme for locating remote objects, a mechanism for marshaling (packing parameters and return values to be distributed) and unmarshaling the object data over the network, a scheme for providing an interface for a remote object in the local address space, and a reference scheme for keeping track of valid reference to an object. Current major distributed object computing platforms include SUN Microsystems J2EE and Microsoft .Net. We will discuss the SUN J2EE JNDI, RMI, and EJB in this section.

Java Naming and Directory Interface

Java Naming and Directory Interface (JNDI) is an API that describes a standard Java library for accessing naming and directory services. JNDI can provide similar services as provided by Internet Domain Naming Service (DNS), Lightweight Directory Access Protocol (LDAP) directory service, RMI Registry service, and file system services. JNDI can be used to provide a seamless interface for accessing all types of enterprise information resources (see Figure 1.12).

A naming service provides a method for mapping a unique identifier (name) to a local or remote object. JNDI provides a consistent API to access the naming services provided by different service providers. The naming directory contains a slightly more sophisticated API used for filtered searching and modifying the hierarchical value in directory and naming services, such as LDAP. Naming spi provides a set of interfaces and objects used by service provider developers. It is used for mapping JNDI calls to a specific service provider.

© 2005 by CRC Press LLC

Remote Method Invocation

Remote Method Invocation (RMI) is a language-centric distributed computing for the Java platform. It leverages Java ubiquity and enables Java-to-Java distributed objects computing. RMI is a simplified distributed object model as compared with CORBA and is easy to use. It supports seamless remote invocation on objects in different VMs.

Java RMI Classes and Interfaces

The RMI system is based on remote interfaces through which a client accesses the methods of a remote object (server.UnicastRemoteObject). The client stub and server skeleton are generated from the remote interface by the rmi compiler; no interface definition language (IDL) is used as is in the CORBA. RMI naming class provides methods (bind/rebind, lookup) for server classes to make remote objects visible to clients (see Figure 1.13).

Example of development of a "Pizza order" application using RMI (see Figure 1.14).

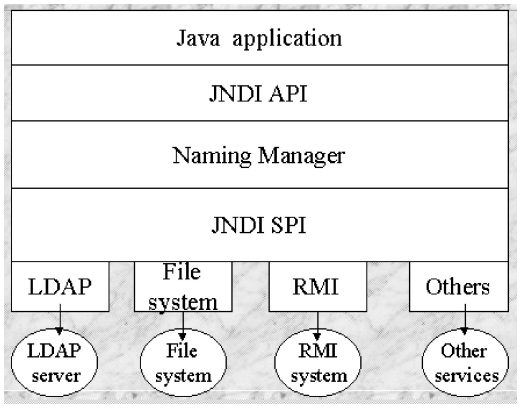

FIGURE 1.12 JNDI architecture.

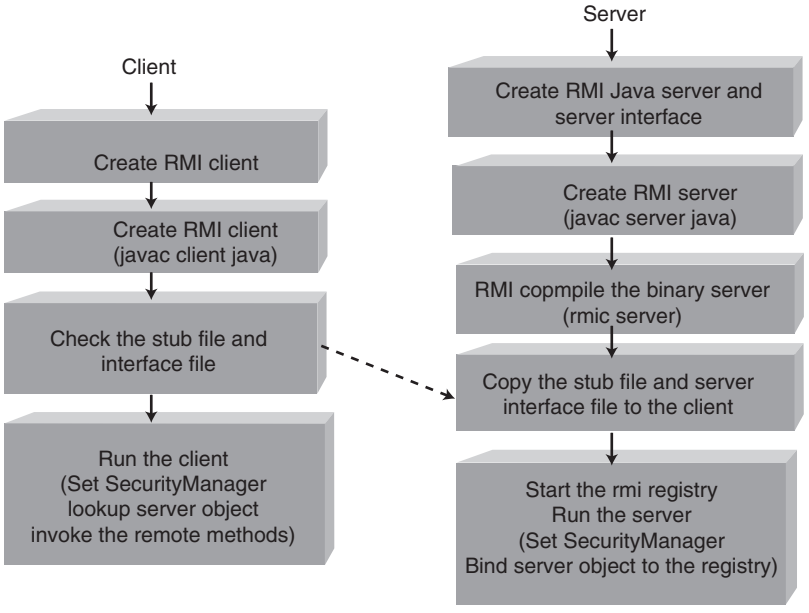

FIGURE 1.13 Client/server development using Java RMI.

© 2005 by CRC Press LLC

```
1.  Develop the Remote Interface
import java.rmi.*;
public interface PizzaServerInterface extends Remote {
        String orderPizza(…) throws RemoteException;
}

2.  Develop the Server Working Object
import java.rmi.*;
import java.rmi.server.*;
public class PizzaServer extends UnicastRemoteObject implements
PizzaServerInterface {
   PizzaServer() throws RemoteException {super();}
   public String orderPizza(…) throws RemoteException {
        // Process pizza order information
      ...
   }

3.  Develop the RMI Server
public static void main(String args[]) {//args[0] is the hostname
      try   {
          // set the security manager
          System.setSecurityManager(new RMISecurityManager());
         // create the local instance of the PizzaServer
          PizzaServer svr = new PizzaServer();
          // put the local instance into the Naming Server
          Naming.rebind("rmi://"+args[0]+"/PizzaServer", svr);
          System.out.println("Pizza Server is ready...");
        } catch (Exception exc) {
          System.out.println("Error! - " + exc.toString());
      }
}

4.  Develop the RMI Client
public static void main(String args[]) {//args[0] is the hostname
        Remote remoteObj = null;
        PizzaServerInterface pizzaInterface = null;
      System.setSecurityManage   r(new RMISecurityManager());
      try   {
          remoteObj =Naming.lookup("rmi://"args[0]"/PizzaServer");
      }catch(Exception   exc){
          System.out.println(exc.toString())System.exit(1);}
      try   {
          if(remoteObj instanceof PizzaServerInterface)
              pizzaInterface = (PizzaServerInterface) remoteObj;
      }catch(Exception   exc){…}
        PizzaOrder pizzaOrder=new PizzaOrder(pizzaInterface);
      pizzaOrder.show();
}
```

FIGURE 1.14 An RMI application development.

RMI-over-IIOP

As compared with CORBA, RMI is easy to program. There is no need to learn separate Interface Definition Language (IDL). RMI simply compiles the remote interface and ports the stubs to the client site. Rmi registry registers the server objects when the RMI server started. Rmi client will look for the server object at the Rmi name spaces. RMI is ideal for communication between Java applications. But CORBA is an OMG standard and allows communication between Java applications and other languages such as C++. To make it compatible to CORBA, SUN introduced RMI-IIOP API.

RMI-IIOP allows interfaces to be defined in RMI, and then generates the IDL from RMI interfaces. It uses the IDL Object-By-Value extensions to run the RMI over CORBA IIOP (Internet Inter-ORB Protocol).

RMI is not a web-based computing technology. It is often used as an underlying network protocol instead of a user-level application protocol. J2EE supports Enterprise Java Bean, which is a much better choice for the user-level-distributed object computing.

© 2005 by CRC Press LLC

Enterprise JavaBeans

Enterprise applications depend upon a vast array of services that are inherently complex. These services include distribution, multithreading, transaction management, resource management, persistent-state management, and security services. The increasing complexity leads to a desire to have a standardized API to the enterprise service and integrating the utilization of the services within a component-model specification.

Enterprise JavaBeans (EJB) is such a component model developed by SUN Microsystems and its partners for developing and deploying object-oriented, multitier, enterprise Java application. EJB specifications hide the server-side computing complexities, such as transaction processing, database access, and resource management (multithreading, connection pooling) from the programmers. EJB defines a standard for server-side component as the JavaBean defines a standard interface for client-side application components.

EJB was designed to meet the following goals (see Figure 1.15):

- Clearly define the way that applications are partitioned: client vs. EJB vs. Server.
- Create a multitiered model that improves scalability and performance.
- Increase reliability by moving the important code to a well-defined container.
- Centralize resources to increase manageability.
- Promote reuse via well-defined, portable components.
- Provide interoperability with non-Java applications such as legacy systems.
- Be compatible with CORBA.

EJB Architecture

EJB component is created and managed at runtime by a container. It can be customized at deployment time. Client accesses to the EJB are mediated by an EJB container and server. An EJB server is a process that manages EJB containers, which manage the beans. It provides access to system services and Java-related services including a name space accessible via JNDI, a transaction service via JTS, and a security service. EJB container is a program entity in the EJB server hosting the EJBs, similar to that in a browser hosting the applets. Container defines the EJB's interactions with the outside world. It creates a safe environment for the bean and provides services to it, such as database accesses, transaction management, the bean's life cycle, and JNDI. Container provides these services to the EJB programmer through the standard interfaces. It makes the EJB as a reusable, write-once, run-anywhere server components.

EJB is a complex component model that not all the commercial Java web servers support. IBM WebSphere Application Server Enterprise Edition and Sun One Application Server are the two Java web servers that support the full services of EJB (see Figure 1.16).

EJB client can be a servlet, a JSP, an application, or other bean. They find the EJB by locating EJB home interface via JNDI and communicate to the home and remote interfaces of an EJB through the proxies (Home stub and EJBObjet stub).

The beans on the server-side have two interfaces: EJBHome and EJBObject. EJBHome is a container-provided object representing the home interface that allows you to create and find EJBs. It will return references

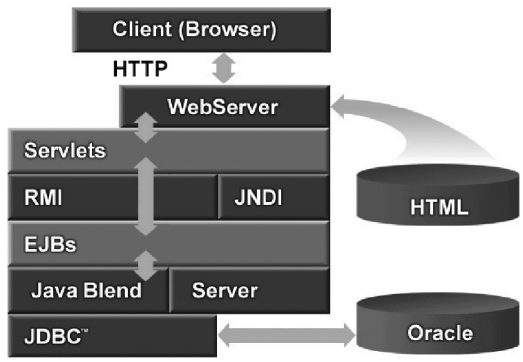

FIGURE 1.15 EJB in web-based computing.

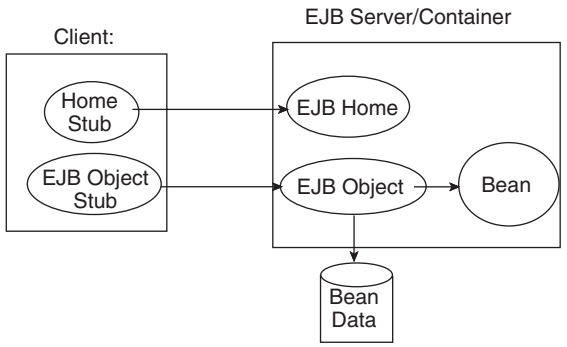

FIGURE 1.16 EJB programming model.

Session Beans Single client, Short lived Do not survive a crash.	**Entity Beans** Multiple clients, Long-lived, Survive a crash.
Stateless Session Beans High Performance & re-usable Single state transaction management.	Bean-Managed Persistence Entity Beans (BMP) Contain code to store and retrieve data
Stateful Session Beans Multi-state transaction management.	Container-Managed Persistence Entity Beans (CMP) Rely on EJB Container to store and retrieve data.

FIGURE 1.17 Differences between the Session Bean and Entity Bean.

to EJBObjects. EJBObject is another container-provided object representing the remote interface that handles tasks such as persistence (in container-managed persistent entity beans), distribution (interface with CORBA and RMI), and support for transactional behavior. The Bean itself implements the business logic.

Type of EJBs

There are two kinds of EJBs: session beans and entity beans. The session beans are normally within a client–web server session to process information and the entity beans are persistent and can reside at the server-side for a long period of time. An example of a session bean can be a login EJB that handles client login functions and an example of an entity bean can be a shopping cart EJB that handles online shopping requests.

The session beans can be stateless or stateful depending on whether some information is stored at the container or not between the client–server interactions. For the stateless session beans, the server can optimize resources by minimizing the number of beans and sharing them. The server does not have to worry about persistence. But clients may come across several beans in one session and the client's remove message may not result in a bean really being removed. For the stateful session beans, clients can reply on a single point of contact on the server. The server manages persistence for long running sessions. But the server has to create one bean per client.

The entity beans can also be managed by the bean itself or by the container. The bean-managed entity beans can optimize resource usage and arbitrary find methods. But it may have to port bean if one changes platforms. The container-managed entity beans have less code in the bean. The container may allow one to change the persistence without recompiling and change containers without recompiling. But it has less control over persistence and may not support all find methods.

Figure 1.17 lists some of their differences.

EJB Development Process (see Figure 1.18)

1. Define Remote Interface for accessing the beans and Home Interface for finding or creating beans, and write the Bean class for processing the business logic.

© 2005 by CRC Press LLC

Example of Create a Stateless Login Session Bean

a. Define the remote interface

```
package loginSessionBean;
import loginSessionBean.*;
/**
 * This is an Enterprise Java Bean Remote Interface
 */
public interface Login extends javax.ejb.EJBObject Remote {

/**
* @return java.lang.String
 * @param user java.lang.String
 * @param epwd byte []
 * @exception String The exception description.
 */
java.lang.String loginVerify(java.lang.String user, byte [] epwd)
    throws java.rmi.RemoteException;
}
```

b. Define the home interface

```
package loginSessionBean;
import loginSessionBean*;
/**
 * This is a Home interface for the Session Bean
 */
public interface LoginHome extends javax.ejb.EJBHome {
/**
 * create method for a session bean
 * @return loginSessionBean.Login
 * @exception javax.ejb.CreateException The exception description.
 * @exception java.rmi.RemoteException The exception description.
 */
Login create() throws javax.ejb.CreateException, java.rmi.RemoteException;
}
```

c. Develop the Session Bean class

```
package loginSessionBean;
import java.rmi.RemoteException;
import java.security.Identity;
import java.util.Properties;
import javax.ejb.*;
import javax.crypto.*;
import javax.crypto.spec.*;
import java.io.*;
import loginSessionBean.*;
/**
 * This is a Session Bean Class
 */
public class LoginBean implements SessionBean {
          private javax.ejb.SessionContext mySessionCtx = null;
          final static long serialVersionUID = 3206093459760846163L;
…
/**
 * ejbCreate method comment
 * @exception javax.ejb.CreateException The exception description.
 * @exception java.rmi.RemoteException The exception description.
 */
public void ejbCreate() throws javax.ejb.CreateException, java.rmi.RemoteException {}
/**
 * getSessionContext method comment
 * @return javax.ejb.SessionContext
 */
```

FIGURE 1.18 An EJB Session Bean development.

© 2005 by CRC Press LLC

```
/**
* @return boolean
 * @param user java.lang.String
 * @param pwd java.lang.String
 */
public String loginVerify(String user, byte[] epwd) {
String decMsg = new String();
String flag = new String();
java.sql.Statement stmt = null;
java.sql.ResultSet rs = null;
java.sql.Connection conn=null;
try{
          byte key[] = "abcdEFGH".getBytes();
          SecretKeySpec secretKey = new SecretKeySpec(key,"DES");
          Cipher cipher = Cipher.getInstance ("DES");
        cipher.init(Cipher.DECRYPT_MODE,secretKey);
          byte[] decryptedMsg = cipher.doFinal(epwd);
          decMsg = new String(decryptedMsg );
          conn = getDBConnection();
          stmt = conn.createStatement();
          rs = stmt.executeQuery("select password from userdetails where userid
='"+user+"'");
        if(rs.next())    {
                if(rs.getString("pa      ssword").equals(decMsg))
                        flag = "true";
                    }
                    else{
                        flag = "false";
                    }
}catch(Exception e){
        System.out.print   ln(e.getMessage());
}
return flag;
}
```

d. Compile, pack, deploys the **Login** Session Bean.
e. Develop the Login EJB Client: JSP

```
<%@ page import = "javax.rmi.*"%>
<%@ page import = "javax.crypto.*"%>
<%@ page import = "javax.crypto.spec.*"%>
<%@ page import = "loginSessionBean.*"%>
<%@ page contentType = "TEXT/HTML" %>

<html><head><title>Login Check</title></head>
<body bgcolor=#a5b56b>
<%String Username = request.getParameter("username");%>
<%String Password = request.getParameter("password");%>
<%String ejbJndiName = "java:comp/env/ejb/LoginBean";%>
<%Login loginbean = null;%>
<%javax.naming.InitialContext ctx=null;%>
<%String pwd = new String();%>
<%String loginverified = new String();%>
<%try {
byte key[] = "abcdEFGH".getBytes();
String msg = Password;
SecretKeySpec secretKey = new SecretKeySpec(key,"DES");
Cipher cipher = Cipher.getInstance ("DES");
cipher.init(Cipher.ENCRYPT_MODE,secretKey);
byte[] encryptedMsg = cipher.doFinal(msg.getBytes());
/////////EJB calling//////////
ctx = new javax.naming.InitialContext();
Object ref = ctx.lookup(ejbJndiName);
if (ref == null) { throw new Exception("ERROR: lookup failed");}
LoginHome home = (LoginHome)PortableRemoteObject.narrow(ref, LoginHome.class);
```

FIGURE 1.18 (continued)

```
loginbean = home.create();
loginverified = loginbean.loginVerify(Username,encryptedMsg);
}catch(Exception ex){ex.printStackTrace();
}
if(loginverified.equals("true")){response.sendRedirect("http://localhost/startpage");
}else{response.sendRedirect("http://localhost/errorpage");}
%>
</body></html>
```

FIGURE 1.18 (continued)

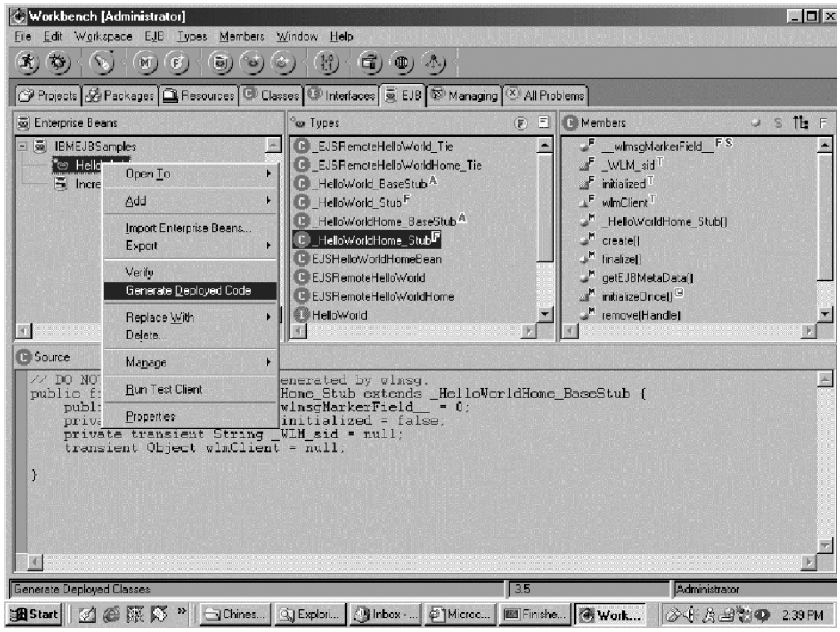

FIGURE 1.19 Generate the EJB deploy code in IBM WS.

2. Deploy Beans to EJB server. (The deployment process generates the client stub and server skeleton files, as well as a series of "helper" and "holder" classes. The exact names, numbers, and contents of these classes will vary with the EJB server and container.)
3. Write EJB clients.
4. Test Beans.

Many Java IDEs such as the IBM WS, SUN One Studio, and Borland JBuilder have the tools built-in to allow the developer to compile, pack, and deploy the EJBs. All the major Java IDEs claim that the EJB compiled and packed in their system can be deployed to any other EJB-supported web servers. But the experiences show that it is much easier to deploy the EJB created from the IBM WS to IBM WAS, deploy the EJB created from SUN One Studio to SUN One Application Server, and deploy the EJB created from Borland JBuilder to BEA WebLogic Server (see Figure 1.19).

Programming rules for session beans (see Figure 1.20):

- Session beans must implement the javax.ejb.SessionBean interface and have at least one method.
- Session beans must implement all of the ejbCreate methods.
- Session beans must implement their remote interfaces.
- The home interface for a session bean must define the create method.
- Stateless beans should only have a create method with no arguments.

© 2005 by CRC Press LLC

Example of Create a Container-Managed Persistence ShoppingCart Entity Bean

a. Define the remote interface

```
package shoppingcartCMP;
/**
 * This is an Enterprise Java Bean Remote Interface
 */
public interface ShoppingCart extends javax.ejb.EJBObject {

/**
* @return void
 * @param item shoppingcart.PurchasedItem
 * @exception String The exception description.
 */
void addItem(shoppingcart.PurchasedItem item) throws java.rmi.RemoteException;

/**
* @return boolean
 * @param item shoppingcart.PurchasedItem
 * @exception String The exception description.
 */
boolean purchasedCart() throws java.rmi.RemoteException;
}
```

b. Define the home interface

```
package shoppingcartCMP;

/**
 * This is a Home interface for the Entity Bean
 */
public interface ShoppingCartHome extends javax.ejb.EJBHome {

/**
 * create method for a CMP entity bean
 * @return shoppingcart.ShoppingCart
 * @param argCartPK int
 * @exception javax.ejb.CreateException The exception description.
 * @exception java.rmi.RemoteException The exception description.
 */
shoppingcart.ShoppingCart create(String argCartPK)
    throws javax.ejb.CreateException, java.rmi.RemoteException;
/**
 * findByPrimaryKey method comment
 * @return shoppingcart.ShoppingCart
 * @param key shoppingcart.ShoppingCartKey
 * @exception java.rmi.RemoteException The exception description.
 * @exception javax.ejb.FinderException The exception description.
 */
shoppingcart.ShoppingCart findByPrimaryKey(shoppingcart.ShoppingCartKey key)
    throws java.rmi.RemoteException, javax.ejb.FinderException;
}
```

c. Develop the CMP Bean class

```
package shoppingcartCMP;
import java.sql.*;
import java.rmi.RemoteException;
import java.security.Identity;
import java.util.Properties;
import javax.ejb.*;
/**
 * This is an Entity Bean class with CMP fields
 */
public class ShoppingCartBean implements EntityBean {
        private    javax.ejb.EntityContext entityContext = null;
```

FIGURE 1.20 An EJB Entity Bean Development.

```
        final static long serialVersionUID = 3206093459760846163L;
        public final static java.util.Hashtable items = new java.util.Hashtable();
        private java.sql.Connection dbConnection;
        public String CartPK = "";
…
/**
 * ejbCreate method for a CMP entity bean
 * @param argCartPK int
 * @exception javax.ejb.CreateException The exception description.
 * @exception java.rmi.RemoteException The exception description.
 */
public void ejbCreate(String argCartPK) throws javax.ejb.CreateException,
java.rmi.RemoteException {
      _initLinks();
        // All CMP fields should be initialized here.
        CartPK = argCartPK;
}
/**
 * ejbPostCreate method for a CMP entity bean
 * @param argCartPK int
 * @exception java.rmi.RemoteException The exception description.
 */
public void ejbPostCreate(int argCartPK) throws java.rmi.RemoteException {}
/**
 * ejbPostCreate method for a CMP entity bean
 * @param argCartPK java.lang.String
 * @exception java.rmi.RemoteException The exception description.
 */
public void ejbPostCreate(java.lang.String argCartPK) throws java.rmi.RemoteException {}
/**
 * ejbRemove method comment
 * @exception java.rmi.RemoteException The exception description.
 * @exception javax.ejb.RemoveException The exception description.
 */
/**
 * Insert the method's description here.
 * Creation date: (5/2/2003 1:18:52 AM)
 */
public void addItem(PurchasedItem item)
{
        PurchasedItem temp = new PurchasedItem();
        if(item!=null) temp = (PurchasedItem)items.get(item.prodname);
      if(temp!=null){
            item.quantity     +=temp.quantity;
            items.put(item.prodname,item);
            System.out.println     ("Item is Updated");
      }
      else   {
            items.put(item.prodname,item);
            System.out.println("Item      is Added");
      }
}
/**
 * Insert the method's description here.
 * Creation date: (5/2/2003 2:03:55 AM)
 * @return boolean
 */
public boolean purchasedCart() {
        //// Buy Pay and Go concept no exchange
        /// get the hash table, sure with inventory,and update inventory
      java.util.Enumeration    allItems;
        java.sql.ResultSet rs =null;
        java.sql.Statement stmt = null;
        PurchasedItem curItem = new PurchasedItem();
```

FIGURE 1.20 (continued)

© 2005 by CRC Press LLC

```
            allItems = items.elements();
            int curQuantity = 0;
          try   {
            java.sql.Connection conn = getDbConnection();
          while(allItems.hasMoreElements()){
              curItem = (PurchasedItem)allItems.nextElement();
              System.out.println("Current Item name is:"+curItem.prodname);
              rs = stmt.executeQuery("select * from Inventory where
productname='"+curItem.prodname+"'");
              if(rs.next()){
                curQuantity = Integer.parseInt(rs.getString("quantity"));
                System.out.println("Quantity is :"+curQuantity);
                if(curQuantity >= curItem.quantity)
                  stmt.executeUpdate("update inventory set quantity ="+(curQuantity-
curItem.quantity));
              }
          }
            }catch (SQLException s){
                System.out.print      ln(s.getMessage());
          }
          return    false;
}
```

d. Compile, pack, deploys the ShoppingCart CMP Bean.

Similar to the Login session bean operations, except the container will generate a list of finder, helper, and other management Java files. The following is the list of the files for the deployment of ShoppingCart CMP in Websphere:

EJSFinderShoppingCartBean.java
EJSJDBCPersisterShoppingCartBean.java
EJSRemoteShoppingCart.java
EJSRemoteShoppingCartHome.java
EJSShoppingCartHomeBean.java
ShoppingCartBeanFinderHelper.java
ShoppingCartKey.java

e. Develop the ShoppingCart EJB client: JSP

```
<%@ page import = "shoppingcartCMP.*"%>
<%@ page contentType = "TEXT/HTML" %>
<html><head><title>Shopping Cart</title></head>
<body bgcolor=cyan>
<form action="http://localhost/tabledetails" method =post name=f1>
<center><img src="shoppingcart.gif"></center><br>
<marquee direction=right><img src="cart.jpg"></marquee><br>
<%String ejbJndiName = "java:comp/env/ejb/ShoppingcartBean";%>
<%Shoppingcart shoppingbean = null;%>
<%javax.naming.InitialContext ctx=null;%>
<%
try{
ctx = new javax.naming.InitialContext();
Object ref = ctx.lookup(ejbJndiName);
if (ref == null) {throw new Exception("ERROR: lookup failed");}
ShoppingcartHome home = (ShoppingcartHome)PortableRemoteObject.narrow(ref,
ShoppingcartHome.class);
shoppingbean = home.create();
Connection con = shoppingbean.getDbConnection();
Statement stmt = con.createStatement();
String query = "SELECT * from tab";
ResultSet rs=stmt.executeQuery(query);
 %>
 <h2><font color=red>Please select from the following Tables : </font></h2>
 <center><select MULTIPLE name="SelectList">
 <%
while(rs.next()) {
  %>
<option value="<%=(String)rs.getString("TName")%>" >
```

FIGURE 1.20 (continued)

© 2005 by CRC Press LLC

```
<%=(String)rs.getString("TName")%></option>
<%
 }
session.setAttribute("con",con);
session.setAttribute("shoppingbean",shoppingbean);
%>
</select></center><center><br>
<input type=submit value=submit>
<%
}catch(Exception e) {
 out.println(e.getMessage());
}
%>
</form></body></html>
```

FIGURE 1.20 (continued)

- Stateful beans must have at least one create method with the argument.
- The client locates the bean through JNDI. It should remove beans when they are done with them.

Programming rules for entity beans:

- Entity beans must implement the javax.ejb.EntityBean interface and have at least one method.
- Entity beans must define a custom primary key class.
- Entity beans must implement all the ejbCreate and ejbPostCreate methods.
- Entity beans must implement their remote interfaces.
- The home interface for a session bean must define the create method.
- The home interface must define the findByPrimaryKey method and can also define other find methods.

Roles in EJB Development

EJB development is a complex process, which usually requires a team of people working together to build, deploy, and maintain the EJBs. Some of the roles for the EJB development are as follows:

- *EJB Developers*: Create the Enterprise JavaBeans (Home interface, bean's remote interface, and bean).
- *Application Assemblers*: Builds applications from EJBs.
- *EJB Deployers*: Uses tools to configure EJB within the runtime environment.
- *Server Providers*: Create and sell EJB servers.
- *Container Providers*: Create and sell EJB containers (an EJB server can have multiple container types).
- *System Administrator*: Oversees the runtime.

1.6 Java Transaction Service

The enterprise computing involves many business transactions, where a transaction is a unit of work that has the ACID characteristics. The ACID stands for Atomic, Consistent, Isolation, and Durable.

- Atomic (all-or-nothing): If the transaction is interrupted by failure, all effects are undone (rolled back).
- Consistent: Effects of transaction preserve invariant properties.
- Isolated: One transaction will not be allowed to see the working state of another's data; transactions appear to execute serially.
- Durable: Effects of a completed transaction are persistent and never lost.

The Java Transaction Service (JTS) implements the Java mapping of OMG Object Transaction Service (OTS). JTS specifies the implementation of transaction manager (TM) that supports the Java Transaction (JTA) specification.

© 2005 by CRC Press LLC

The Java Transaction API (JTA) specifies local Java interfaces between a Transaction Manager and the parties involved in a distributed transaction system. Two-phase commit protocol is used to allow multiple resource to update within a single transaction with ACID properties.

Phase 1:

1. TM: send "prepare" message to all the Resource Managers (RMs)
2. RMs: return "ready" messages back to the TM.

Phase 2:

3. TM (after received the "ready" message from all the RMs): send "commit" message to all the RMs.
4. RMs: return "OK" messages back to the TM.

Example of Java Code using JTA:

```
try {
  trans.begin();
  ... do work ...
  trans.commit();
} catch (Exception exp) {trans.rollback();}
```

Transactions and EJBs

Currently, the EJB supports the flat transaction (not nested transaction, i.e., transaction inside another transaction). EJB specification supports distributed transactions for both session and entity beans. The EJB container implements the transaction demarcation and management. So the burden of managing transaction is shifted to the container and the EJB server provider and the Java developer can declaratively specify transaction semantics without the implementation details. EJB server and container provide low-level services such as two-phase commit, interaction with databases, and transaction propagation.

1.7 J2EE web services

Web services are independent of any particular operating systems, programming languages, or databases. Therefore, it quickly becomes the preferred technology for the web-based development. J2EE supports the following web service standards developed recently.

- XML (Extensible Markup Language) — Distributed Data Specification.
- SOAP (Simple Object Access Protocol) — Distributed Information Exchange in HTTP.
- WSDL (Web Services Description Language) — Web service description.
- UDDI (Universal Description, Discovery and Integration) — Web service Registration.

Data, services, or systems configured in XML are much easier to process on the Internet. Distributed objects accesses using SOAP simplify the message exchanges than the CORBA-styled ORB protocol. Web services described in WSDL can provide a powerful invocation for the web clients, and UDDI provides a simple web services lookup for the web clients.

J2EE web service is a programmable application component. It provides transparent services through the web to the users. A web service defines a business process, not a technology implementation so that it enables a rapid and simple creation and integration of "business services." J2EE supports the web services via XML and standard web protocols.

J2EE Web Service Description

J2EE describes the web services using WSDL that defines an XML grammar for describing web services as collections of message-enabled endpoints or ports. In WSDL, the abstract definition of endpoints and

© 2005 by CRC Press LLC

messages is separated from their concrete deployment or bindings. A binding is a concrete protocol and data format specifications for a particular endpoint type. An endpoint is defined by associating a web address with a binding, and a collection of endpoints defines a service.

J2EE Web Service Implementation

J2EE wraps the server objects using XML-based RPC and exposes them as web services. It complies with the SOAP specification. Once a web service component is implemented, a client can send a message to the component as an XML document and the component can send an XML document back to the client as the response.

J2EE implements web service as a JAX-RPC (Java API for XML-based RPC) service endpoints by wrapping the existing Java classes and applications or as a stateless EJB session bean by wrapping the EJBs. The resulting wrapper is a SOAP-enabled web service that conforms to a WSDL interface based on the original EJB's methods. The J2EE web services architecture is a set of XML-based frameworks, providing infrastructures that allow companies to integrate business-service logic that was previously exposed as proprietary interfaces.

J2EE supports web services via the Java API for XML Parsing (JAXP). This API allows developers to perform any web service operation by manually parsing XML documents. JAXP is for processing XML data using applications written in the Java programming language. It leverages the parser standards SAX (Simple API for XML Parsing) and DOM (Document Object Model) so that one can choose to parse one's data as a stream of events or to build an object representation of it. JAXP also supports the XML Stylesheet Language Transformations (XSLT) standard, giving control over the presentation of the data and enabling one to convert the data in to other XML documents or to other formats, such as HTML. Current J2EE SDK included a Java web services Developer's Pack (JWSDP) for the web service development.

J2EE Web Service Publishing, Discovery, and Binding

J2EE uses the registries to publish, discover, and bind web services. Registries contain the data structures and taxonomies used to describe web services and web service providers. A registry can either be hosted by private organizations or by neutral third parties. Java API for XML Registries (JAXR) is used for interoperating with multiple-registry types. JAXR allows its clients to access the web services provided by a web services implementer, exposing web services built upon an implementation of the JAXR specification.

J2EE Web Service Invocation and Execution

J2EE uses the Java API for XML-based RPC (JAX-RPC) to send SOAP method calls to remote parties and receive the results. JAX-RPC enables Java developers to build Web Services incorporating XML-based RPC functionality according to the SOAP 1.1 specification. The SOAP is a simple, lightweight XML-based protocol that defines a messaging framework for exchanging structured data and type information across the web. Web service recipients operate as SOAP listeners and can notify interested parties (other Web Services, applications, etc.) when a Web Service request is received. The SOAP listener validates a SOAP message against the corresponding XML schemas as defined in a WSDL file. The SOAP listener then unmarshals the SOAP message. Within the SOAP listener, message dispatchers can invoke the corresponding Web Service code implementation. Finally, business logic is invoked to get the reply. The result of the business logic is transformed into a SOAP response and returned to the Web Service caller.

1.8 Conclusion

This article briefly introduced enterprise computing using J2EE technology. Figure 1.21 summarizes the J2EE applications in web-based computing.

J2EE supports both "thin" clients that only need a browser to run and "fat" clients that may need a set of Java packages to execute the applications including the Web services. J2EE Web container supports JSP

© 2005 by CRC Press LLC

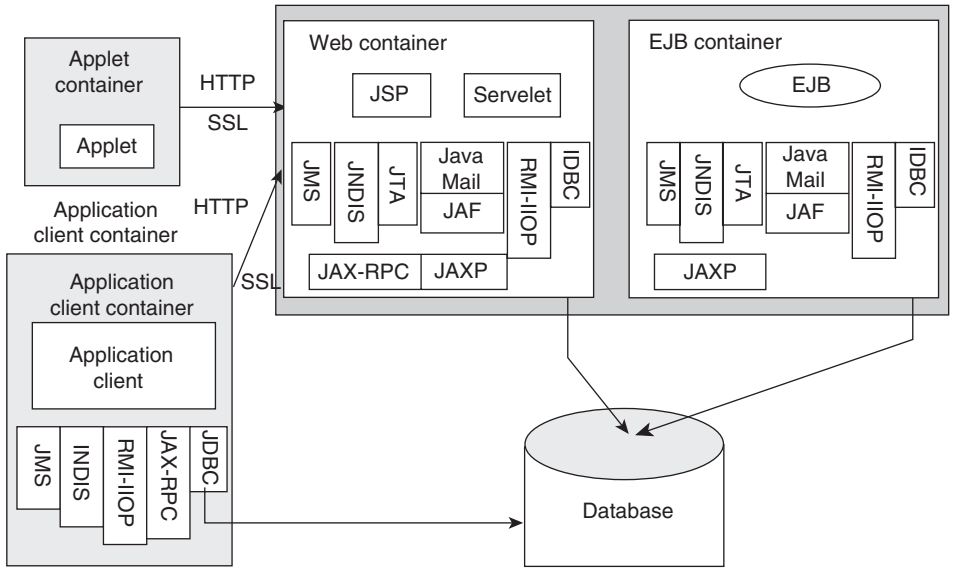

FIGURE 1.21 Web-based enterprise computing using J2EE.

and servlet. Both JSP and servlet can be used to process the business logic and generate the dynamic HTML contents. A common practice is to use the JSPs for the client interactions (similar to the ASPs in Windows .Net) and servlets for the server working objects execution (similar to the VisualBasic, VisualC++, or C# objects in Windows .Net). The EJB container hosts the EJBs for the server components computing. An enterprise Java web server and application server can host many EJB containers, one for each application. J2EE supports a large set of APIs for variety of services. Some of them, such as JMS (Java Message Service), JavaMail, and JAF (JavaBeans Activation Framework), are not discussed in this article.

J2EE is a major web-based enterprise level computing technology. It relies on the Java technologies developed, and adapted many advantages of the distributed object computing component models such as CORBA. J2EE has been chosen as the enterprise computing technology by a wide range of companies and organizations because of its multi-platform capability. (Microsoft .Net works mostly on the Window platforms.) Particularly, J2EE has a dominant influence on the UNIX and LINUX platforms, which are the major enterprise server platforms of today's enterprise computing.

2.8 The C# Programming Language

Martin v. Löwis and
Peter Tröger
University of Potsdam

Microsoft has published the .NET framework in 2000 as an integral component of their Windows family of operating systems. It is an execution environment for application code that makes many aspects of the underlying hardware and operating system transparent. In particular, it allows application developers to abstract from the programming language, from the deployment procedures used to get the application to the user, and, to a certain degree, from the operating system, computer hardware, and network infrastructure on which the user runs the application.

Microsoft has accompanied the .NET framework with a number of software tools that support the analysis, design, programming, testing, and deployment of applications of the .NET framework. The Microsoft Visual Studio .NET line of products integrates many of the development activities for a .NET application — in addition to supporting the traditional way of developing software for the Windows operating system (which is now called "native" code).

While .NET is designed to be language independent (using mechanisms that will be presented later), Microsoft has introduced the new programming language C#, which gives full access in a convenient syntax to all aspects of the framework. Consequently, we will use C# throughout this chapter, and only mention other languages supported by .NET in order to demonstrate the language independence.

2.1 Characteristics of the .NET Framework

The .NET framework consists of two major components: the *common language runtime* (CLR) and the *.NET class library*. The CLR is the core of the framework; it includes the execution engine proper for .NET applications. The CLR provides a "virtual" environment for execution, meaning that the application code has no way of directly interacting with the computer hardware. Instead, all application operations are controlled through the CLR. This approach of a virtual machine is shared with a number of other systems, such as the Smalltalk or Java virtual machines. It allows safe and secure execution of code: the

© 2005 by CRC Press LLC

virtual machine can detect certain error conditions in the application code, and report the detected errors in a reliable manner (safety). It can also detect attempts of malicious code to gain access to a system that has not been granted to that code, and reject such attempts (security).

Unlike many earlier implementations of virtual machines, the .NET framework is not bound to a single programming language. Instead, an explicit design goal was support for multiple languages. This goal has been achieved through three mechanisms: a *common intermediate language* (CIL, the byte code of the .NET framework), a *common type system* (CTS), and a mechanism to invoke arbitrary "native" code of the underlying platform.

The *common intermediate language* as approach is, in principle, shared with many other virtual machines: all languages implemented in virtual machines translate the high-level constructs of the programming language into lower-level primitive operations, and it turns out that the primitive operations are mostly independent from the programming language. Still, the precise choice of primitive instructions (byte codes) constrains the expressiveness of the virtual machine and the features of programming languages that can be implemented on that machine. Even though all application logic is expressed in terms of byte code instructions, execution is still efficient when run on the Microsoft implementation of the .NET framework. In the Microsoft implementation (and, indeed, most alternative implementations), this is realized by compiling CIL code into machine code just before it is executed (*just-in-time compilation*) (see Figure 2.1).

In addition to the common intermediate language, .NET introduces the notion of a *common type system*. Just like the instruction set defines the building blocks for algorithms, the common type system defines the building blocks for the data structures. The notion of a type system shared across multiple languages is unique in the .NET framework; most virtual machines only target a single language in their type system — even though they could possibly execute different languages with the instruction set. The common type system of .NET covers both built-in types (integers, floating point numbers, pointers etc.), as well as structured types (classes, interfaces). It supports both *value types* and *reference types*. Values of value type get copied in parameter passing and assignment, do not have an identity independent from their state, and they are stored on the stack. Values of reference types do have an identity, assignment or parameter passing only transfers a reference, and they are stored in the heap. Conversion between value types and reference types is supported by means of operations called *boxing* and *unboxing* that are performed implicitly by the runtime when needed, for example, when assigning a value-type variable (such as integer) to a reference-type variable (such as object). Values are stored in typed *locations*. This allows type-safe execution of all CIL code.

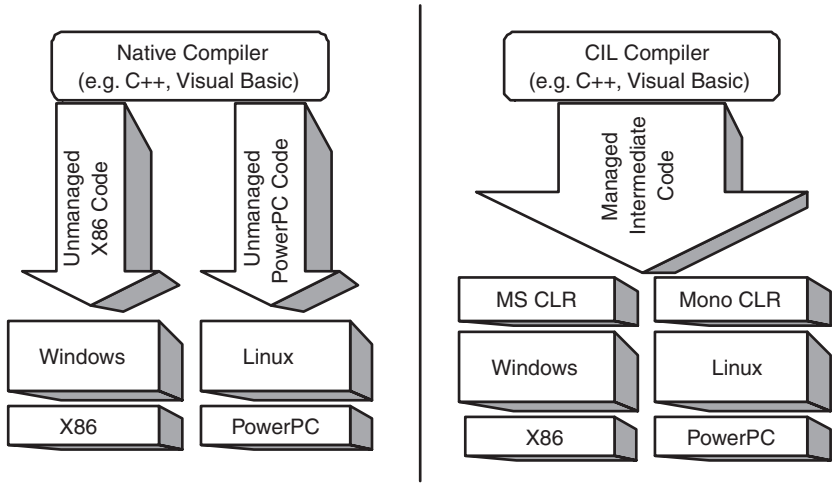

FIGURE 2.1 Managed code concept.

© 2005 by CRC Press LLC

With the CIL, and the common-type system, most features of the widely used programming languages can be represented adequately. However, some language constructs just cannot be expressed using these abstractions. A compiler tool targeting .NET then has the choice of either dropping the feature of the language, or of reverting to native (machine) code. The .NET framework provides explicit hooks to incorporate native code into the runtime system; if these mechanisms are used, the resulting application will lose some of its transparencies (e.g., independence from the microprocessor architecture). An application code that is completely under the control of the runtime system is called *managed code*; a code that runs natively on the processor is called *unmanaged*.

The type system is object-oriented, meaning that references always refer to objects that are instances of classes. Classes support inheritance, polymorphism, and late binding; a class can implement multiple interfaces. Multiple inheritance of classes is not supported in the CTS; languages that support that feature (such as C++) cannot use it in conjunction with managed types. In the case of C++, this leads to the definition of a "managed C++" syntax with several new keywords (e.g., to mark CTS-compliant classes) and slightly changed language semantic. The Microsoft C++ compiler supports a mixture of managed and unmanaged code in a project, mainly to simplify the migration of the existing C++ code to the .NET environment.

The class hierarchy of the type system is single-rooted in the class *System.Object*. All values provide runtime information about their type, including information about the inheritance, implemented interfaces, public and private fields, and public and private methods. This feature is commonly known as *reflection*, and it allows application to dynamically discover and use properties of objects. To implement reflection, .NET stores meta-data about the classes of an application along with the application.

Furthermore, access to fields and operations is not restricted to the current operating system process, or even to the local computer: .NET provides transparent access to objects located remotely — subject to certain semantic and administrative constraints. This functionality is offered in the *System.Remoting* classes of the framework [Rammer02].

As .NET is designed to support multiple programming languages, interoperability across programming languages becomes an issue. Along with the .NET specifications, Microsoft developed the CLS, which describes constraints to which programming languages adhere in order to interoperate with other languages. A CLS-compliant class can be used across programming language, which, for example, allows developers to inherit a class in one language from a base class written in another language. Programming language tools use the meta-data stored in assemblies to discover the available classes, and reverse-map them into the programming language constructs.

Applications of the .NET framework are physically represented in *assemblies*, which are typically files available on a local or remote disk, or downloadable through some network protocol such as HTTP. The assembly contains everything needed to run the application. As a result, deployment of an assembly might not involve anything more than copying the assembly file onto the local computer, without requiring to run a local installation routine to make the software operational. Microsoft has coined the term *xcopy deployment* to describe this approach (named after the Microsoft DOS utility xcopy.exe).

As code is easily downloadable from remote locations, security becomes an important issue: code downloaded over the network might not be trustworthy, and might maliciously attempt to modify or delete data of the computer user, to spy out data and send them to remote locations, or to sabotage the local computer installation. .NET uses a sandboxing approach to execute trusted code, similar to the sandboxing used in Java implementations. However, .NET allows the administrator very fine-grained control over what software does, and it supports the execution of partially trusted code: if a trusted code is invoked from an untrusted code, the trusted code, by default, runs with less privileges than it would normally have. The default settings prevent software downloaded from remote locations to do much harm, and the administrator of a network can easily customize settings networkwide to tighten or loosen control over untrusted code.

Microsoft has submitted major parts of the .NET platform to standardization organizations. In particular, European Computer Manufacturers Association (ECMA) has published the standards ECMA-334 on C#, and ECMA-335 on the CLR. These standards have been forwarded to ISO, and are now also published as ISO/IEC 23270:2003 and ISO/IEC 23271:2003, respectively [ISO03a, ISO03b]. This allows other

© 2005 by CRC Press LLC

software vendors to reimplement .NET, and to port it to other computer systems. While the Microsoft .NET framework product (in its version 1.1) is only available on Win32 systems (Windows 98/NT and successors) on Intel x86 processors, ports to other systems are available. Microsoft Research has published the *Rotor* package for noncommercial purposes, which ports .NET to Apple OS X (using PowerPC processors) and FreeBSD (using x86) [Stutz03]. The *GNU Mono* project allows execution of .NET applications on Linux systems, using various processors: x86, PowerPC, IBM S/390, and Intel StrongARM (although only the x86 port uses just-in-time compilation).

Microsoft has also started supporting the .NET platform on embedded devices, targeting primarily hand-held personal information systems. This product is known as *Compact Framework*. At the time of this writing, PocketPC and Windows CE.NET are supported, on ARM, MIPS, and Hitachi SH3 processors. In Compact Framework, tradeoffs have been made between the .NET feature set on the one hand and the available computing power and memory of embedded devices on the other. As a the result, the Compact Framework supports only a subset of the functions available in the .NET framework.

To support development of .NET applications, Microsoft has updated the Visual Studio product to incorporate compilers, debuggers, and other tools specifically designed for .NET; the result product is named *Visual Studio .NET* (VS.NET). New in this tool suite is a C# compiler, which only supports development of .NET application. The C++ compiler available in earlier products is still available, but it got extended with the *managed C++* mode. Furthermore, the *Visual Basic* language including its compiler was redesigned to support .NET only.

2.2 The CLR

The CLR acts as an execution environment in the .NET framework architecture. It is responsible for managing the assembly execution and all runtime-related services. The CLR provides certain "core" functions to the application, which are made available through byte code instructions and library classes. It performs garbage collection on objects that have been allocated and are not used anymore. It also performs several runtime checks such as boundary checks on array indices in order to prevent applications to run over the array end. In case of errors, the runtime system is capable of raising language-independent exceptions. It also supports user-defined exception handling in a language-independent way, allowing those CLR-compliant exceptions to travel across programming language boundaries. The CLR also provides support for multithreading through a set of synchronization mechanisms and an efficient thread-pooling strategy. The realization of all security infrastructure aspects is another major task of the CLR.

In the typical .NET application, the source code written in some programming language is compiled using a language-specific compiler. This compiler generates CIL byte code. The ECMA definition of CIL includes the object model, the distinction of value and reference types, and means to integrate managed (CIL) code and unmanaged (native) code. The exact runtime-semantics of these means is implementation-defined and can differ between vendor-specific variations of the CLR.

For the execution of a CIL binary, a *runtime host* loads a CLR instance. Different runtime hosts for .NET applications allow the customization of the managed code execution regarding the requested CLR/Framework version, CLR build type (workstation vs. server), garbage collection settings, and other specific properties. In case of the Microsoft .NET implementation, there are runtime hosts for Internet Explorer (MIME filter), ASP.NET (ISAPI filter), Microsoft SQL Server (for stored procedures), and Windows Shell. Most developers will get in touch only with the Windows Shell runtime host since it is activated when starting a .NET application in the regular manner from Windows Explorer.

Microsoft .NET compiles the CIL of a called method once into native code before executing it for the first time. Before doing so, a consistency check is performed on the byte code, to detect erroneous or malicious code that violates the type system. This aspect is called *checked execution* (equivalent to the byte code verification in the Java Virtual Machine).

The Microsoft CLR also provides an integrated support for debugging and profiling, allowing the developer convenient access to the runtime state of the .NET virtual machine. Profiling data can be used to detect "expensive" code, and are thus a mechanism to improve the performance of the resulting application.

2.3 Metadata

As one of its most interesting features, .NET allows declarative metadata information in assemblies. Mandatory metadata, which is included by the compiler automatically, describes the assembly itself (i.e., name, version, cultural information, and security settings) and its defined types. In addition, the metadata stored for a type (class, interface) or a member (method, field, property) are extensible, by means of *attributes*. An attribute is an annotation, which is, at runtime, represented by an object. In particular, several predefined attributes in the framework class library are used to represent security attributes, customization of GUI builders, transactional behavior of objects, COM interworking and integration of native code, and declaration of serialization properties of class members:

Custom implementations of attributes are also possible by deriving from the *System.Attribute* class:

These attributes can be used exactly like the predefined ones:

2.4 Application Development and Execution

To develop .NET applications, various development environments are available at the time of this writing. Microsoft itself offers the Visual Studio .NET product. Borland has the "*C#Builder for the Microsoft® .NET Framework*" product. A number of free software projects are enhancing their own development environments; most noteworthy is the *SharpDevelop* tool by Christoph Wille.

Most of these tools support primarily C#, as this language gives access to .NET features in the most direct way. In addition, several tools have been developed that support other languages, either as integrated environments or as stand-alone compilers. In addition to C#, compilers are available for Visual Basic .NET, C++, J# (a Java look-alike defined by Microsoft), Eiffel, COBOL, Oberon, APL, Fortran, Mondrian, Haskell, Mercury, and others.

Independent from the programming language chosen, the compiler will translate the source code into CIL code, and store this code in a file on disk called a *module*. One or more of these modules form an assembly, which is a deployable representation of the program. One file in the assembly will contain the *manifest*, which is an on-disk representation of the metadata of the application (information about classes, fields, methods, and so on). There are two kinds of assemblies: executable applications (.EXE) and libraries (.DLL).

At runtime, an executable and a set of libraries together form the application. In managed code, the operating system's notion of address spaces does not directly translate to the execution of the code — instead, much more fine-grained protection is applied. The notion of a .NET application domain (*AppDomain*) is introduced as an isolated execution context for a set of assemblies and objects created through these assemblies. Within an AppDomain, objects can directly refer to each other, and methods can be called directly. Multiple AppDomains can coexist in a single address space inside the runtime, allowing efficient execution of multiple AppDomains, for example, within a web server. Access to objects in other AppDomains (whether in the same OS process, on the same machine, or a different one) is only possible through network communication, typically done using remoting. Normally, the runtime host assigns a newly loaded assembly to the default AppDomain.

As assemblies are developed, multiple versions of the same assembly might become available that are not be completely compatible. In the past, concurrent deployment of multiple versions of the same "native" library (.DLL) on Windows has caused significant maintenance problems; these problems are colloquially known as "DLL hell" caused by the fact that the identity of a DLL is based only on its file name. With .NET, concurrent installation of multiple versions of the same library is possible, and applications will only use the libraries for which they were tested originally. This is achieved by means of a *strong name* of an assembly, which not only includes the file name but also the version of the library, the culture (locale) for which it was developed, and a cryptographic hash. The latter not only guarantees that no two libraries have the same name; as the hash is cryptographically signed, it also allows detecting malicious replacement of a library with a Trojan horse. The runtime is responsible for checking version information, and it throws an exception in case of a mismatch.

© 2005 by CRC Press LLC

2.5 Security

To allow users to execute code from remote locations without risking the integrity and privacy of their own data, .NET implements access restrictions for "untrusted" code [Freeman03]. Assemblies in an AppDomain are assigned permissions at the time the assembly is loaded, and these permissions are then used to grant or deny operation calls made by the assembly (*Code Access Security*). The permissions granted are based on the *trust* into a specific assembly; trust is established by *evidence* that proves that the assembly is trustworthy. *Evidence* can be based on the zone an assembly originates from (local computer, local network, internet), on the source Uniform Ressource Identifier (URI) of the assembly, on the digital signature, or on the strong name of the assembly.

Using the evidence established, .NET considers certain administrative *policy* settings to compute the permissions that it grants. The policy settings are hierarchical, with the hierarchy levels being enterprise, machine, user, and application domains. Permissions denied on a higher level of the hierarchy cannot be granted on the lower level; however, the lower levels can further restrict the permissions. This is achieved on load time by checking the permissions from the enterprise level down to the application domain level, intersecting the resulting permission sets. If a permission is granted in all policy levels, the assembly gets the permission. This is useful in the context of large company installations where an administrator can override user-specific security settings through the deployment of appropriate enterprise security policies.

On each level of the policy hierarchy, certain *code groups* are defined; the evidence is then used to determine all groups that an assembly belongs to. Each group is assigned a *permission set*, which defines the permissions being granted. The effective permission set for an assembly in the context of one policy level is the union of all applicable code group permission sets. During security check, the runtime traverses the code group tree with "depth search" (see Figure 2.2). For each group, it checks the membership condition with the assembly evidence information and adds the code group permission set to the assembly if the condition evaluates to true. The traversal continues successively to all the subgroups until the leaf group is reached or the condition is not satisfied.

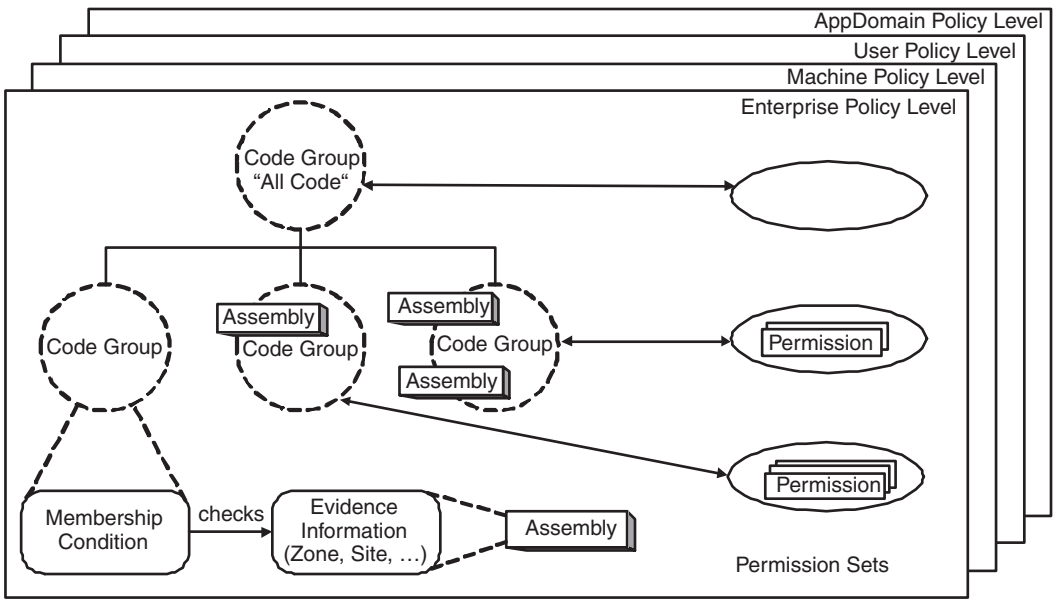

FIGURE 2.2 NET code access security.

© 2005 by CRC Press LLC

The .NET runtime comes with several predefined code groups and named permissions sets (e.g., *FullTrust*, *Execution*, *Nothing*, *Internet*, …); however, every concept in the .NET security model is extensible through an own implementation.

In addition to the administrative management of security policies, .NET also supports programmatic management in the assembly itself, using both a declarative and an imperative style. Using predefined attributes, an assembly, a class, or method can declare that it requires certain permissions; execution will fail if these permissions have not been granted. An assembly can also declare that certain permissions should not be granted to the application, even if the assembly has the appropriate evidence. This allows users to develop a code that cannot be abused, for example, through malicious application input. As a third possibility, the developer can declare requests for optional permissions.

To determine at runtime whether a permission has been granted, a stack walk is made, so that calls from untrusted code to trusted code can only use the permissions of the untrusted code. A certain mechanism allows trusted code to elevate its permissions beyond those of the caller; this mechanism should be initilized with care.

In cases where the declarative syntax is not powerful enough, an imperative approach (using explicit library calls) can be used. This is more tedious to use, but allows to base decisions on data only available at runtime. Additionally, the security mechanism can be applied to a subset of the execution path, like a part of a method.

Permissions based on evidence of the code only cover execution of an untrusted code. Another common scenario for access control includes restrictions based on the identity of the user. The .NET system provides *role-based security*, where access checks are made based on the role in which the current user acts. To use role-based security, .NET first establishes the *identity* and the *principal* of the user, for example by considering authentication data that the user has provided. At runtime, every thread has one assigned principal, which itself has an assigned identity. Based on the established principal, the application can request assignment of roles. In .NET 1.1, this is done only in an imperative way, without support for declarative or administrative management of principals or roles. This feature interoperates with the role-based security of COM+ 1.0.

2.6 Deployment

In the simplest case, .NET applications can be deployed by just copying them into the target directory, and running them from there. There is no need for registration of applications or libraries with the system, unlike COM. If a library is meant to be used by multiple applications, it must be installed by copying them into the *global assembly cache* (GAC). This can be done programmatically, using command line tools, or interactively by drag-and-drop.

Once an assembly is deployed, management of the assembly on the computer becomes available. The administrator can manipulate the security settings of the assembly (by putting it into an appropriate code group), and she can manipulate the *binding* of the application. By default, an assembly requires the precise versions-dependent assemblies to run. If a new version becomes available, old applications will continue to use the old version. If this is not desired, the administrator can redirect (rebind) the application to use the newer version.

VS.NET supports various additional scenarios for the development of deployable applications. A *setup project* allows the creation of a Microsoft Installer (.msi) file, which provides a user interface for customization and feature selection during the installation of an application. In addition, an installer file allows the automatic deployment of an application to a group of computers, using Windows *group policy*.

A *web setup project* allows automatic deployment to a Web server from within VS.NET, using a proprietary communication protocol. Such a project includes registration of the application in the Web server, and provides means for remote configuration and debugging.

A *merge modules project* allows the creation of *merge modules*, which are reusable building blocks for the creation of installer files.

© 2005 by CRC Press LLC

Finally, a *CAB project* allows the creation of cabinet files, which allow automated installation of ActiveX controls in web browsers.

2.7 Framework Class Library

In addition to the bare execution environment, the .NET framework includes a rich library of classes that support various kinds of applications.
In particular, there are class libraries for:

- Organizing data structures (object container libraries).
- Access to operating system features (file and terminal I/O, threading).
- Reflection and management of code properties.
- Networking libraries (TCP and UDP communication, and libraries on top of TCP, such as HTTP).
- Computing in integral and binary and decimal floating-point numbers.
- Generation and parsing of XML (XPath, XSLT, XSD).
- Serialization of object graphs into a stream of bytes.
- Cryptographic services.
- Security (authentication, authorization, and access control).
- Accessing remote objects over the network (*remoting*).
- Development of graphical applications (GUI: Windows Forms, 2D drawing).
- Access to relational databases (ADO.NET).
- Development of Windows services.
- Development of Web services.
- Development of Web applications (ASP.NET, WebForms).

The *base class library* (BCL) of the .NET framework is part of the ECMA specification, and it contains as a subset the primitive types, string processing (based on Unicode), regular expressions, object collections, custom attributes, reflection, and threading.

The windows forms library provides access to the windowing system, with classes representing various input and output controls. In addition, the drawing library provides access to *GDI+* (graphics device interface) for video and printing device-independent programming.
Some of the other libraries mentioned above will be presented in more detail below.

Active Data Objects (ADO.NET)

The ADO.NET library (in the assembly *System.Data*) provides access to various databases through a consistent programming interface. The databases are typically relational databases that are accessed either locally or over a network. ADO.NET does not directly implement the logic to access a database. Instead, it can incorporate various preexisting generic database adapters, such as ODBC or OLE DB. In addition, database vendors can provide database adapters specifically designed for ADO.NET.

The ADO.NET object model defines a set of interfaces that a database provider must implement. The *DataReader* objects, implementing the *IDataReader* interface, offer access to the result of a query to a particular database type. This result can be generated through the usage of appropriate *Connection* and *Command* objects. The access to the result set is read-only (meaning that data cannot be modified) and with a forward-only cursor (meaning that results are retrieved in a sequential order, processing each result record only once).

The recommended way for working with query results in ADO.NET is the *DataSet* approach. DataSet objects are tightly integrated with the Windows Forms and WebForms library, which allows convenient development of database visualization applications through the usage of a *DataGrid* object. A DataSet object is an in-memory representation of tables, relationships, and constraints. It does not necessarily represent a relational database; instead, the on-disk representation could just as well be a text file. The DataSet is an off-line representation, which means that all cursor operations are local to the cache only. Modifications to the DataSet are possible, and will be written back on application request.

© 2005 by CRC Press LLC

The association between the DataSet and the data source is established through a *DataAdapter* object. Microsoft .NET ships with four data adapters: OleDbAdapater, SqlDataAdapter (for MS SQL Server), OdbcDataAdapter, and OracleDataAdapter. The adaptors rely on the functionality of the underlying DataReader, Command, and Connection object implementation for the particular database. The SQL statements required for retrieving and updating data are customizable for a particular adapter in order to implement specific behavior, that is, the usage of stored procedures.

In addition to the disconnected mode of operation with a DataSet, ADO.NET also supports direct access to data sources by means of database connections. Using the underlying connection and command objects directly, concurrent and transactional modifications of a database become possible.

ADO.NET not only operates on relational database; in particular, it provides access to XML files by means of *XMLReader* objects. The dataset of an XML file can be described through an XML Schema, which the xsd.exe tool compiles into an appropriate application code (in C#, Visual Basic, JScript, or Visual J#). Using this code, a DataSet can then read and write XML files.

Active Server Pages (ASP.NET)

ASP.NET is a framework for the development of dynamic web pages, similar to ColdFusion or PHP. It consists of a .NET library (the assembly *System.Web*), and an Internet Server Application Programming Interface(ISAPI) filter for Internet Information Server (IIS). Alternatively, the Mono project offers an ASP.NET implementation that runs on the Apache webserver. The framework supports various typical aspects of a dynamic web application, such as the state management, the integration of static and dynamic parts of a web page, and the processing of HTML forms.

The framework defines an object model for the structuring of web pages named *WebForms*. A web form is a collection of "server-side controls," which are objects that render themselves as an HTML fragment. ASP.NET combines these fragments together with the static HTML fragments to form the dynamic page. Standard controls are provided for the HTML forms elements; these controls support server-side validation of the input (along with the creation of dynamic HTML displaying the error message in case of a validation failure). User-defined controls give reusable chunks of dynamic HTML, allowing integration of the same logic into multiple pages.

Active server pages are stored in .aspx files, which follow a *code-behind* philosophy: the HTML source contains references to the controls; the actual application logic of the control is stored in a separate C# file. Directly integration of source code into the HTML page is also supported.

Session management is fully transparent in ASP.NET; control objects retain their state across multiple accesses to the same control within the same session. The necessary state information is encoded in the HTML pages, and sent back to the web server by the web client.

An ASP.NET application can be easily extended to support mobile devices through the *mobile web forms* library (*System.Web.Mobile*).

Interoperability with the Component Object Model

In the last decade, Microsoft has favored the Component Object Model (COM) and the ActiveX set of technologies as the primary architecture for developing reusable software components. As a result, huge investments in this technology have been made in the industry, making COM the primary means of programming interface on Microsoft Windows systems.

With the appearance of .NET, developers have a strong interest in continuing the use of such components. In particular, certain kinds of application logic (such as the Internet Explorer) are not directly available in .NET, but would be available through COM interfaces. Consequently, Microsoft has put significant effort into making usage of COM in .NET as seamless as possible.

To use a COM object from a .NET application, .NET creates a *Runtime Callable Wrapper* (*RCW*) as a mediator. This wrapper is transparently derived from a COM-type library in VS.NET, or by means of a command line utility. The RCW interfaces between the managed and the unmanaged code; in particular,

© 2005 by CRC Press LLC

it converts the calling conventions, exceptions, and the type system appropriately. The garbage collection in .NET also integrates with the COM memory management: disposal of the RCW causes the COM object to be released. In addition to using the RCW, late binding (through the IDispatch interface) is also possible.

Calling .NET objects through COM interfaces is also possible: .NET transparently generates *COM Callable Wrappers* (*CCW*) as mediators; these primarily offer the *IDispatch* and *IUnknown* interfaces. Assemblies exposing COM interfaces must be signed with a strong name, .NET classes implementing COM classes must have a parameter-less constructor, and classes and methods that are intended to be COM-accessible must have the *COMVisible* attribute. A command line tool takes care of the registration of the assembly as a COM server; the .NET library mscoree.dll then acts as the COM server.

By means of the COM interoperability, WinForms applications can integrate ActiveX controls. Some COM+ features (transactions, object pooling, activation, events) are directly exposed through the assembly *System.EnterpriseServices*; applications must use this library to make use of these features.

Interoperability with the Win32 API

Many of the traditional operating system services (file and terminal I/O, process, thread, and memory management) are available in the .NET base class library. A number of more advanced features of the Win32 API (such as serial ports), or special hardware libraries are not currently accessible through standard .NET API. To give programmers still full access to all platform functions, .NET provides the means to directly bind system functions to .NET functions, by means of the *DLLImport* attribute for function declarations. Code that uses this functionality is, of course, now bound to the Win32 API, and loses its portability.

Web Services

To allow cross-enterprise application integration, the notion of web services and the SOAP protocol has been proposed as an emerging technology. .NET gives easy access to this technology, with support on various levels of the framework [Esposito03]. As the SOAP protocol is based on the exchange of XML documents, the XML processing libraries in .NET (*System.Xml*) provide the foundation for web services support.

In addition to this, two different programming interfaces for Web services are available. On the one hand, the *Remoting* framework (implemented in the assembly *System.Remoting*) provides application developers with the abstraction of remote procedures. While the framework is more general than just web services, a specific configuration allows usage of SOAP as one possible way of communicating remote procedure calls.

In addition, the *Web Services* library (assembly *System.Web.Services*) provides a separate programming interface. It integrates with ASP.NET, and supports the attribution of methods as *WebMethod*. The creation of a web service in VS.NET results in the deployment of an .asmx file on the web server. The ASP.NET runtime framework (in IIS) will then transparently translate SOAP requests into calls to such a method, loading the .asmx page as needed. At the end of the call, the result value or exception is converted back into a SOAP response.

ASP.NET also transparently generates "service help pages," which contain a simple HTML form allowing interactive invocation of the web method; appending "?WSDL" to the service's URL causes dynamic generation of a Web Services Definition Language (WSDL) description of the service. As SOAP is an extensible protocol, the web services library provides the application with means to detect and process additional SOAP headers and extensions.

To consume a Web service, VS.NET supports importing WSDL files, either through a wizard or using a command line utility. The WSDL specification is converted into C# proxy code, which means that the service can be used like a local object. VS.NET can maintain a reference to the WSDL URL in the project, to allow updates of the proxy code if the WSDL specification changes.

© 2005 by CRC Press LLC

2.8 The C# Programming Language

The C# language is in its syntax very similar to Java and C++ [Archer02]. Semantically, it is a "wrapper" around the CLR: it provides syntax for all features of the CLR, and declarations and actions directly map into the corresponding CLR features. Most concepts of C# are similar to Java approaches; however, a number of minor differences become apparent when Java users are first confronted with this language:

- Methods are not automatically *virtual*. Instead, methods that are intended to be overridden must be declared as virtual. Methods that override base class methods must be declared using the *override* keyword. If overriding is not desired, the *new* keyword indicates that the method has no relationship with the base class method of the same name and signature. The *final* keyword indicates that the virtual function cannot be overridden anymore. Applied to a class, it indicates that inheriting from the class is not allowed. On a data member, it indicates that the member is read-only in subclasses.
- Different parameter passing modes are supported, indicated by keywords: *in* indicates call-by-value (this is the default), ref indicates call-by-reference, and *out* indicates call-by-reference without the need to initialize the parameter on input.
- The *internal* keyword declares a class or method to be available only within an assembly; this is similar to the package-private visibility of Java.
- In a *catch* clause, the list of exceptions can be omitted, meaning that all exceptions are caught by the clause.
- Nested classes in C# are always static; inner classes as available in Java are not supported.
- The file names have no significance on the naming of classes and namespaces (unlike Java, where the file name and the class name must match).

A number of features are new in C#, compared to Java:

- C# offers the notion of *properties*, which are used syntactically like class members (i.e., using the syntax "object.property"). Unlike plain members, a property access (read or write) causes the invocation of a property access method.
- C# classes can act like indexable arrays, similar to overloading the operator[] in C++. The index operation method works with an accessor definition similar to properties:
- The *foreach* keyword allows iteration over an indexable collection.
- *Delegates* are a mechanism to support functions/methods as objects. They are similar to function pointers in C, except that they are type-safe, and in that they support *bound methods* (i.e., method pointers incorporating the target instance object). A delegate is declared through the keyword *delegate*:

This declares a delegate taking no arguments, returning no value. Values of the delegate can be created by passing a function or method:

The resulting delegate value can now be called as if it was a function:

- C# supports native, type-safe enumerations.
- C# supports unsigned integer types.
- C# supports structures, which are class-like value types. Structures can have constructors, methods, indexers, properties, operators, can contain nested types, and can implement interfaces. Structures are useful for implementing user-defined values. Unlike classes, they do not support inheritance, and structure constructors must have arguments.
- C# supports multi-dimensional arrays (not just arrays of arrays, like Java).
- Special syntax (using brackets) is provided to declare CLR attributes. These attributes can have parameters and can only be applied to the set of C# language constructs (i.e., methods, members, classes, ...), which are specified by the attribute implementation. By convention, all attributes end with the "Attribute" name; however, C# does not require this suffix:

Normally, it should be relatively easy for an experienced Java programmer to apply his knowledge to the C# programming language. Microsoft pushes C# as the primary implementation language for the

© 2005 by CRC Press LLC

framework and included the language specification in the ECMA standard; therefore, C# will maintain the role as most suitable .NET programming language in the future development of the .NET framework.

3.1 Introduction

The Unified Modeling Language (UML) is the new industry standard for modeling software-intensive systems. Modeling, which is as old as engineering, is the designing of software applications before coding. It is an essential part of large software projects, and helpful for medium and even small projects as well (OMG 2003).

UML was conceived as a general-purpose language for modeling object-oriented software applications. The language represents a further abstraction step away from the one provided by high-level programming languages, which are close to the underlying implementation technology. The easiest answer to the question "what is UML?" is, according to Quatrani (2001), the following: "*UML is the standard language for specifying, visualizing, constructing, and documenting all the artifacts of a software system.*" The above terms are explained in Holt (2001) as follows:

> To *specify* means to refer to or state specific needs, requirements or instructions concerned with a complex system. To *visualize* means to realize in a visual fashion or, in other words, to represent

© 2005 by CRC Press LLC

information using diagrams. To *construct* means to create a system based on specified components of that system. To *document* means to record the knowledge and experience of the software in order to show how the software was conceived, designed, developed verified and validated.

UML is methodology-independent, which means that UML can be used as a notation to represent the deliverables defined by the methodology regardless of the type of methodology used to perform the system's development, that is, whether it is rigorous such as the Unified Process (Jacobson et al. 1999a) or lightweight such as Extreme Programming (Paulk 2001). In any case, the methodology will guide the engineer in deciding what artifacts to produce, what activities and what workers to use to create and manage them, and how to use those artifacts to measure and control the project as a whole (Booch et al. 1999).

The 12 diagram types that can be used to model every aspect of the system make UML extremely expressive, allowing multiple aspects of a system to be modeled at the same time. However, this expressiveness comes at a price. UML is extremely large with many notational possibilities (LeBlanc 2000). In this chapter, a subset of the UML that represents the core of the language is presented. This subset will allow the reader to understand the basic concepts of the language and communicate through UML diagrams, the knowledge of the system that is under development. The evolution of the language and its use in different application domains, especially in the real-time domain and in the control and automation domain, are also considered. A reference is also made to UML CASE tools that support the engineer to analyze the application's requirements and design a solution to meet requirements. Throughout the article, an elevator control system that is used to control an elevator with many cabins is used as a running example.

The remainder of this chapter is organized as follows. The next section provides a brief overview of the evolution of the UML. In Section 3.3, an introduction to the basic object-oriented concepts is given. Then, in Section 3.4, the most important UML diagrams are presented with examples that highlight their basic constructs. The mechanisms for extending UML in different application domains are discussed in Section 3.5. In Section 3.6, the Real-Time UML profile is considered and a brief description of the basic constructs of this profile is given. The current use of UML in control and automation is considered in Section 3.7. In Section 3.8, the problem of selecting a case tool is discussed and a reference to commercially available tools is made. Finally, conclusions are given.

3.2 History of UML

In the last few years, a large number of methods have been proposed, to support the creation of models for software systems. Until 1989, the proposed methods followed the structured approach with the structured analysis and structured design (SA/SD), created by Yourdon and Constantine in 1987, to be considered the most widely used method. An updated version of this method, called Modern Structured Analysis, was published in 1989 by Yourdon. However, this method did not attain wide acceptance since (a) the complexity of today's systems is almost impossible to be handled by the traditional procedural-like approaches and (b) many new proposals following the more promising object-oriented (OO) approach appeared at the same time. The great advantage of the OO paradigm, which has been gradually accepted during the last decade, is the conceptual continuity across all phases of the software development process (Capretz 2003). In the 1990s, at least 20 OO methods have been proposed in books and many more have been proposed in conference and journal papers. A survey and a classification scheme for OO methodologies can be found in Capretz (2003). In the same article, the author states that

> after more than thirty years since the first OO programming language was introduced, the debate over the claimed benefits of the OO paradigm still goes on. But there is no doubt that most new software systems will be OO; that no-body disputes.

Wieringa (1998) surveyed state-of-the-art structured and OO development methods. He identifies the underlying composition of structured and OO software specifications and investigates in which respect OO specifications differ essentially from structured ones. The last specification method in his catalog of OO methods is the UML version 1.0.

© 2005 by CRC Press LLC

The UML started out as a collaboration among three outstanding methodologists: Grady Booch, Ivar Jacobson, and James Rumbaugh. As a first step, Booch and Rumbaugh collaborated to combine the best features of their individual OO analysis and design methods (Booch 1994; Rumbaugh et al. 1991) and presented at OOPSLA in 1995 the Unified Method version 0.8. At that time, the Unified Method was both a language and a process. Later, Jacobson joined the group and contributed the best features of the OOSE methodology (Jacobson 1992). The result of this collaboration was the separation of the language from the process, which was later described in Jacobson et al. (1999b). The language was defined and was presented in 1996 as UML 0.9. Later in January 1997, they submitted their initial proposal as UML 1.0. Since then, the standardization odyssey of UML has been in evolution.

Kobryn (1999) placed the end of this odyssey to 2001, but UML 2.0 is still under discussion. Crawford (2002) notes that "proposals of the UML2 are now under consideration, and what's clear is the future is unclear." As Miller (2002) argues, UML1 unified several of the competing schools of modeling; however, some equally important ideas for good OO design did not influence the language. Furthermore, several problems have been cited (e.g., Kobryn 1999; Dori 2002; Kobryn 2002) and are awaiting a solution in UML2. A spirited debate on the future of UML is in evolution. Five groups submitted proposals in response to the OMG RFPs, but hopefully there is a desire for a consensus version (Miller 2002). They all agree that UML2 should be in the context of OMG's Model-Driven Architecture (MDA) initiative (Miller and Mukerji 2001), which considers as primary artifacts of software development not programs, but models created by modeling languages. UML artifacts should be used to create the platform-independent model (PIM), which should then be mapped by a model compiler into a platform-specific model (PSM) as Mellor (2002) states.

The large number of practitioners and researchers who have adopted UML at a rate exceeding even OMG's most optimistic predictions is a strong argument for UML2 to follow an evolutionary rather than revolutionary approach. However, as Selic et al. (2002) state, "the same forces have also created a strong pressure to improve the effectiveness of UML and provide it with a multitude of new features." The one thing that is accepted by all parties is that the language's popularity has confirmed the urgency for a standard communication medium for humans and software tools. It is already widely accepted that UML2 will drive the software development industry for the next decades.

3.3 Basic OO Concepts

Page-Jones and Weiss (1989) state that, "the OO approach is a refinement of some of the best software engineering ideas of the past. " Capretz (2003) claims that the background of the OO paradigm stems from many different research fields. The most important of them are: system simulation with classes and objects, operating systems with monitors, data abstraction with types and encapsulation, and artificial intelligence with frames. Pressman and Ince (2000) in their introduction to OO concepts state:

> We live in a world of objects. These objects exist in nature, in manmade entities, in business, and in the products that we use. They can be categorized, described, organized, combined, manipulated and created. Therefore, it is no surprise that an object-oriented view would be proposed for the creation of computer software- an abstraction that enables us to model the world in ways that help us to better understand and navigate it.

Therefore, the *object* is the basic concept of the new approach instead of the *process,* which was the basic concept in early structured methodologies. An object, as defined by Booch (1994), "represents an individual, identifiable item, unit, or entity, either real or abstract, with a well-defined role in the problem domain." The object is the atomic unit of encapsulation and is used for the decomposition of the system. An object has:

- state,
- behavior, and
- identity.

© 2005 by CRC Press LLC

The structure and behavior of similar objects are defined in their common *class* (Booch 1994). An object contains attributes that represent the object's state, and operations, called methods, which define the behavior of the object. Methods specify the response of objects to received messages. They accept parameters and have access to object's attributes; they usually result in a state change. Each object is composed of two parts: the interface and the implementation. The implementation is the inner workings of the object and is hidden from the outside (information hiding). The interface is visible to other objects that use it to get the services provided by the object.

A system is considered as an aggregation of discrete objects that collaborate in order to perform work that ultimately benefits an outside user. The collaboration between objects that compose the system is obtained through the exchange of messages. *Message passing* is a means of communication among objects within an application.

3.4 UML Diagrams

As was already noted, UML is a language for visualizing, specifying, constructing, and documenting the artifacts of a software-intensive system. A language provides a vocabulary and the rules for combining words in that vocabulary for the purpose of communication. The vocabulary and rules of the UML focus on the conceptual and physical representation of a system. They define how to create and read system models; but they do not define what model should be created and when they should be created. This is why a methodology should be used throughout the development process. Erikson and Penker (1998) discriminated the following three kinds of rules: syntactic, semantic, and pragmatic rules. According to them, (a) the syntax defines how the symbols should look and how they are combined, (b) the semantic rules define what each symbol means and how it should be interpreted by itself and in the context of other symbols, and (c) the pragmatic rules define the intentions of the symbols through which the purpose of the model is achieved and becomes understandable for others.

In UML, a system is represented using multiple models. Each model describes the system from a distinctly different perspective. The following three kinds of views are defined at the top level (Rumbaugh et al. 1999):

Structural classification. Views of this category consider the things of the system and their relationships with each other. The following UML classifiers represent things: class, use case, component, and node. The static view is expressed through class diagrams, while the use case view is expressed through use case diagrams and the implementation view is expressed through component and deployment diagrams that constitute the classification views of this category.

Dynamic behavior. Views of this category describe the different aspects of the application's dynamic behavior, that is, its behavior over time. Views of this category include: (a) the state machine view, which is expressed through statechart diagrams, (b) the activity view, expressed through activity diagrams, and (c) the interaction view, expressed through sequence and collaboration diagrams.

Model management. Views of this category describe the organization of the system models into hierarchical units. The model management view crosses the other views and organizes the application's models during development and configuration control. The generic unit for models is the package. The class diagram is used to express the organization of the system models into hierarchical units.

The remainder of this section presents the basics of the most important diagrams of the above categories.

Use Case Diagram

The use case diagram was introduced by Jacobson (1992) as the basic artifact for requirements modeling. The diagram, which models the functionality of the system as perceived by outside users, usually contains a set of use cases, actors, and their relationships. The construct of actor is used to model what exists

© 2005 by CRC Press LLC

outside of the system and the construct of use case to model what should be performed by the system. Figure 3.1 shows the notational elements of the above constructs of the use case diagram. An *actor* characterizes and abstracts an outside user or related set of users that interact with the system. Actors are the only external entities that interact with the system. A *use case* defines a specific way of using the system. It specifies the interaction that takes place between one or more actors and the system. Each use case constitutes a complete course of events initiated by an actor. It defines the behavior of some aspect of the system without revealing its internal structure. However, later, during subsequent analysis modeling, the objects that participate in each use case are determined (Thramboulidis 2003). A *relationship* represents an association between use cases. *Dependency*, *generalization,* and *association* are the most commonly used relationships.

Figure 3.2 shows part of the elevator control system use case diagram where the "ElevatorCabin at floor, " the "Select destination," and the "Request cabin" use cases are shown. Figure 3.3 provides a draft description of the "ElevatorCabin at floor" use case.

Use case diagrams were adopted by the majority of OO methodologies as a means for capturing and documenting requirements. Lee and Xue (1999) note this when they state:

> Use case approaches are increasingly attracting attention in requirements engineering because the user-centered concept is valuable in eliciting, analyzing and documenting requirements. One of the main goals of requirements engineering process is to get agreement on the views of the involved users, and use cases are a good way to elicit requirements from a user's point of view. An important advantage of use case driven analysis is that it helps manage complexity, since it focuses on one specific usage aspect at a time.

Use case models play a key role in the development process. They are used as input to several activities in the software development process. Jacobson, et al. (1999a) note this by capturing the dependencies between the use case model and the other models in the context of the Unified Process. Figure 3.4,

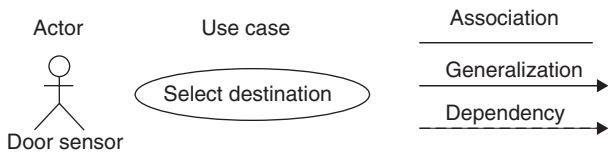

FIGURE 3.1 Basic constructs of use case diagrams.

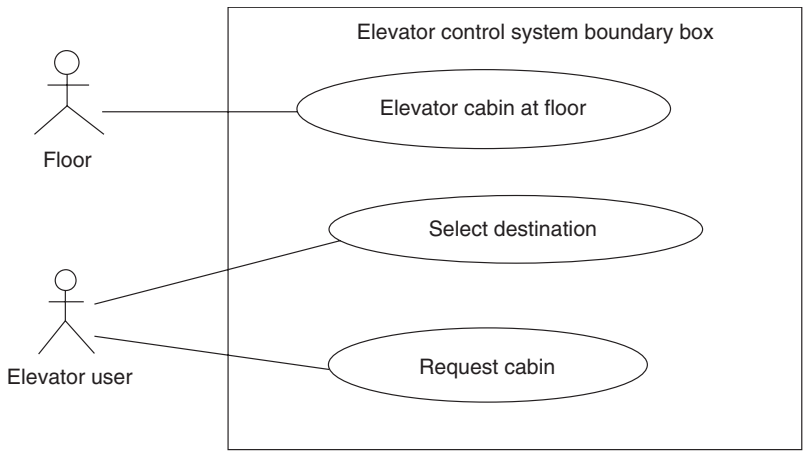

FIGURE 3.2 Example use case diagram of the elevator control system.

© 2005 by CRC Press LLC

Use case: Elevatorcabin at floor
Actor: Floor
Description: The use case starts when the floor notifies the system through a sensor that a cabin has arrived at its floor. The system checks if the specific cabin has to stop at this floor or there is a pending request from the external button of this floor. If the cabin has to stop, the system stops the cabin and the use case in terminated. If there is a pending request from the specific floor external button, the system checks if the cabin can serve the request. If the cabin can serve the request, the system has to stop the cabin and the use case is terminated. Otherwise the request is postponed to be served later by other cabin and the use case is terminated.
Exceptional flow of events: -

FIGURE 3.3 Description of the "ElevatorCabin at floor" use case.

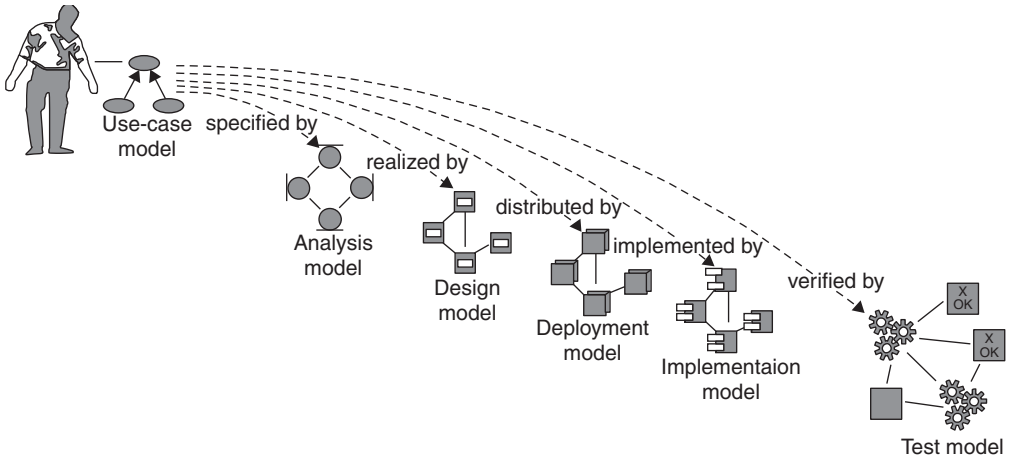

FIGURE 3.4 Use case model dependencies with the other models of the development process (Jacobson et al. 1999a).

taken from Jacobson et al. (1999a), highlights the core role of use case models in the development process.

It is widely accepted that the quality of the use case model has an important impact on the quality of the resulting software product. Software inspection, one of the most efficient methods for verifying software, may be used to ensure the quality of the use case model. Anda and Sjoberg (2002) present a taxonomy of typical defects in use case models and propose a check-list-based inspection technique for detecting such defects.

Although use cases were first introduced as a means to capture functional requirements, there is a trend to expand the whole concept to cover nonfunctional requirements as well. Alexander (2003) presents a way for using use and misuse cases to elicit security requirements. A misuse case is a use case from the point of view of an actor hostile to the system under development. Misuse cases have many interesting applications and interact with use cases in interesting and helpful ways. A use/misuse analysis can complement existing analysis, design, and verification practices.

Class Diagram

The class diagram can be considered as an evolution of the Entity Relationship Diagram (ERD), the main diagram used for many years in information modeling. The large difference between the two diagrams is that the class, which is the basic construct of the class diagram, has, in addition to the structure of the entity, behavior that is described by a set of operations. A class diagram is composed of classes and their relationships.

© 2005 by CRC Press LLC

Berard (1993) defines the class in the following way:

> A class is often defined as a template, description, pattern or blueprint for a category of very similar items. Classes are used as templates or "factories" for the creation of specific items that meet the criteria defined in the class.

An implementation-influenced definition is given by Rumbaugh et al. (1991):

> A class describes a group of objects with similar properties (attributes), common behavior (operations), common relationships to other objects, and common semantics.

A class is represented in UML by a rectangle that is divided into three compartments as shown in Figure 3.5, which represents the `ElevatorCabin` class. The part in the top contains the name of the class (`ElevatorCabin`), the second part contains the attributes, and the last part contains the operations. `MaxPersons`, `maxLoad`, `load`, and `cabinSize` are the only attributes of the `ElevatorCabin` in this representation. `MoveUp`, `moveDown`, `stop`, `accelerate`, `decelerate`, and `getLoad` are the operations that define the behavior of any instance of this class. The `accelerate` operation instructs the ElevatorCabin instance to increase its speed to the maximum `velocity`. The value of the *`ec1.getLoad()`* expression is the current load of the specific ElevatorCabin `ec1`.

The main relationships among classes are: associations, composition and aggregation relationships, generalization/specialization relationships, and the various kinds of dependency such as realization and usage.

An association defines a relationship between two or more classes, denoting a static, structural relationship between them. The association `Controls` in Figure 3.6 defines a relationship between `ElevatorControler` and `ElevatorCabin`. An association is inherently bidirectional. Multiplicity must be specified for both sides of the association to define the number of instances of one class that may relate to a single instance of the other class. For the `Controls` association, for example, the multiplicity is "*one*" for the `ElevatorControler` end and "*many*" for the `ElevatorCabin` end. This means that an `ElevatorControler` may control one or more ElevatorCabins; but an `ElevatorCabin` has to be controlled by only one `ElevatorControler`.

Composition and aggregation are used to represent the relationships between the parts and the whole. Composition is stronger than aggregation, which is stronger than association. The composition represents a physical relationship between the whole and its parts. Aggregation is likely to be used to model

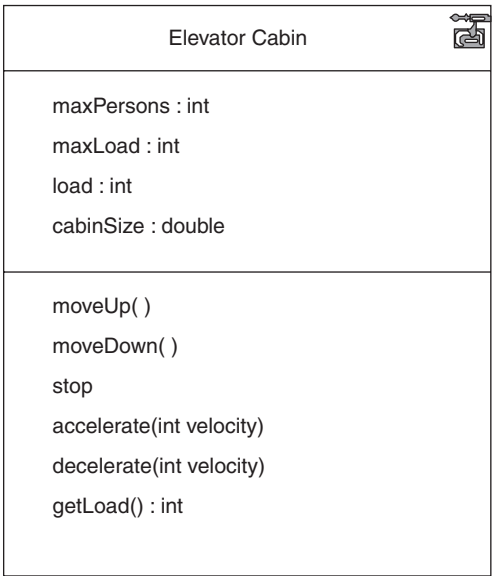

FIGURE 3.5 The `ElevatorCabin` class .

© 2005 by CRC Press LLC

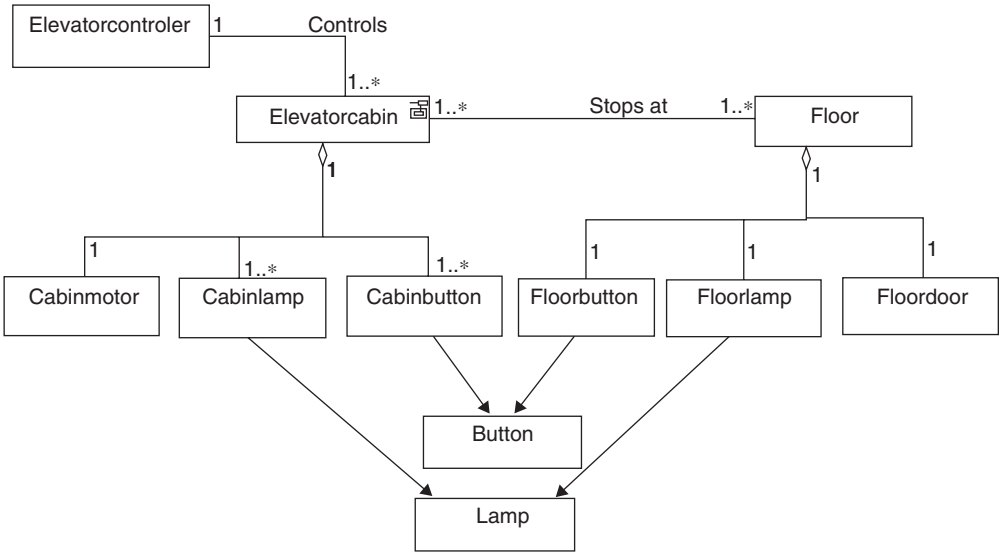

FIGURE 3.6 Class diagram of the elevator control system (part).

conceptual classes rather than physical classes. A part may belong to more than one aggregation. An example of composition relationship is the one connecting the `ElevatorCabin` in Figure 3.6 with its physical components `CabinMotor`, `CabinLamp`, and `CabinButton`.

The generalization/specialization (gen/spec) relationship is used to represent the special kind of association between two classes in which one class represents a general concept and the other a specialization of this general concept. The class `Button` in Figure 3.6, which is referred to as a *superclass* or *ancestor* class, represents the abstract concept Button. It is used to abstract the common structure and behavior of both cabin buttons and floor buttons. The class `CabinButton`, which is referred to as a *subclass or descendent* class, represents the specific type of button used in the ElevatorCabin. Each subclass inherits the properties of the superclass but then extends these properties in different ways. Some authors call this relationship inheritance; but inheritance is the mechanism of the implementation environment used to implement the gen/spec relationship.

Statechart Diagram

Statecharts were defined by Harel (1987) as a notation that extends the finite-state machines. Statecharts overcoming the limitations of traditional FSMs while retaining the benefits of finite state modeling became popular for modeling system behavior in the traditional structured analysis paradigm. Coleman et al. (1992) extended statecharts with three basic extensions, that is, hierarchy, concurrency, and broadcast communication, to produce modular, hierarchical, and structured descriptions in the context of the OO design. Harel and Gery (1997) claim that statecharts form the core of the emerging UML to produce a fully executable language set for modeling OO systems. Modern CASE tools exploit statecharts (a) to allow the developer to produce fully executable models and (b) to obtain automatic code generation.

The statechart diagram describes the behavior of the system. To avoid the "state explosion" problem, a statechart in UML specifies all behavioral aspects of the instances of a class. A statechart contains states connected by transitions. States are represented by boxes with rounded corners, while transitions are indicated by arrowed lines. Transitions are fired by events; they may cause the execution of actions attached to the transition and they usually take the object to a new state. Figure 3.7 shows the statechart of the `ElevatorCabin` class of the elevator control system. When the Elevator is initialized, each `ElevatorCabin` instance is in the `idle` state, which is called the initial state. When an `ElevatorCabin` instance accepts the `MoveUp` message from the `ElevatorControler`, a

© 2005 by CRC Press LLC

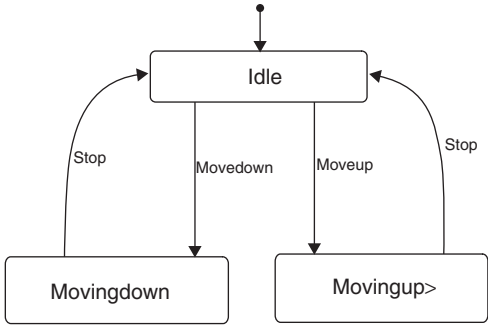

FIGURE 3.7 The ElevatorCabin statechart diagram.

transition is fired and the `ElevatorCabin` instance changes its state to `movingUp`. A `stop` message fires the transition from the `movingUp` state to the `idle` state.

A state may have entry and exit actions, that is, actions that are executed on entering and exiting the state, respectively, as well as internal transitions, that is, transitions that are handled without changing the state. A state may have substates. This feature supports the construction of statecharts of different levels of abstraction and allows concurrency to be handled by using substates (Coleman et al. 1992).

A transition is usually more complex than the one presented in Figure 3.7. A transition has: (a) a source and a target state, (b) a guard condition (optional), (c) an event trigger that fires the transition if the guard condition is true, and (d) optionally an action, which is an executable atomic computation that may act on the same or other objects.

Sequence Diagram

Class diagrams model the static perspective of an OO system. During the execution of such a system, its objects interact with each other to provide a higher-level behavior. Interaction diagrams in the form of sequence or collaboration diagrams are used to model these interactions, which capture the dynamic aspects of the system.

The sequence diagram shows the sequence of messages, which are exchanged among roles that implement the behavior of the system, arranged in time. It shows the flow of control across many objects that collaborate in the context of a scenario, that is, the individual history of a transaction. The sequence diagram is mainly used to show the behavior sequence of use cases. The sequence diagram of Figure 3.8, for example, shows the sequence diagram of the "ElevatorCabin at Floor" use case. Time is represented vertically in the diagram; hence, the first message is the `cabinAtFloor` that is sent from the `FloorSensor` instance to the `ElevatorControler` object. The `ElevatorController` object then sends a message to the specific `cabinControler` object that is identified by the corresponding parameter of the `cabinAtFloor` message. It then sends a message to the `FloorButton` object that corresponds to the parameter `floorNo` of the `cabinAtFloor` message to check if there is a pending request in this floor.

Sequence diagrams differ from collaboration diagrams in the following features (Booch et al. 1999):

1. The sequence diagram uses the lifeline to highlight the existence of the object for the duration of the interaction. Usually, the objects that appear in an interaction are in existence for the whole duration of the interaction. The lifelines of these objects are drawn from the top of the diagram to the bottom. However, an object may be created or destroyed during the interaction and its lifeline starts after the corresponding message for creation (<<create>> stereotype) and ends with the corresponding message for destruction (<<destroy>> stereotype).
2. The sequence diagram shows the focus of control represented by a thin rectangle that shows the period of time during which the object is active, that is, performs an action as a response to a message that has accepted.

© 2005 by CRC Press LLC

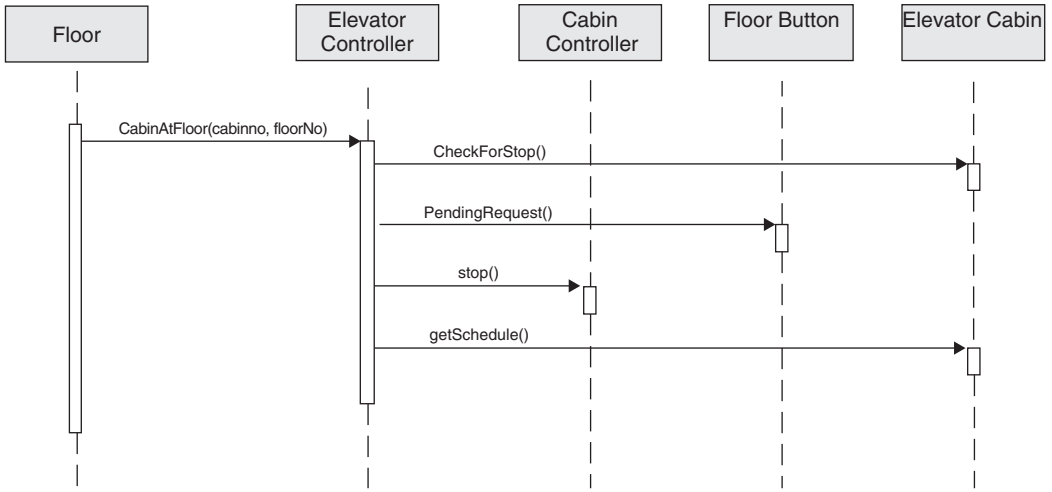

FIGURE 3.8 A simple sequence diagram from the elevator control system.

Collaboration Diagram

A collaboration or Object Interaction diagram (Thramboulidis and Agavanakis 1995) represents the objects that collaborate for the specific behavior to occur and the meaningful links between them. It captures some of the dynamic aspects of message passing required for the realization of a particular behavior. Objects are represented by rectangles, while links representing associations in the context of the particular collaboration are shown by lines connecting rectangles. Sequence numbers preceding the message descriptions indicate the sequence of messages in time. Collaboration diagrams are used during the design phase to model use cases as well as to show the implementation of an operation provided by an object in collaboration with other objects. An example of a collaboration diagram from the elevator control system is given in Figure 3.9.

Collaboration diagrams help in determining the operations of the objects, because the arrival of a message to an object usually invokes an operation. However, during analysis, emphasis is on capturing the information passed between objects rather than the operations invoked (Gomaa 2000). Later during design, it is decided if two different messages arriving at an object invoke different operations or the same.

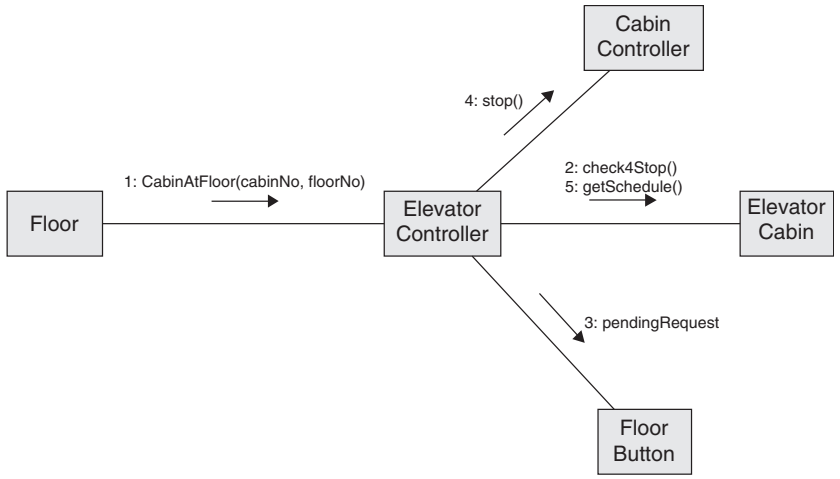

FIGURE 3.9 A simple collaboration diagram from the elevator control system.

© 2005 by CRC Press LLC

In the latter case, the name of the message is handled as a parameter of the operation. The decision for the kind of message, that is, synchronous or asynchronous, is postponed to the design phase.

Collaboration diagrams have two features that distinguish them from sequence diagrams (Booch et al. 1999). The first one can be used to show how an object is linked to another. A path stereotype such as <<local>> is attached to the receiver's object end of a link, to show that the receiving object is local to the sender. The second one is the sequence number that is used to indicate the time order of a message. The sequence number prefixes the message and increases monotonically for each new message in the flow of control. Dewey decimal numbering, for example, 1.1 for the first message nested in message number 1, is used to indicate nesting in messages.

3.5 Extending UML

UML 1.4 is currently used for modeling of just about any type of applications, running on any type and combination of hardware, operating system, programming language, and network. The language's flexibility allows the modeling of distributed applications on any middleware on the market. It is used at different application domains and different levels of abstraction in the system's development process. Examples of application domains where UML has a growing acceptability during the last years are embedded systems (Lee 2000; Svarstad et al. 2001), real-time systems (Selic 2000), and industrial automation and control systems (Thramboulidis 2001; Young et al. 2001; Heck et al. 2003; Thramboulidis and Tranoris 2003).

UML's extensibility mechanisms, namely stereotype, constraints, and required tags, are used to create profiles for the specific application domains. These profiles are primarily intended to tailor UML toward a specific domain by giving to modelers (a) access to common model elements and (b) terminology from the specific domain. A profile is a way of packaging UML specializations. Examples of such profiles are: UML for real-time modeling, UML for data modeling, UML for web modeling, UML for business modeling, UML profile for schedulability, performance and time (OMG 2002), and UML profile for Common Object Request Broker Architecture (CORBA).

A number of other profiles have been proposed. Kobryn (2000), for example, explores the synergies between object modeling and component modeling, by focusing on UML component modeling capabilities to examine the possibilities of using the language to support the leading enterprise component architecture standards EJB and COM+. He claims that standard UML profiles should be defined for these specific component technologies. Moreover, he believes that as components enter more into the mainstream business computing, UML will evolve from OO to component-based modeling language. Yacoub and Ammar (2001) describe an approach that utilizes UML modeling capabilities to construct applications using patterns. They define techniques and composition mechanisms by which patterns can be integrated and deployed in the design of software applications. Design patterns promise early reuse benefits at the design stage (Gamma et al. 1995). As Larsen (1999) states,

> Designing systems using components and proven solutions elevates the abstractions at which engineers work. Productivity and quality are the two main drivers this approach brings. *Productivity* will be positively affected by using abstractions for analysis, design and development. *Quality* will be positively affected by reusing known, proven solutions and the components that implement them.

Larsen (1999) discusses and illustrates the use of UML for designing component-based frameworks using patterns. A good interrelationship between patterns, frameworks, and components can also be found in his article. To enhance the UML's usefulness as a graphical programming language, Bjorkander (2000) proposes a merging of UML with the Specification and Description Language (SDL) (Ellsberger et al. 1997). The objective for this combination is to permit the expressive power of UML to coalesce with SDL's strengths of coherence and semantics. Medvidovic et al. (2002) assess the UML's expressive power for modeling software architectures in the manner in which traditional software architectural languages (ADLs) model architectures. They present two strategies for supporting architectural concerns within UML. One of these strategies uses UML without any extension while the other incorporates to UML, using its extension mechanisms, useful features of traditional ADLs.

© 2005 by CRC Press LLC

3.6 Real-Time UML

The use of the OO paradigm in real-time systems has caught on more slowly than in general-purpose applications (Bihary and Gopinath 1992). However, the problems that caused such a delay have already been dealt with and the OO paradigm is becoming the model of choice for the majority of real-time systems. A number of research teams have been exploring real-time OO languages, usually as extensions to existing OO languages. Even more OO analysis and design methods were considered as a means to confront the complexity of the new generation real-time embedded systems. Selic et al. (1994) describe the real-time object-oriented modeling (ROOM) that brings together the power of OO concepts tailored specifically for real-time systems, with an iterative and incremental process that is based on the use of executable models. ROOM is presented as a systems development methodology composed of the following three elements: (a) a modeling language, (b) modeling heuristics, and (c) a framework for organizing and performing development work. Douglas (1999) describes an embedded systems programming methodology for the development of real-time systems. This methodology uses: (a) best practices from object technology and (b) the industry standard UML. Gomaa (2000) presents Concurrent Object Modeling and Architectural Design Method (COMET), an OO methodology that covers requirements modeling and, analysis and design of distributed and real-time applications. A number of other approaches that address the analysis and design of real-time systems using the OO paradigm have also appeared during the last years.

To create a standard in this area, in 1998, the OMG appointed a special working group that is called Real-Time Analysis and Design Work Group, to examine the issue of applying UML in the real-time domain. This group gathered requirements from experts in academia and in industry and from vendors of real-time software, and decided to issue a number of RFPs. Of the proposals, the most important one seems to be the one that combines ROOM with the basic notation of UML. The remainder of this section is mainly based on Selic and Rumbaugh (1998), Selic (1999), and Gullekson (2000), where a detailed presentation of the Real-Time UML constructs and the way they are used for the modeling of real-time systems can be found.

The Real-Time UML utilizes the concepts that have been originally defined in the ROOM methodology and used for years for the development of real-time systems using the OO programming paradigm. It represents them using the extension mechanisms of UML to provide a UML profile for the real-time domain. The Real-Time UML profile focuses on the category of real-time systems that are characterized as complex, event driven, and usually distributed. Selic and Rumbaugh (1998) state that:

> Automatic control applications belong to this category of systems along with telecommunications, aerospace and defense systems. For the development of such applications the architecture plays the primary role. A well-defined architecture must not only support the construction of the initial system but must easily accommodate the system's evolution that is forced by new system requirements. Real-Time UML incorporates among other things the concepts of ROOM that constitute a domain specific architectural definition language. These concepts have proven their effectiveness across hundreds of diverse large-scale industrial projects.

We next describe the constructs of the UML that are divided into two major groups:

1. constructs for modeling structure and
2. constructs for modeling behavior.

Modeling Structure

Class diagrams and collaboration diagrams are used to capture the logical structure of the system. Entities that constitute the system, as well as the relationships between them such as communication and containment relationships, are identified. Class diagrams capture universal relationships among classes, while collaboration diagrams capture relationships that exist only within a particular context, as, for example, within the context of a use case. The following three constructs are defined to model structure:

© 2005 by CRC Press LLC

- capsules,
- ports, and
- connectors.

The *capsule* is defined using the stereotype extension mechanism of UML as a specialization of the general UML concept of class. The capsule is used to represent an entity of the system that has its own thread of control, that is, an active object. Figure 3.10 shows the `DoorController` capsule of the elevator control system. A capsule interacts with the other capsules or the environment through one or more boundary objects called ports. There are no public operations or other public parts to support the interaction of the capsule with the environment. Figure 3.11 shows the `ElevatorController` capsule to interact with the `FloorDoor` capsule.

The *port* is an object that implements a specific interface of the capsule and plays a particular role in the collaboration that the capsule has with other objects. Figure 3.12 shows the ports that the `DoorController` capsule uses to collaborate with its environment. These are `ElevatorPort`, `DoorSensorPort`, and `DoorMechanismPort`. To capture the complex semantics of these interactions, ports are associated with protocols. Each protocol defines the valid flow of information between connected ports, that is, it captures the contractual agreements between communicating capsules. Each port plays a specific role in some protocol, that is, it implements the behavior specified by that protocol role. This is why each port has its own identity and state. Ports do not map directly to UML interfaces that are purely behavioral without implementation structure.

A *connector* is used to represent a communication channel that provides the transmission facilities that are required for the implementation of a connection between capsule ports. Connectors can only be used

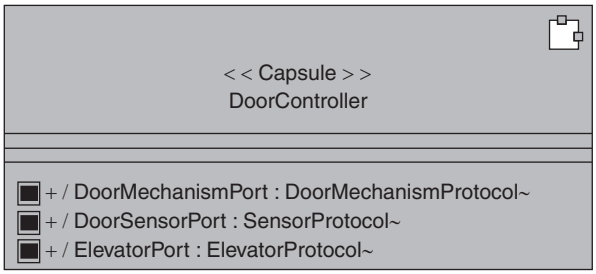

FIGURE 3.10 The `DoorController` capsule.

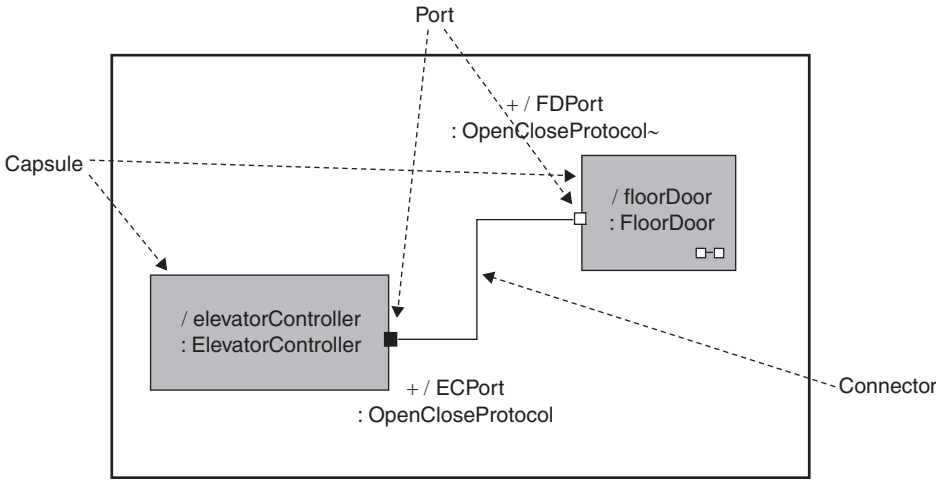

FIGURE 3.11 Capsules interact with each other through one or more boundary objects called ports.

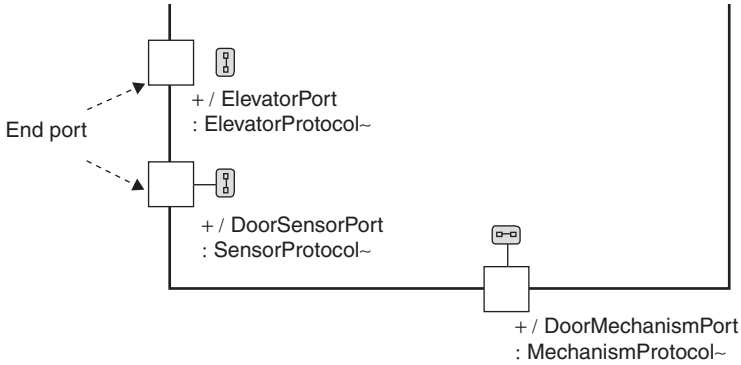

FIGURE 3.12 Ports of the `DoorControler` capsule.

to interconnect ports that have complementary roles in the protocol associated with the connector. The difference between connectors and protocols is that protocols are abstract specifications of desired behavior, while connectors are physical objects whose action is to convey signals between the connected ports. A connector may have physical properties and is usually an object with state and behavior. The actual class that is used to implement a connector is an implementation construct. For the representation of connectors, there is no need for extension mechanisms. A binary protocol connector is represented by a line that is drawn from one port to the complementary one, as the one shown in Figure 3.11 between the `ElevatorController` and `FloorDoor` capsules.

A capsule may have a state machine that represents its dynamic behavior. The state machine has control of all the internal structures of the capsule and interacts with the capsule's environment, sending and receiving signals through ports. Figure 3.13 shows the state machine of the `DoorController` capsule. According to it, its initial state is `DoorClosed`. The event `openDoor` from the `ElevatorController` fires the transition to the `DoorOpening` state.

The capsule's structure is represented by a collaboration diagram, which specifies the capsule's ports, its subcapsules, and its connectors. The collaboration diagram of Figure 3.14 shows the structure of the `FloorDoor` capsule, which is composed of the `DoorSensor`, `DoorController`, and `DoorMechanism` subcapsules and the `Elevator` port. The same information is represented with the class diagram of Figure 3.15. Ports, subclasses, and connectors are strongly owned by the capsule and cannot exist independent of it. This is why the composition instead of the aggregation relationship was selected.

Ports are of two kinds: relay ports and end ports. Relay ports are used to allow subcapsules to communicate with the outside of the capsule; thus, they are connected to subcapsules as, for example, the port `FDport` of the `FloorDoor` capsule shown in Figure 3.14. End ports, which are connected to the capsule's state machine, are the source or sinks of all messages sent by the capsule. The port `ElevatorPort`, `DoorSensorPort`, and `DoorMechanismPort` of the `DoorController` capsule in Figure 3.12 are all end ports.

Modeling Behavior

The basic constructs used for modeling behavior are protocols and state machines. The modeling of time, with timing services, is of great interest for the modeling of behavior as well.

A *protocol* is a special type of UML collaboration that is used for the specification of behavior that exists between communicating capsules. This behavior is specified by defining the set of valid message exchange sequences between two or more active objects. Protocols are defined independent of the specific objects that communicate using this protocol. This makes protocols independent of the specific context; thus, their reusability is of a high degree. Inheritance can also be used to specify new protocols as specializations of already defined protocols. Protocols are defined in terms of protocol roles. Each protocol comprises a set of participants, each of which plays a specific role in the protocol. Each protocol

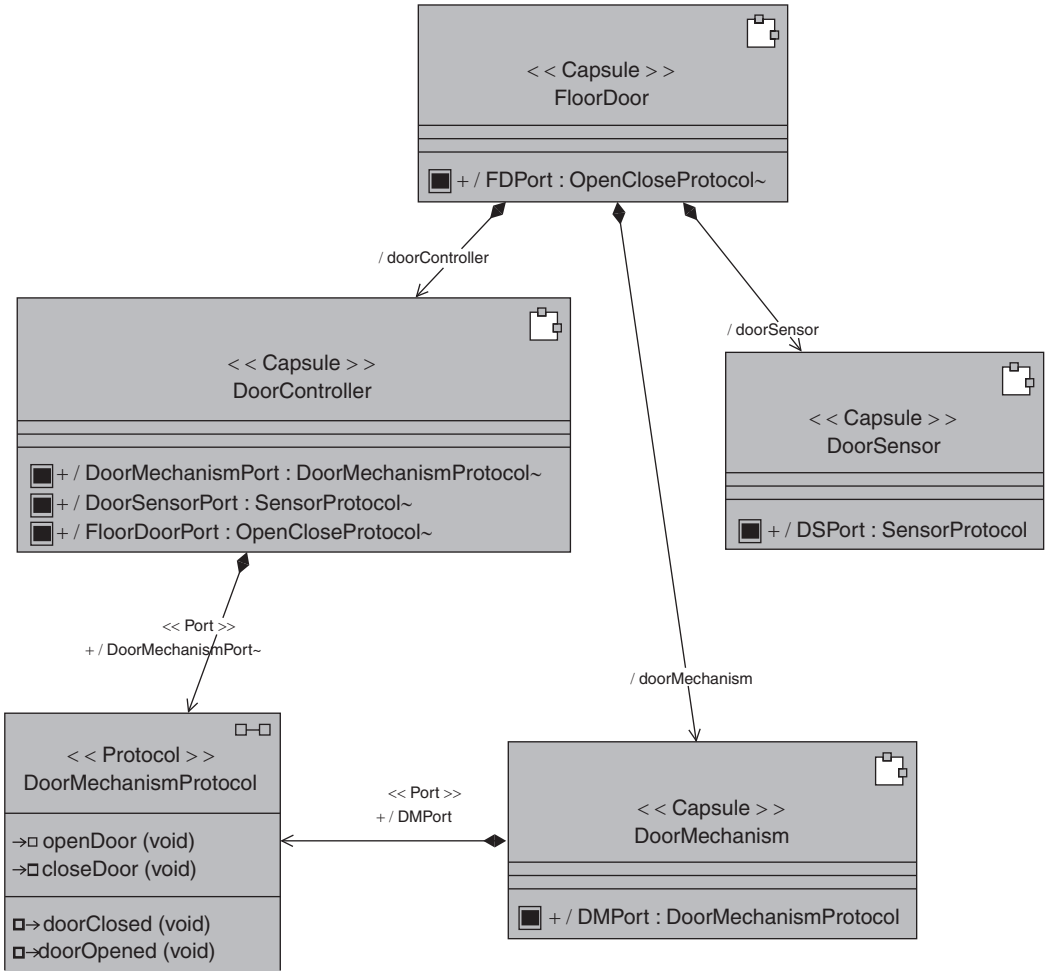

FIGURE 3.15 Class diagram for the `FloorDoor` capsule.

role is specified by a unique name and the set of valid incoming and outgoing signals that are received and sent by that role. It also defines the set of valid message orderings. Protocol roles are represented by the <<protocolRole>> stereotype that has two compartments: one for the incoming signals and the other for the outgoing ones. Binary protocols, that is, protocols with two participants, are the most common. Their advantage is that only one role, which is called base role, has to be specified. The other role called conjugate is defined by simply inverting incoming and outgoing signal sets; this inversion operation is called conjugation.

Figure 3.16 shows the `DoorMechanism` protocol that is used for the specification of behavior that exists between the communicating capsules `DoorController` and `DoorMechanism` of Figure 3.14. The icon shown in the upper right corner of the `DoorMechanismProtocol` capsule is used to identify binary protocols. `OpenDoor` and `closeDoor` are the incoming signals for the base role of this binary protocol, while `doorClosed` and `doorOpened` are its outgoing signals. In this case, since the protocol is binary, the role state machine and the protocol state machine are the same. The state machine and the interaction diagrams of a protocol role are represented using the standard UML notation.

The *handling of time* is the most important issue in most real-time systems. Real-Time UML defines the following two forms of time-based situations: (a) the ability to trigger activities at a particular time of day and (b) the ability to trigger activities after a certain interval has expired from a given point in time. Real-Time UML defines the time service facility that can be accessed through a standard port and

© 2005 by CRC Press LLC

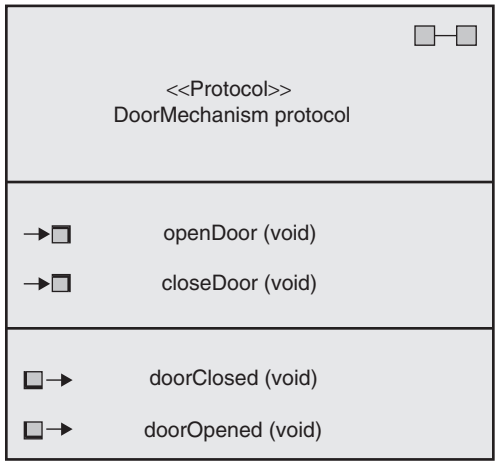

FIGURE 3.16 The binary protocol `DoorMechanismProtocol`.

converts time into events. These events are then handled in the same way as traditional signal-based events. A state machine that uses the time service may be notified with a "timeout" event when a particular time of day has been reached or when a particular interval has expired. The time service is provided by protected end ports, which are of type "TimeServiceSAP," where SAP stands for Service Access Point.

Real-Time UML has wide acceptance in academia and many researchers are working on different aspects related to it. For example, Selic (1999) demonstrates the feasibility of UML to model recourses and thus predict crucial system properties before fully implementing a system. He proposes the incorporation of a generic QoS framework into UML to provide a standard way of producing quantifiable and, hence, precisely analyzable software models. He and Goddard (2000) present a method for capturing the temporal parameters of a real-time application in a Real-Time UML model so that schedulability analysis can be performed early in the design phase. The proposed method enriches Real-Time UML and enhances the modeling of real-time systems by capturing more temporal parameters and making them first-class attributes in the model. It also ensures that a real-time system modeled with Real-Time UML is schedulable and this analysis can begin early in the design phase.

3.7 Applications of UML in Control and Automation

The majority of today's distributed control systems consist of industrial-grade computers or PLCs, which are interconnected by dedicated fieldbus networks. The market is dominated by a small number of very large corporations with proprietary solutions. The most common design and analysis tool for control systems is MATLAB. Unfortunately, the family of MATLAB products tends to generate monolithic rather than component-based C language code, which makes the validation and code update more difficult (Heck et al. 2003).

The OO approach has attracted the interest of researchers in control and automation from the early 1990s (beginning of the 1990s). Aarsten et al. (1996) described the G++ pattern language for the design of distributed control systems, and reported their experience, gained in the field of computer-integrated manufacturing (CIM) and from a project involving cooperative autonomous robots. They claim that although the existence of design patterns is often very valuable for solving isolated design problems, a domain-specific language does the same but to the whole development project. Grady and Liang (1998) describe their OO approach to enhance the ability of companies to respond rapidly to changes in the market environment. They present an OO extension to the design with modules approach, which involves selecting the module combination to best satisfy the given set of requirements. Traub and Scharft (1999) present an OO real-time framework for distributed control systems.

© 2005 by CRC Press LLC

In the last few years, there has been a trend to use UML in control, industrial automation, as well as in industrial enterprise integration. Several papers present examples of using the UML in many different levels of manufacturing information systems. However, there is a wide gap between the state of the art in software engineering and the state of practice in industrial applications. As reported by Lewis (2001), today's control applications are usually developed in the form of large monolithic software packages that are difficult to maintain, modify, and extend. The engineering tools used in the development and deployment processes address a little, or not at all, dimensions such as modularity, flexibility, extensibility, reusability, and interoperability. Advances in software technologies may facilitate the development and deployment of complex control systems. Heck et al. (2003) give a tutorial overview of specific new software technologies that are useful for the implementation of complex control systems. They claim that component-based architectures and the OO approach are very promising technologies for the control and automation application domain.

In an attempt to define an open standard for distributed control systems (DCSs), the International Electro-technical Commission (IEC) has defined the basic concepts and a methodology for the design of modular, reusable DCSs. The IEC61499 standard defines the Function Block (FB) as the main building block and the way that FBs can be used to define robust, reusable software components that constitute the DCS.

So, what is the future in control and automation software development? We discriminate three possible directions:

1. UML-based approach;
2. FB-based approach; and
3. A hybrid approach integrating UML with the FB concept.

We next refer briefly to these approaches.

The UML-Based Approach

According to this approach, the standard UML notation is used to produce the models of the control system. This is the approach proposed by many researchers (Douglas 1999; Gomaa 2000; Young et al. 2001; Mosemann and Wahl 2001; Bonfè and Fantuzzi 2003). Better results will be obtained using the profile for real-time modeling and the profile for schedulability, performance, and time.

The major disadvantage of this approach is that it is a completely new approach for practitioners in control and automation, who are mainly accustomed to IEC languages and concepts.

The FB-Based Approach

This approach, which is the one proposed by the evolving IEC standards 61499 and 61804, is based on the FB construct. Although many researchers are already working on different aspects of the IEC proposal (e.g., Vyatkin and Hanisch 2001; Brennan and Norrie 2001; Fletcher and Norrie 2001; Thramboulidis and Tranoris 2001), the absence of tools and products that are compliant with this approach is evident. The Function Block Development Kit (FBDK) by Rockwell Automation (see at http://www.holobloc.com/fbdk/README.htm for a detailed description of the tool and a free downloaded version) and CORFU-FBDK (Thramboulidis and Tranoris 2003) are the only known tools supporting this approach.

However, it should be mentioned that the *IDA architecture,* which is proposed by the IDA group (http://www.ida-group.org), proposes an application model that is based on the reference architecture defined in IEC61499. Also, the *Profinet Engineering Model,* which is the proposal of the Profibus User Organization to achieve open distributed automation, even though it is non-IEC-compliant, is planning to have an IEC-compliant mapping in the near future.

The major advantage of this approach is that it exploits the experience of industry's practitioners and easily integrates the large number of existing legacy applications and systems. However, it does not exploit all the benefits of object- and component-based technologies.

© 2005 by CRC Press LLC

The Hybrid Approach

This approach integrates the UML notation with the FB concept. However, this integration is done from different perspectives. Brennan et al. (2002) describe two approaches for modeling decentralized Manufacturing Systems with UML capsules. They propose the modeling of the control system at the conceptual level using Real-Time UML and then they propose a mapping of Real-Time UML to IEC 61499 models that are used for the implementation of control application. However, it is quite difficult for control engineers to model in Real-Time UML.

Another approach (Thramboulidis 2001; Thramboulidis and Tranoris 2003; Tranoris and Thramboulidis 2003) considers the use of the UML notation in the requirements specification phase using the concept of use case. It next proposes the transformation of the UML models to FB-based models through a specific tool. The FB design models are next used for the development of the control application. One can consult the CORFU site (http://seg.ee.upatras.gr/corfu) for several white papers that describe this approach and to obtain an evaluation/demonstration version of the engineering tool that is based on this approach.

In any case, a UML profile for control and automation should provide the best alternative for the development of control applications. Such a profile should primarily intend to tailor UML toward the control and automation domain. It should provide to modelers: (a) access to common model elements and (b) terminology from the control and automation domain.

3.8 UML CASE Tools

In the last few years, the number of CASE tools that support the UML notation has increased dramatically. A list of UML CASE tools can be found at http://dmoz.org/ Computers/Programming/ Methodologies/Modeling_Languages/Unified_Modeling_Language/Tools/ as well as at http://www.qucis.queensu.ca/Software-Engineering/_tools.html.

The software developer has several choices; but it is quite difficult to make the right choice. The large number of unsuccessful attempts to introduce CASE tools in the development process forced the software community to give considerable attention to the establishment of processes for the formal assessment of case tools (Mosley 1992; Le Blanc and Korn 1994; Kitchenham and Pickard 1998). Working groups created by authorities such as the Software Engineering Institute (SEI) and the IEEE, which seek to advance the state of practice in software development through the use of good tools for system and software engineering, resulted in the IEEE 1462 standard, which defines guidelines for the evaluation and selection of CASE tools (IEEE Std 1462, 1998). However, a formal assessment following the standards is a very costly and time-consuming task. Even more, some weaknesses have been identified to standards and reported so far (e.g., Lundel and Lhngs 2002).

A less formal assessment is usually adopted. In such an assessment, issues such as ease of use, robustness, functionality, round-trip engineering, model navigation, repository support, support for reusability, ease of insertion, and quality of support must be considered very carefully. A good list of evaluation criteria can be found at http://www.objectsbydesign.com/tools/modeling_tools.html. Several articles report evaluation processes and results that may be used appropriately in the CASE tool selection process (Budgen and Thomson 2002; Frankel 2000; Ypsihe 2000; Eichelberger 2002; Post and Kagan 2000; Artim 2003). We next refer briefly to three commercially available CASE tools:

(A) *The IBM Rational Rose.* A family of model-driven development tools that can be used with many IDEs such as IBM VisualAge, Visual Studio 6.0, Borland JBuilder and other Java, C++, and Ada IDEs. The Rational Rose family includes products that address all types of application needs, including business and enterprise/IT applications, software products and systems, and embedded systems and devices. Information on this family of tools can be found on-line at: http://www.rational.com/products/rose/index.jsp?SMSESSION=NO

(B) *Rhapsody by I-Logix.* Rhapsody provides, according to I-Logix, a collaborative Model-Driven Development (MDD) environment for system and software engineers to work in an iterative fashion,

© 2005 by CRC Press LLC

analyze and make rapid system and software design changes, generate the application, and test it quickly and efficiently. The development of real-time embedded applications is supported by a special tool, which is based on executable models (I-Logix 2003). The tool for embedded systems is very flexible. A real-time framework in the source code form is provided with the tool; thus, users can easily adapt the generated code for any other operating system, including proprietary in-house systems. There is a Free Developer's Trial for 30-day provided by Rhapsody. An overview of the tool can be found on-line at: http://www.ilogix.com/products/rhapsody/index.cfm

(C) *Tau Generation2 by Telelogic.* Tau Generation is a family of role-based and model-centric tools for real-time software and systems development. Tau/Developer™ is a stand-alone tool based on UML, for the design, analysis, and development of advanced real-time applications. According to Telelogic, the tool enforces the engineer to make a shift from the traditional labor-intensive code-centric programming to the highly efficient MMD. According to Telelogic, the tool supports executable UML models with behavioral specifications. The tool's philosophy is that the specifications must be validated at an early stage for timely and cost-effective error correction. Information is available on-line at: http://www.taug2.com/

There are also some free CASE tools. Among them, we specify the following:

- *Visual Paradigm for UML.* A visual development platform. http://www.geocities.com/millermax2001/casetool.html
- *Argo/UML.* A free open source UML tool. http://argouml.tigris.org/
- *Poseidon for UML (Community Edition).* http://www.gentleware.com/adgate.php4?in=odb&banner=poseidonCE&url=/products/poseidonCE.php3

3.9 Conclusions

UML is the *de facto* standard for software development. A large number of practitioners and researchers have adopted UML in many different application domains at a rate exceeding even OMG's most optimistic predictions. Even though UML has emerged as a language for modeling OO systems, it is now evolving to a component-based modeling language. UML2 is expected to be in the context of the OMG's Model Driven Architecture initiative, which considers as primary artifacts of software development not programs, but models created by modeling languages. This ensures that UML will drive the software development industry for the next decades.

However, UML is a very elaborate language. A long time is required to learn the language and efficiently use it in the software development process. In this paper, we have presented a subset of the UML language that includes the most commonly used diagrams to model the most important aspects of software systems. In particular, we have presented the basic concepts regarding use case diagrams, class diagrams, statecharts, and sequence and collaboration diagrams. These diagrams have specific constructs and semantics to enable the software developer to model the most important views of the system under development.

One of the most important features of UML is its ability to be extended and specialized in different application domains. Even though UML's flexibility allows the modeling in different application domains and at different levels of abstraction during the system's development process, the powerful set of extensibility mechanisms, which are provided by the language, allows the definition of profiles for any specific application domain. A profile is primarily intended to tailor UML toward a specific domain by providing modelers access to common model elements and terminology from the specific domain. This considerably enhances productivity and quality in the development process. We have briefly presented the real-time UML profile that focuses on the category of real-time systems that are characterized as complex, event driven, and usually distributed. We have described the most important constructs of the profile, including capsules, ports, connectors, protocols, etc. that are utilized to create executable models for the system under development.

As expected, UML has attracted the interest of researchers from the control and automation application domain. It is believed that component-based architectures and the OO approach are very promising

© 2005 by CRC Press LLC

technologies for this application domain and the best way to exploit these technologies is through the use of UML. However, it is not yet clear as to how the UML will be utilized in this domain. We have described three possible directions that are already adopted by researchers in this area. Finally, we have made a reference to the family of CASE tools that support UML. The great number of commercially available and free downloaded CASE tools makes the selection a very costly and time-consuming task. Standards may be used to simplify this task, but a less formal assessment is usually adopted to select the tool that addresses the specific developer's requirements.

4.8 The Microsoft .NET Framework
4.9 Future Trends: Resource Management and Quality-of-Service

Andreas Polze
Hasso-Plattner-Institute at University Potsdam

Middleware is connectivity software that consists of a set of enabling services that allow multiple processes running on one or more machines to interact across a network. Middleware functions as a conversion or translation layer. It is also a consolidator and integrator. Custom-programmed middleware solutions have been developed for decades to enable one application to communicate with another that either runs on a different platform or comes from a different vendor or both. Today, there is a diverse group of products that offer packaged middleware solutions.

Middleware is essential to migrating mainframe applications to client/server applications and providing communication across heterogeneous platforms. This technology evolved during the 1990s to provide for *interoperability* in support of the move to client/server architectures. The most widely publicized middleware initiatives are the Open Software Foundation's *Distributed Computing Environment* (DCE), Object Management Group's *Common Object Request Broker Architecture* (CORBA), and Microsoft's COM/DCOM (*Component Object Model (COM), DCOM*) with its successor Microsoft.NET. The Java programming language and its runtime environment support Remote Method Invocation (RMI) on the language level, which may be seen as an integration of middleware support into the programming language — an idea that can also be found in the .NET languages.

Although middleware systems are often designed to transparently manage the distribution of processes and objects as well as communication across machine boundaries, common programming interfaces between applications are also considered middleware. For example, *Open Database Connectivity* (ODBC) enables applications to make a standard call to all the databases that support the ODBC interface.

© 2005 by CRC Press LLC

4.1 Overview and Classification

As outlined in Figure 4.1, middleware services are sets of distributed software that exist between the application and the operating system and network services on a system node in the network.

Middleware services provide a more functional set of Application Programming Interfaces (API) than the operating system. Network services implemented on the middleware layer allow an application to:

- Locate communication partners transparently across the network, providing interaction with another application or service.
- Be independent of network services.
- Be reliable and available.
- Scale up in capacity without losing function.

Middleware can take on the following different forms.

TP Monitors

The transaction processing monitor (TP monitor) was perhaps the first product to be called middleware. TP monitors provide tools and an environment for developing and deploying distributed applications. Located between the requesting client program and the databases on the server side, a TP monitor ensures that all databases are updated properly.

TP monitors tend to do far more than coordinate and monitor transactions across multiple data resources. They also enhance the performance, reliability, and scalability of server-side systems. To achieve these enhancements, TP monitors establish a framework for creating server-side applications. A TP monitor can reliably and efficiently manage the resources needed by applications that conform to the TP monitor's rules.

Customer Information Control System (CICS) and IMS/TM (a message-based transaction manager) are the transaction processing workhorses of the mainframe environment. On UNIX systems, BEA's TUXEDO, BEA's TOP END, and IBM's Encina are the most widely used TP monitors.

Messaging Middleware

Message-Oriented Middleware (MOM) provides program-to-program data exchange, enabling the creation of distributed applications. MOM is analogous to email, in the sense that it is asynchronous and requires the recipients of messages to interpret their meaning and to take appropriate action. MOM provides a common interface and reliable transport between applications. If the target machine is down or overloaded, it stores the data in a message queue until it becomes available. The messaging system may contain business logic that routes messages to the appropriate destinations and reformats the data as well.

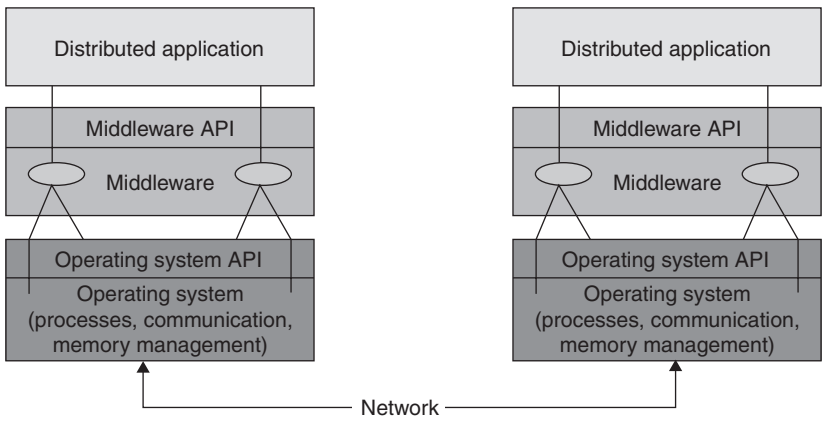

FIGURE 4.1 The middleware layer.

© 2005 by CRC Press LLC

The predominant messaging product for managing asynchronous communication between applications is IBM's MQSeries. MQSeries has been ported to all major server platforms. In conjunction with the Component Object Model (COM), Microsoft introduced its own messaging system, Microsoft Message Queue Server (MSMQ). MSMQ and MQSeries offer much the same functionality.

Distributed Processing

Remote Procedure Calls (RPCs) enable the logic of an application to be distributed across the network. Program logic on remote systems can be executed as simply as calling a local routine. The SUN RPC, introduced with the implementation of the network file system (SUN NFS), as well as the DCE RPC, which also served as the technical foundation of Microsoft's COM, are the most prominent examples of remote procedure call implementations.

Extending the procedural programming model of RPC, *Object Request Brokers* (ORBs) enable the objects that comprise an object-oriented application to be distributed and shared across heterogeneous networks. Distributed object systems such as CORBA, DCOM, .NET, and EJB enable processes to be run anywhere in the network. In contrast to messaging middleware, RPCs and ORBs typically implement synchronous interaction between processes (components/objects).

Database Middleware

Middleware provides a common interface between a query and multiple, distributed databases. Using either a hub and spoke architecture or a distributed architecture, it enables data to be consolidated from a variety of disparate data sources.

Application Server Middleware

A Web-based application server that provides interfaces to a wide variety of applications is used as middleware between browser and legacy systems. Application servers have supported a wide range of server-side processing, with SUN's Java 2 Enterprise Edition (J2EE) as a prominent example. WebServices are a promising route toward standardization of application server interfaces.

4.2 Usage Considerations

The main purpose of middleware services is to help solve many application connectivity and interoperability problems. However, middleware services are not a panacea:

- There is a gap between principles and practice. Many popular middleware services use proprietary implementations (making applications dependent on a single vendor's product).
- The sheer number of middleware services is a barrier to using them. To keep their computing environment manageably simple, developers have to select a small number of services that meet their needs for functionality and platform coverage.
- While middleware services raise the level of abstraction of programming distributed applications, they still leave the application developer with hard design choices. For example, the developer must still decide what functionality to put on the client and server sides of a distributed application (Bernstein 1996).

The key to overcoming these three problems is to fully understand both the application problem and the value of middleware services that can enable the distributed application. To determine the types of middleware services required, the developer must identify the functions required, which fall into one of three classes:

1. Distributed system services, which include critical communications, program-to-program, and data management services. This type of service includes RPCs, MOMs, and ORBs.

© 2005 by CRC Press LLC

2. Application-enabling services, which provide applications access to distributed services and the underlying network. This type of services includes TP monitors and database services such as Structured Query Language (SQL).
3. Middleware management services, which enable applications and system functions to be continuously monitored to ensure optimum performance of the distributed environment.

4.3 Distributed Objects and Distributed Processing

Among the middleware approaches listed above, distributed objects have the biggest potential to solve a wide range of challenges faced by designers of large software systems. Some of these challenges include component packaging, cross-language interoperability, interprocess communication, and intermachine communication. The distributed processing and distributed object architectures, which have been introduced over the last decade, exhibit different strengths and weaknesses based on their ability to meet this challenge.

For our discussion, we divide distributed object architectures into two categories: component architectures and remoting architectures. We define *component architectures* as architectures that focus primarily on component packaging and cross-language interoperability. In contrast, *remoting architectures* focus primarily on support for remote method invocation on distributed objects.

Primary examples for remoting architectures are the Open Software Foundation's (OSF) Distributed Computing Environment (DCE) — which actually is a distributed processing environment based on the RPC paradigm (purely procedural) — and the Object Management Group's (OMG) Common Object Request Broker Architecture (CORBA). The notion of component packaging and deployment has only recently been added to CORBA 3.0.

The predominant component architectures are Microsoft's Component Object Model (COM) — which mainly addresses packaging and deployment of binary component as well as cross-language interoperability — and the JavaBeans and Enterprise Java Beans (EJB) component models introduced by SUN Microsystems. Both COM and EJB address remoting to some extent: the COM model has been extended to Distributed COM (DCOM) using an extended version of DCE RPC as transport. EJB supports client/server communication based on Java Remote Method Invocation (RMI). RMI is special, as it integrates closely with the Java language without requiring a special Interface Definition Language (IDL) to describe component interfaces accessible for remote invocations.

In an evolutionary sense, Microsoft's .NET is the newest and most advanced component architecture available in the market today. Similar to Java, .NET is based on a machine-neutral intermediate language format and just-in-time compilers. .NET adopts a fundamentally new and sound approach to cross-language interoperability as it starts with a common object model and type system applicable to all .NET languages (among them, C#, C++, Visual Basic, Jscript, Eiffel#, Cobol, Scheme, and more to come). .NET extends COM as it makes metadata — runtime-type information, which was optional for COM components — mandatory for each .NET component (so-called assemblies). .NET implements a remoting architecture (.NET Remoting), which is comparable to Java RMI in the sense that it closely integrates with the .NET programming languages and does not require any special IDL.

We will now discuss prominent examples for object-oriented middleware systems in some detail.

4.4 The Distributed Computing Environment (OSF/DCE)

In the mid-1980s, the Open Software Foundation (OSF) was set up by a group of major computer vendors, among them IBM, DEC, and Hewlett-Packard with the initial goal of developing a new version of UNIX, over which they, and not AT&T/SUN, had control. This goal was achieved with the release of the Mach-based OSF/1 operating system. However, many of the OSF consortium's customers wanted to build distributed applications on top of OSF/1 and other UNIX variants. OSF/1 responded to this by issuing a "Request for Technology," which ultimately led to the design of the OSF Distributed Computing Environment (DCE) (DCE 1995).

© 2005 by CRC Press LLC

DCE supports a distributed client/server-programming model. User processes act as clients to access remote services provided by server processes. Some of these services are part of DCE itself, but others belong to the application and are written by application programmers. The DCE RPC is the basis for all communication in DCE. To access a service, a client process issues an RPC to a (possibly) remote server. The server acts on the requests and (optionally) sends back a reply. DCE handles the complete mechanism, including name resolution (locating the server), binding to it, and performing the call. DCE provides an IDL and a compiler, thus allowing a server programmer to describe the remotely callable procedures made available by his application. In order to cope with machine-dependent data representations, the DCE IDL compiler generates code for mapping C data structures onto a network format.

Besides the RPC mechanisms, DCE provides a thread package, allowing multiple threads of control to exist in the same process at the same time. Some versions of UNIX provide threads themselves, but using DCE provides a standard thread interface across systems. The DCE thread implementation is mapped onto native operating system threads whenever possible.

Besides the DCE architecture, Figure 4.2 depicts a number of central services implemented in the DCE environment. Standard services are the time, directory, and security service.

The *distributed time service* provides clock synchronization among machines in a DCE cell. Clock synchronization is a necessary prerequisite for the predictable behavior of many other services, among them the directory service. The DCE *directory service* can be seen as a general naming service, which keeps track of the location of all resources in the system. These resources include machines, printers, servers, data, and much more, and — due to the directory service's hierarchical structuring scheme — they may be geographically distributed across the world. The directory service provides for location-transparent resource access. The *distributed file service* is a worldwide file system that provides a transparent way of accessing any file in the system in a standard manner. It can be either built on top of a host's native file systems or can be used instead of them.

The *security service* implements access control (authentication and authorization) for all kinds of resources in the DCE environment. The DCE authentication procedure uses the Kerberos system developed at M.I.T. Authorization in DCE is handled by associating an Access Control List (ACL) with each resource. The ACL

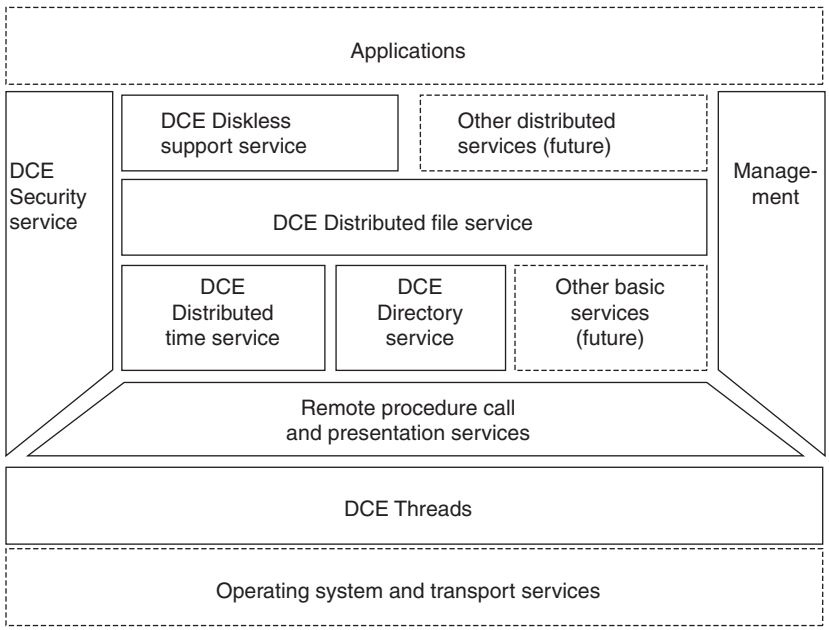

FIGURE 4.2 DCE architecture and services.

© 2005 by CRC Press LLC

instructs as to which users, groups, and organizations may access the resource and which operations they are entitled to invoke on the resource. Resources may be as coarse as files or as fine as database entries.

Although DCE has pioneered distributed computing in various respects, it has never been complete. DCE provides many facilities and tools; however, it lacks certain runtime management and debugging aids, and did not really keep up with newer software engineering approaches such as object-oriented programming.

4.5 The Common Object Request Broker Architecture (CORBA)

The OMG was founded in 1989 as a consortium of eight companies (3Com, American Airlines, Canon, Data General, Hewlett-Packard, Philips Telecommunications, Sun Microsystems, and Unisys). Today, the OMG exists as an international nonprofit organization of more than 800 software developers, network operators, computer vendors, research institutions, and commercial computer users.

Figure 4.3 depicts the Object Management Architecture (OMA) (Soley 95), as specified by the OMG. OMA describes software architectures for application interoperability, independent of the applications' implementation languages, locations, operating systems, and hardware platforms.

The Object Request Broker (ORB) is the central element of the OMA. Comparable to a software bus, the ORB serves as a universal communication means for various objects in heterogeneous distributed systems. A CORBA object is represented to the outside world by an interface with a set of methods. A particular instance of an object is identified by an object reference. The client of a CORBA object acquires its object reference and uses it as a handle to make method calls, as if the object was located in the client's address space. The ORB is responsible for all the mechanisms required to find the object's implementation, prepare it to receive the request, communicate the request to it, and carry the reply (if any) back to the client. The object implementation interacts with the ORB through either an Object Adapter (OA) or through the ORB interface (see Figure 4.4). In order to implement communication across machine boundaries, multiple ORB instances residing on different machines in the network interact typically using Internet InterORB Protocol (IIOP), which is a specialization of the General InterORB Protocol (GIOP).

The architectural design of the ORB has been described in the CORBA specification, which appeared in version 1.1 in 1991 and exists in version 3.0 today. The CORBA specification emphasizes the following characteristics (CORBA 1995):

Object-orientation: Objects are the basic architectural units in CORBA. An object in the sense of the OMA is characterized by its object reference, a unique identifier. CORBA objects are not necessarily objects in the sense of a programming language. In contrast to fine-grained, short-lived lightweight programming language objects, CORBA objects are often coarse-grained and are rather comparable to operating system processes.

Distribution transparency: CORBA programs access remote objects by the same means as local objects. The exact location of a given server object is typically hidden from client programs.

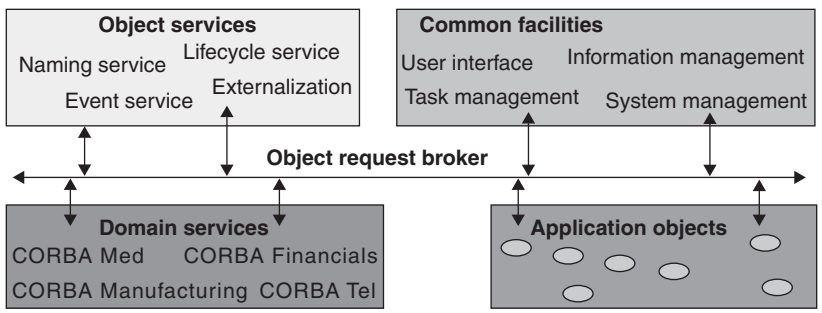

FIGURE 4.3 The object management architecture.

© 2005 by CRC Press LLC

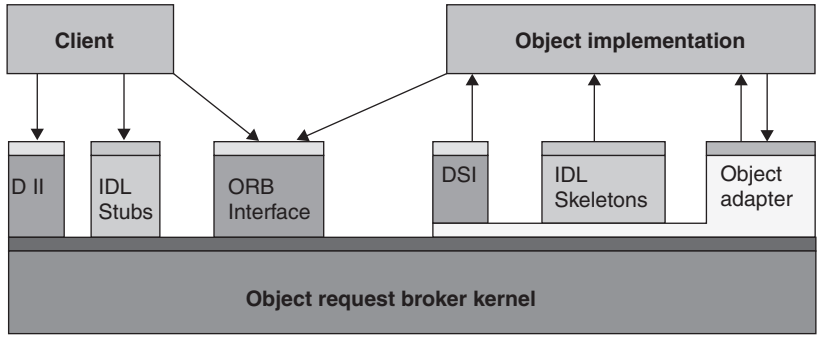

FIGURE 4.4 ORB interfaces.

Efficiency: The ORB architecture specified by OMG is general with respect to actual implementations, allowing for efficient implementations, which may minimize the overhead for local client/server communication (i.e., using shared memory or no interprocess communication at all).
Hardware, operating system, and language transparency: Components of a CORBA program can be implemented using varying operating systems, hardware architectures, and programming languages. This is achieved using a language-neutral interface definition language (CORBA IDL) for components. The OMG has specified language mappings from IDL to a number of implementation languages.
Openess: Using the ORB as a software bus allows for interoperability among components of different vendors. This avoids vendor-lock and opens up the opportunity for domain-specific component markets. However, although the CORBA IDL may serve as a platform-independent description of component interfaces, there is no binary component format standardized by OMG — which makes marketing of binary components for multiple ORB implementations on varying platforms at least difficult.

There exist a variety of commercial and open source CORBA implementations. Compatibility tests and benchmarks (Amar 1998; Gokhale 1997; Vinoski 1997) demonstrate that CORBA is well suited for distributed object-based applications.

The recent CORBA 3.0 standard introduces a number of related new specifications, which specifically address issues in integrating CORBA with Java and the Internet (in contrast to the intranet) as well as quality of service control. Most notable are the following changes (Siegel 2001):

CORBA Component Model (CCM) — introduces the notion of server-side components into CORBA and addresses packaging and deployment for CORBA components. CCM provides for interoperability with EJB.
Objects passable by value (valuetypes) — valuetypes definitely improve integration with Java and also serve as the basis for the XML/Value mapping (released as part of CORBA 2.3).
Java-to-IDL mapping — this mapping allows Java RMI objects to interoperate over the network like CORBA objects using CORBA object references.
XML/Value mapping — standardizes the representation of an XML document as a collection of native CORBA types.
CORBA Firewall Specification — allows firewalls to be configured for CORBA using access rules for IIOP traffic.
CORBA Messaging — encompasses both asynchronous and messaging-mode invocations of CORBA objects as well as Quality of Service Control.
Real-Time CORBA — extends the CORBA architecture with resource control mechanisms for real-time applications running on a real-time operating system in a controlled environment.
Fault-Tolerant CORBA — standardizes redundant software configurations and systems that give CORBA robust and reliable performance (when run on redundant hardware).
Minimum CORBA — defines a small-footprint CORBA configuration that is aimed at embedded and card-based systems.

© 2005 by CRC Press LLC

4.6 Microsoft's (Distributed) Component Object Model (COM/DCOM)

In the early 1990s, Microsoft made a strong commitment to Object Linking and Embedding (OLE). Although OLE allowed for interoperability among applications, component packaging and cross-language interoperability were insufficiently addressed by OLE. Microsoft addressed these issues with the subsequent COM (COM 95), which became the foundation for a wide range of technologies, among them the OLE Control Extension (OCX) — later renamed as *ActiveX* (visual COM controls). COM is the dominant component architecture in use today. This is not very surprising since COM is the component architecture for today's most dominant desktop operating system — Microsoft Windows (98/ME and NT/2000/XP). Recently, Microsoft coined the acronym COM+ to identify the bundling of the COM infrastructure with a number of component services.

DCOM is the distributed extension to COM that builds an object remote procedure call (ORPC) layer on top of DCE RPC to support remote objects. A COM server can create object instances of multiple object classes. A COM object can support multiple interfaces, each representing a different view or behavior of the object. An interface consists of a set of functionally related methods. A COM client interacts with a COM object by acquiring a pointer to one of the object's interfaces and invoking methods through that pointer, as if the object resides in the client's address space. COM specifies that any interface must follow a standard memory layout, which is the same as the C++ virtual function table (Rogerson 1996). Since the specification is at the binary level, it allows integration of binary components possibly written in different programming languages such as C++, Java, and Visual Basic.

COM supports a language-neutral IDL — actually an extension of DCE IDL — that is used to describe the interface of a COM component. Using IDL, the designer of a COM component can describe the interfaces, methods, and properties that are supported by the component. Client applications rely on the IDL definition of the COM component rather than on implementation-specific details such as programming language and implementation platform.

As depicted in Figure 4.5, COM supports the following three styles of servers for implementing components:

1. *In-process server:* An in-process server is implemented as a dynamic linked library (DLL) that executes within the same process space as the application. The performance overhead of invoking an in-process server is small (in the order of an ordinary function call). An in-process server is commonly referred to as an *ActiveX* control.
2. *Local server:* A local server executes in a separate process space on the same computer. Communication between an application and a local server is accomplished by the COM runtime system (implemented in OLE32.DLL and SVCHOST.EXE). The performance overhead of using a local server is typically an order of magnitude greater than that of using an in-process server.
3. *Remote server:* A remote server executes on a remote computer. DCOM provides an RPC-based infrastructure that is used to manage communication between the application and the remote server. The performance overhead of using a remote server is typically an order of magnitude greater than that of using a local server.

An application that uses a COM component may request to be connected to a specific type of server if it wishes to do so — however, it is not required to know what type of server it is using. After a client has obtained a COM object instance handle, client interaction with the COM object is the same regardless of server location. This allows for great flexibility during the design of a component-based system.

COM is a very mature component architecture that has many strengths. Thousands of third-party ActiveX controls (in-process COM components) are available in the market today. Microsoft and other vendors have built many tools that accelerate development of COM-based applications. Microsoft is also providing advanced services such as Microsoft Transaction Server (MTS) and Microsoft Message Queuing Server (MSMQ) to support the development of enterprise multi-tier systems. Microsoft has been using the name COM+ to identify the bundling of the COM runtime with those services.

© 2005 by CRC Press LLC

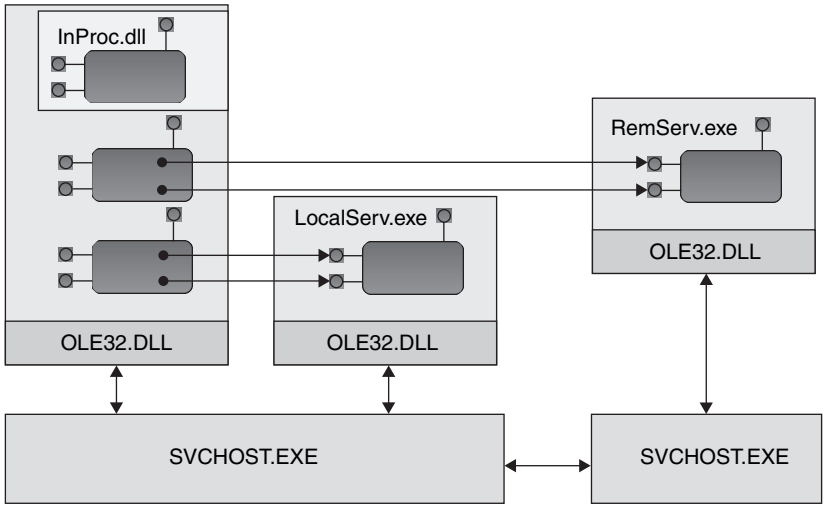

FIGURE 4.5 Styles of COM server components

Especially platform limitations — COM support is extremely limited on UNIX and mainframe platforms — as well as a less than perfect integration of the COM IDL type system with those of the component implementation languages present weaknesses that prevent COM from being an ideal single distributed component-based computing environment. However, Microsoft has carried on many of COM's concepts into the new .NET framework — which has the potential to alleviate most of COM's limitations.

4.7 Java and the Remote Method Invocation Model

The pervasive influence of Java has resulted in several Java-based distributed object architectures. The most ubiquitous is the Java RMI, a remoting architecture that shipped in 1997 with version 1.1 of the Java Development Kit (JDK). Java RMI is a Java-only solution that provides an elegant mechanism for allowing remote invocations on Java objects.

The usage of Java RMI continues to increase because it provides the remoting infrastructure for Enterprise JavaBeans and future systems like SUN Microsystems' JavaSpaces (which actually pick up the concept for de-coupled communication via a tuple space first introduced with the Linda coordination language (Gelernter and Carriero 1992) and Jini. The most significant disadvantage of Java RMI is that it can be used only with the Java programming language. Using both Java RMI and CORBA can alleviate this disadvantage. In fact, the Java-to-IDL mapping recently added to CORBA 3.0 eliminates the need to use Java RMI in many situations.

At the most basic level, RMI is Java's RPC mechanism. RMI has several advantages over traditional RPC systems because it is part of Java's object-oriented approach. Traditional RPC systems are language-neutral, and therefore are essentially least-common-denominator systems — they cannot provide functionality that is not available on all possible target platforms.

RMI is focused on Java, with connectivity to existing systems using native methods. This means RMI can take a natural, direct, and fully powered approach to implement a distributed computing technology that allows to incorporate Java functionality throughout a system in an incremental, yet seamless way.

The primary characteristics of RMI are:

Object orientation: RMI can pass full objects as arguments and return values, not just predefined data types. The programmer can pass complex types, such as a standard Java hashtable object, as a single

© 2005 by CRC Press LLC

argument. In existing nonobject-based RPC systems, the client would have to decompose such an object into primitive data types, ship those data types, and than recreate a hashtable on the server. RMI allows shipping objects directly across the wire with no extra client code.

Mobile behavior: RMI can move behavior (class implementations) from client to server and server to client. Operations, such as checking constraints on user input, can therefore be checked on the client side — providing faster feedback to the user and less load on the server — without installing any new software on the user's system.

Design patterns: Passing objects from server to client and *vice versa* allows extending object-oriented technology into distributed computing, such as two- and three-tier systems. All object-oriented design patterns rely on different behaviors for their power; without passing complete objects — both implementations and type — the benefits provided by the design patterns movement are lost.

Safety and securety: RMI uses built-in Java security mechanisms to ensure system integrity when users are downloading implementations. RMI uses the security manager defined to protect systems from hostile applets to protect the systems and network from potentially hostile downloaded code. In extreme cases, a server can refuse to download any implementations at all.

Easy to write/easy to use: RMI makes it simple to write remote Java servers and Java clients that access those servers. A remote interface is an actual Java interface. A server has roughly three lines of code to declare itself a server, and otherwise is like any other Java object.

Connects to existing/legacy systems: RMI interacts with existing systems through Java's native method interface JNI. Using RMI and JNI, Java clients can still use existing server implementations. Similarly, RMI interacts with existing relational databases using JDBC without modifying existing non-Java source that uses the databases.

Distributed garbage collection: RMI uses its distributed garbage collection feature to collect remote server objects that are no longer referenced by any clients in the network.

Because of its use in technologies such as Enterprise JavaBeans, JavaSpaces, and Jini, Java RMI will be found in many large software systems. It currently appears, however, that Java RMI will not dominate as a general remoting architecture because of its reliance on a single programming language.

4.8 The Microsoft .NET Framework

Microsoft announced the .NET initiative in July 2000. The .NET platform is a new development framework with a new programming interface to Windows services and APIs, integrating a number of technologies that emerged from Microsoft during the late 1990s. Incorporated into .NET are COM+ component services, the ASP web development framework, a commitment to XML and object-oriented design, support for new web services protocols such as SOAP, WSDL, and UDDI, and a focus on the Internet (Thai and Lam 2002).

.NET also marks a departure from earlier component systems by requiring each component (assembly in .NET jargon) to carry meta-data. Meta-data are used by the system for integration with legacy technologies, such as COM; however, since component meta-data are extensible from the programming language level through the *attribute* construct, .NET allows the programmer to explicitly express component properties and requirements, such as security, resource usage, timeliness, or fault-tolerance assumptions.

.NET responds to the following trends in the middleware arena today:

Distributed computing: .NET provides a remoting architecture that exploits open Internet standards, including the Hypertext Transfer Protocol (http), Extensible Markup Language (XML), and Simple Object Access Protocol (SOAP).

Componentization: .NET extends the previous COM component model but provides a significantly simpler way to build and deploy components.

Enterprise services: .NET supports the development of scalable enterprise applications without writing code to manage transactions, security, or pooling.

© 2005 by CRC Press LLC

Web paradigm shifts: Over the last few years, web application development has shifted from connectivity (TCP/IP), to presentation (HTML), to programmability (XML and SOAP). A key goal in .NET is to enable software to be sold and distributed as a service.

Maturity factors: Although .NET is a relatively new framework, it builds upon the mature COM+ technology and services.

Comparable to the XML/Value mapping introduced with CORBA 3.0, .NET provides a bidirectional mapping between XML and objects in .NET. For example, a class can be expressed as an XML Schema Definition (XSD), an object can be converted to and from an XML buffer, a method can be specified using the XML-based Web Services Description Language (WSDL), and an invocation (method call) can be expressed using the XML-based SOAP protocol.

The Microsoft .NET platform consists of five main components. At the lowest layer lies the operating system, which can be one of a variety of Windows platforms (CE, ME or 2000/XP) — and, since a substantial part of the .NET framework has been made publicly available as Shared Source Common Language Infrastructure (SSCLI or Rotor) and ported — the UNIX-based FreeBSD and Mac OS X operating systems. On top of the operating system lies the .NET framework (the Common Language Runtime (CLR) plus a collection of library classes), a series of Windows-based .NET Enterprise Server products, and .NET Building Block Services (such as .NET My Services). At the top layer of the .NET architecture resides a development tool — Microsoft Visual Studio.NET.

The COM component framework allowed for component reuse on the binary level. However, in order to use COM components from different languages, the programmer had to obey COM identity, lifetime, and binary layout rules. Also, programmers were required to write plumbing code to create COM components. Being based on a *Common Type System* (CTS), all .NET classes are ready to be reused at the binary level from any of the .NET implementation languages.

Microsoft .NET supports not only *language independence* — as COM did — but allows for *language integration*. This means .NET classes can inherit from each other, catch exceptions, and take advantage of polymorphism across different languages. The CTS specifies that any entity in .NET is an object, derived from a root class System.Object. The CTS supports the general concepts of classes, interfaces, delegates (which support callbacks), reference types, and value types.

Figure 4.6 shows the structure of the .NET framework. The Common Language Runtime (CLR) forms the most important component of the framework. Comparable to the Java Virtual Machine (JVM), the CLR activates objects, performs security checks on them, lays them out in memory, executes them, and garbage collects them.

Conceptually, the CLR and JVM are similar in that they are both runtime infrastructures that abstract the underlying platform differences. However, while the JVM currently only supports the Java language, the CLR supports all languages that can be represented in the CIL. Microsoft has submitted the Common Language Infrastructure (CLI), which is a functional subset of the CLR, to European Computer Manufacturers Association (ECMA) for standardization; thus, a third-party vendor could theoretically implement a CLR for additional operating system platforms.

In Figure 4.6, the layer on top of the CLR is a set of framework base classes, comparable to the Java class library. These classes support input/output functionality, text and string manipulation, security management, network communications, thread management, reflection functionality, as well as other functions. The framework base classes also implement .NET remoting — an object-based interaction scheme that is comparable to Java RMI.

On top of the framework base classes is a set of classes that provide support for data management and XML manipulation. The data classes also support persistent data management. Finally, classes in three different technologies (Web Services, Web Forms, and Windows Forms) extend the framework base classes and the data and XML classes. Web Services support the development of lightweight distributed components, which will work even in the face of firewalls and Network Address Translation (NAT) software. These components support wide-area distributed computing, because Web Services employ standard http and SOAP.

4.9 Future Trends: Resource Management and Quality-of-Service

The abstractions offered by various middleware frameworks can be used to provide resource management in a distributed system at a high level. These abstractions can be designed to be rich enough to subsume the three kinds of low-level resources an operating system manages: communication, processing, and storage (memory and disks). Middleware abstractions are also from an end-to-end perspective not just of a single host, which allows for a more global and complete view to a resource management system. Distributed objects are promising, as they not only encapsulate but also cleanly integrate all three kinds of resource into a coherent package. This completeness helps distributed resource management and makes it easier to provide for load balancing, mobility transparency, and overall system reliability.

Distributed systems are inherently very dynamic, which can make them difficult to program. Resource management is a prerequisite for predictable system behavior; but is often not enough for most distributed applications. Starting from the late 1990s, distributed systems research has begun to focus on providing comprehensive Quality-of-Service (QoS), an organizing concept referring to the behavioral properties of an object or system, to help manage the dynamic nature of distributed systems (Zinky *et al.* 1997). The goal of the research is to capture the application's high-level QoS requirements and then translate them down to low-level resource managers. QoS can help runtime adaptation. But it also helps the applications evolve over their lifetime to handle new requirements or to operate in new environments, issues more in the domain of software engineering but also of crucial importance to users and maintainers of distributed systems.

Recent middleware frameworks, like the CORBA 3.0 Component Model (CCM), or the Microsoft .NET framework, allow the expression of nonfunctional component properties, such as resource requirements, timing and security constraints, or fault-tolerance assumptions on the component level using language constructs (like C# and .NET attributes) or component meta-data (like CCM's deployment descriptors). Aspect-Oriented Programming (AOP) is a relatively new discipline that focuses on cross-cutting concerns (targeting many components of a system simultaneously) and nonfunctional component properties. AOP investigates software engineering approaches toward predictable component-based systems. This research opens up new venues for middleware-based architectures on the enterprise level.

5.1 Overview

Microsoft component technologies are of central importance for Automation and Control, if for no other reason, because they are the basis for OLE for Process Control (OPC), the standard for SCADA/PLC integration. Another reason is, of course, the predominance of MS Windows as the operating systems for microcomputers, which makes Microsoft's component model the most widely used in the world. In addition to this is the large number of applications developed using Visual Basic, perhaps the most widely used programming language nowadays, which generates components even if the programmer is unaware of them.

The word "component" has different meanings for different people. As defined in this chapter, it refers to the smallest piece of software built to be reused in binary format, packing inside the same file a set of related (according to designer view) functionalities. A component is developed according to a *component model*, which is, simply stated, a set of standards and implementations to allow its use and reuse, including,

© 2005 by CRC Press LLC

among others, binary file format, life cycle control (how is it found, how to load/unload), and invocation conventions (how to execute a function inside the component, passing parameters, and getting results back).

It is worth separating the component model from its *runtime environment*, as long as the same component can be run in different environments. For some technologies, there is a one-to-one correspondence (such as in CORBA); but for Microsoft technologies, a component built under one model can be run in different runtime environments. A component runtime environment can provide a large number of services, to allow comfortable development of business applications: transactional control, security, administration are among the most important ones.

Over the recent years, Microsoft provided a number of technology frameworks for components, with similar names but different functionalities. The literature does not provide a uniform view. Given the above definitions, MS component technology includes the following *component models*:

- Component Object Model (COM), which also includes Distributed COM (DCOM) for local (inside only one computer) or remote components.
- .NET[1]: The newest Microsoft achievement in component technology, providing language-independent components.

As *runtime environments*, Microsoft developed:

- MS Windows operating system, providing basic services for locating and component load/unload.
- COM+, providing transactional control, security, administration, and some other services for COM and .NET components.
- .NET, providing about the same services as COM+, but solving many of the problems found in it.

This chapter provides an overview of each of these component models and runtime environments.

5.2 Scope

COM/DCOM/COM+/.NET is a lengthy subject for a single chapter, more so considering different audiences (programmers, architects, end-users, etc.). Therefore, this chapter is devoted to technical audiences, exploiting the subject on its functional aspects. No source code examples are provided; but there are plenty in the references cited.

From all aspects included particularly in component runtime environments, special attention has been devoted to basic mechanisms and Automation and Control requirements, particularly on the shop floor level. Therefore, enterprisewide requirements, such as transactional control and security, more related to the upper levels of CIM pyramid and data-centric systems, are not discussed in this chapter.

Microsoft component-related technologies have a long history. Many concepts were formulated; some have not lasted. As far as possible, the material presented here corresponds to what is available on MS Windows 2000, which closely resembles MS Windows XP. No attempt has been made to provide a broader view, covering the various MS operating systems versions (Windows 95, 98, ME, NT) nor update packages made available by Microsoft. The technologies involved do not have a strict version control numbering (at least, not publicly available), making it impossible to characterize its current status by version numbers.

5.3 Some on the Past and Present

The need for loadable modules to ease application development had been recognized in the late 1960s (Tannenbaum, 1987). In the process of generation of an executable program, after compilation of source code into binary modules, it is necessary to link all compiled modules to libraries of existing modules. This link process can be done:

- Statically, meaning that all object and library modules will be assembled in a single, executable module.
- Dynamically, meaning that some object and library modules will be only loaded in runtime.

[1]It shall be read as "dot net."

© 2005 by CRC Press LLC

Microsoft's MS DOS only allowed for static linking; but the possibility of dynamically loaded libraries (known as DLL) has been present since the first version of its Windows operating system, in the mid-1980s. At that time, a DLL was simply a bunch of functions, packaged in a single file, in a predetermined binary format, allowing to determine which functions were included and where they were inside the file.

Object-oriented concepts were spreading very fast and soon Microsoft realized its potential. In the process of creating its client-side (Windows 9x) and server-side operating systems (known as Windows NT and its successors), the need for an object-oriented component model was clear, and the COM model was therefore specified, in 1992 (Microsoft, 1995).

COM components are the basis of the Microsoft's Compound Document Model, perhaps better known as Object Linking and Embedding (OLE) automation. Every MS Office end-user, for instance, uses OLE when he or she inserts an MS Excel worksheet into an MS Word document and edits it from MS Word. In other words, the worksheet is a compound document and every application complying with OLE (as MS Excel) provides a set of functions to allow for in-place (i.e., inside MS Word) activation. OPC, described elsewhere in this book, is also an application based on this standard. As shown in Figure 5.1, OLE is actually a set of higher-level technologies built upon COM, supporting user-interface-oriented features for application integration and task automation.

For programmers, since Visual Basic version 3 back in the very beginning of the 1990s, OLE has become extremely important in the use of visual components. For the first time, appealing visual interfaces could be drawn using drag-and-drop of visual components and with very little programming effort. The acronyms VBX (Visual Basic Custom Control), OCX (OLE Custom Control) and ActiveX correspond to three versions of OLE components, showing an evolution from 16-bit, incomplete object-oriented model to full 32-bit, object-oriented components.

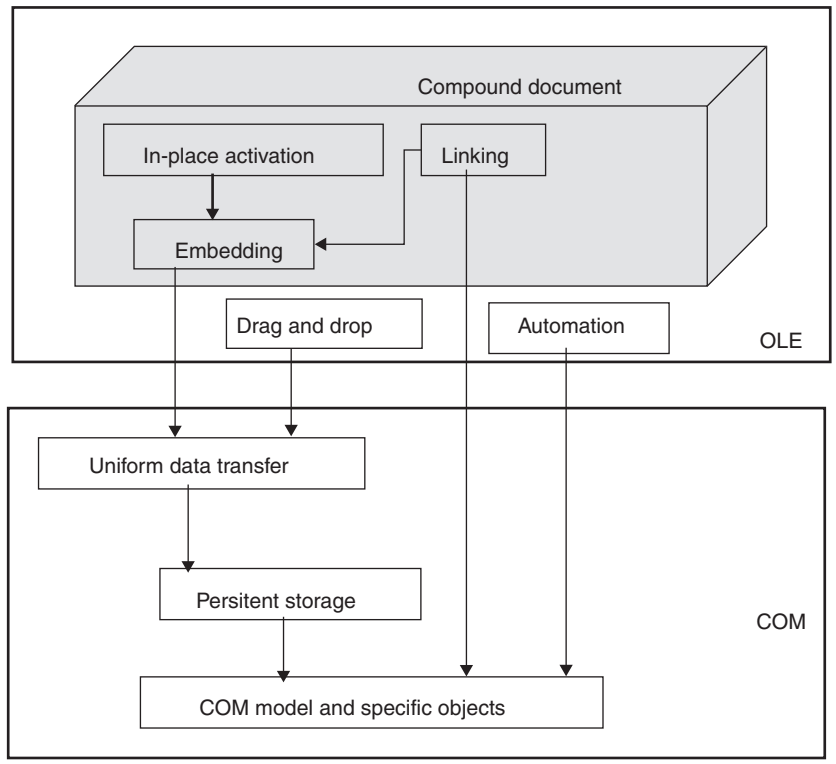

FIGURE 5.1 OLE and COM (based on Microsoft, 1995).

© 2005 by CRC Press LLC

COM specification defines three types of *server*, that is, "some piece of code that structures some object in such a way that COM 'implementor locator' services can run that code and have it create objects" (Microsoft, 1995). They are as follows:

- In-process server, when a server is loaded within client running process. In other words, the component is activated as a local call, as any other function in the same program.
- Local server, when a server runs in a separate process from the client's, but on the same machine.
- Remote server, when a server runs on a machine other than the client's.

The set of specifications for remote servers is known as DCOM. DCOM was previously called "Network OLE" and is based on Open Software Foundation's Distributed Computing Environment, Remote Procedure Call (DCE-RPC) (OSF, 1995), a mid-1980s environment for distributed applications. DCOM appeared in 1995.

But component activation is not sufficient to comfortably develop components for mission critical applications; a comprehensive environment is needed, encompassing transactional control, component administration, security, just-in-time activation, object pooling, synchronization, event, and asynchronous messaging. Microsoft first announced during its 1997 Professional Developers Conference its plans to build such an environment and called it COM+. Today, the acronym COM+ is heavily overloaded and misused, meaning this runtime environment and new versions of COM specification (Lowy, 2001). In this text, COM+ will be used to refer only to the runtime environment, leaving COM as meaning a component model.

In 1998, Microsoft first released its Microsoft Transaction Server (MTS), combining the features of a transaction processing (TP) monitor and an object request broker, the first element to build a scalable environment for application with easy administration by a graphical tool (MMC, Microsoft Management Center). MTS is one of Microsoft's greatest technological achievements, bringing to its platform functionalities only available on mainframes (such as CICS), easy-to-use, configurable, and manageable from graphical interfaces. MTS was then integrated into Internet Information Services (IIS) and Distributed Transaction Coordinator (DTC) remained as the transaction manager for distributed transactions.

Components do not include everything required to build real applications. Therefore, about the same time, Microsoft announced Windows DNA (Distributed Internet Applications Architecture), a set of system services and applications to tie in a single model all the requirements, including (Redmond III, 1999):

- *Presentation services*: HTML, DHTML, scripting, graphical components, Win32 API.
- *Application services*: Internet Information Server (IIS, Microsoft's web server), MSMQ (asynchronous messaging), MTS, COM+.
- *Data services*: ADO, OLE DB.
- *System services*: directory, security, management, networking, and communications.

MS Windows XP, a direct descendent from Windows 2000, includes COM+1.5, the latest COM+ version. It includes SOAP services, configurable transaction isolation level, application partitioning for large-scale environments, pooling and recycling, enabling/disabling/pausing, and improved managing capabilities, among others (Lowy, 2001).

COM+1.5 immediately preceded .NET. Some authors refer to .NET as COM+ (Nilsson, 2002), mainly because .NET was based on ideas (not code) of COM+. COM+ is not dead; as stated before, it can host COM and .NET components, which means they are a natural (perhaps the only) choice to support the addition of new functionalities on legacy systems built upon it.

.NET as a component model brings (Nilsson, 2002):

- A common runtime environment for any programming language, allowing for language interoperability.
- Automatic memory allocation/de-allocation (garbage collection).
- Inheritance, including inter-language inheritance.
- Strong security model, confining execution path and data to allowed portions.

© 2005 by CRC Press LLC

- No need for IDL or interface declarations; methods can be used and declared directly within classes.
- New forms of remote method invocation, especially SOAP.

As a runtime environment, .NET includes:

- Transactional semantics, security, component administration, JITA (just-in-time activation), and other functionalities as in COM+.
- Business-oriented servers, such as BizTalk Server for B2B process automation, Commerce Server for e-commerce, Content Management Server for multimedia content publishing over the Web, Identify Server for single sign-on, and others.

Clearly, .NET builds upon COM/COM+ and the Internet a new application development framework, requiring the revision of well-established concepts and workflows. As Microsoft states, '.NET is a vision and a set of software technologies for connecting information, people, systems and devices.'

In what follows, each of the above-mentioned technologies is briefly described in more technical terms.

5.4 COM/DCOM

COM is an open standard, is publicly documented, and addresses the building of a component-based architecture. It is a distributed, object-oriented model. As stated before, it is the core technology for all Microsoft's component architectures. DCOM is the name by which a part of COM specification is known, related to remote method invocation. Therefore, DCOM is just a part of COM.

To describe a component model, it is necessary to characterize the following:

- The component interface, that is, the methods it will expose to clients.
- An identification mechanism, that is, the "name" or "unique identification" of an object to allow it to be found among hundreds (perhaps thousands) of different objects.
- Runtime environment requirements, that is, what is assumed as runtime responsibilities to allow a component to be created and deleted, or its life cycle.
- Invocation process, that is, how a component is found, its interface returned to client, and how to handle parameters passing to and back from the component, including data type conversion.

It is important to note Microsoft's attempt to conceal all complexities involved in creating COM components. A Visual Basic programmer, for instance, can create COM components without knowing any of the concepts discussed here, just because VB development tools are able to conceal all these details. But they are there, allowing components to communicate.

Client–server Model

Most of the time, a synchronous invocation of a component's method is what is need. Synchronous invocation, also known as the client–server communication model, involves, as shown in Figure 5.2, the following:

1. server object creation,
2. implementation location,
3. interface returned to client,
4. interface method invocation.

COM introduces the idea of location transparency, allowing a server to be:

- In-process, when it runs inside client's process.
- Local, when it runs in a process different from the client's, but on the same machine.
- Remote, when the server runs on a different machine.

These three situations are illustrated in Figure 5.3.

When running in-process, the component becomes a part of client's process, allowing for a direct invocation almost as if they were statically linked. But when running in local- or remote-mode, a

© 2005 by CRC Press LLC

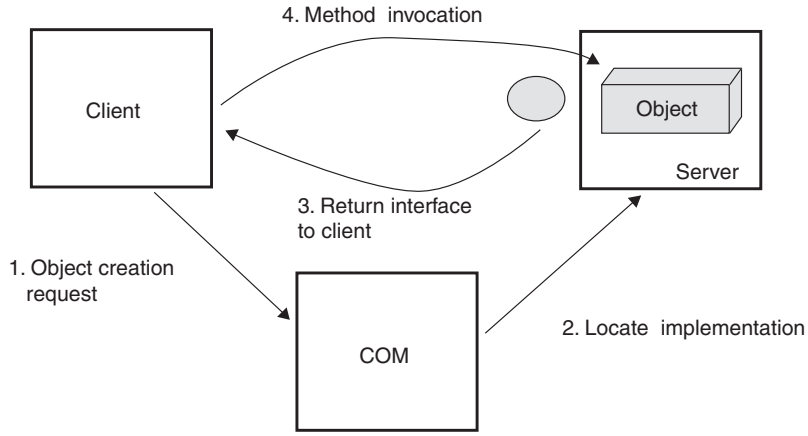

FIGURE 5.2 Client–server model (based on Microsoft, 1995).

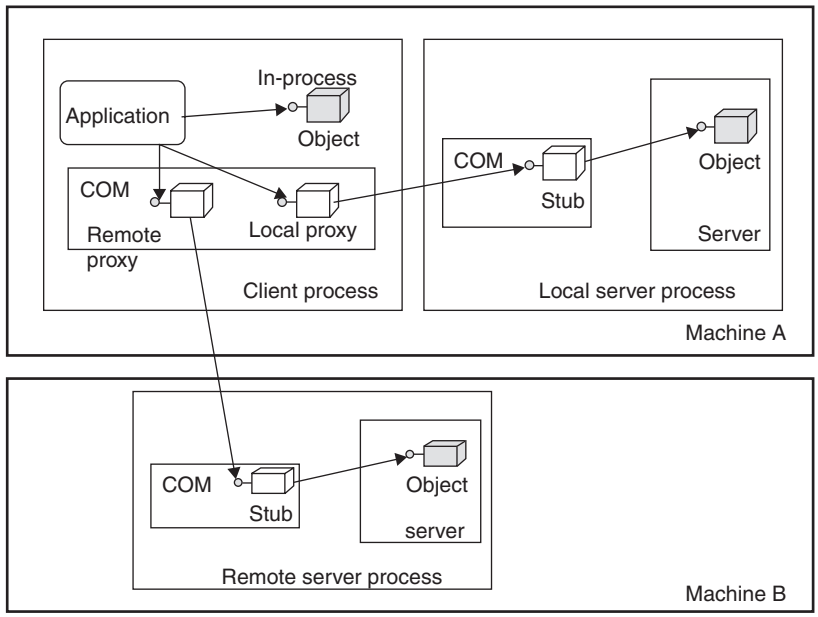

FIGURE 5.3 COM servers (based on Microsoft, 1995).

proxy-stub mechanism (similar to CORBA's stub-skeleton) is generated. A proxy is a local (to client) view of the component; its responsibility is to pass a method invocation request to the corresponding stub, converting parameters into a standard format.[2] On method return, the method output results are passed back to the proxy, which converts it back to the caller's data type and returns control to the client.

Interfaces and Objects

A component is characterized by its interface, that is, the methods it exposes to clients. Often referred as a "contract" between client and object, the interface determines the method's name and input parameters, output results and, in some cases, exceptions thrown.

[2]This process of converting parameters in a standard format to/from stubs is known as marshaling.

© 2005 by CRC Press LLC

Interfaces can be specified in Microsoft Interface Definition Language (MIDL). These are discussed here, even bearing in mind that most COM programmers (especially VB) have never heard of them. So, by understanding these interfaces, the "magic" behind them, which would otherwise go unnoticed, is revealed. It is important to note that COM is a binary specification, independent of any source-level tools used to create components. In other words, it is not mandatory to generate an interface definition using MIDL to create COM components; they can be directly generated in binary format.

Code 1 shows an example of interface specification in MIDL.

```
[obiect, uuid (b5483f00-4f6c-101b-alc7-00aa00389acb)]
interface ICalc : IUnknown {
      [id(1),helpstring ("method add")]
      HRESULT add ([in] int x,[in] int y, [out, retval] int* r);
}
```

Code 1 MIDL (simplified) example.

If you have already read the chapter on CORBA, you will immediately notice the similarities between them. It is not a coincidence; both COM and CORBA were inspired by Open Software Foundation's DCE-RPC. But DCE-RPC is function (not object) oriented, while MIDL has been extended to provide object-oriented semantics, especially interface inheritance and method overload, resulting in what is called ORPC (Object RPC).

Code 1 is quite straightforward to understand the following:

- The object attribute determines ORPC coding generation, as opposed to DCE-RPC.
- The uuid attribute (universal unique identifier) provides a universal unique identifier to this interface; more on this in what follows.
- The interface keyword states the beginning of an interface declaration; in this case, it was named as ICalc and inherits (as all COM components) from *IUnknown* interface.
- The attribute id determine a numeric identifier for the add method within ICalc interface, while helpstring gives a human readable name for this method.
- Finally, the add method is declared. All synchronous methods in COM must return HRESULT. The [in] and [out] clauses specify parameters input and output.

An interface must be implemented by some object to be callable. But from COM's point of view, only the interface matters.

Returning to Figure 5.3, the client maintains a pointer to the interface. This pointer is actually a pointer to an array of pointers to interface member functions. Therefore, even on in-process method invocation, there is a double indirect address resolution to actually invoke a method. This situation is illustrated in Figure 5.4.

These data structures are necessary to control an object's life cycle, because COM infrastructure must be aware of which interfaces are in use and when to free those not needed anymore.[3]

Basic Interfaces

COM defines two basic interfaces: *IUnknown* and *IDispatch*. All COM components implement one or the other, which is the same to say that all COM interfaces must inherit from one or another. The bottom line is that all COM components implement IUnknown since IDispatch inherits from it. *IUnknown* has three methods:

- QueryInterface(), which allows a client to request any other interface that the object supports.
- AddRef(), called every time a new client requests access to an interface.
- Release(), a function complementary to AddRef(), called by a client to notify that it is not requiring access to the object anymore.

[3]This mechanism is also known as "smart pointers."

© 2005 by CRC Press LLC

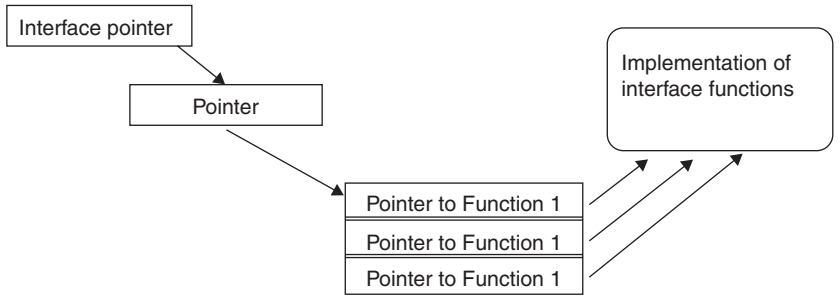

FIGURE 5.4 Interface data structures.

AddRef() and Release() control object life cycle, while QueryInterface() allows a client to gain access to an interface implemented by some object.

IUnknown is central to COM model because it provides the basic mechanism to retrieve an interface. Since all COM components must implement IUnknown, the QueryInterface() method can be called on any component, allowing to retrieve an interface. It reveals another aspect of interface-based component construction: a single object (or component) may support a number of interfaces.

IDispatch inherits from *IUnknown* and has four methods:

- GetIDsOfNames(), which maps a single member and an optional set of argument names to a corresponding set of numeric (integer) method identifier (DISPIDs or Dispatch ID).
- Invoke(), which provides access to properties and methods exposed by an object.
- GetTypeInfo(), which gets the type information for an object.
- GetTypeInfoCount(), which retrieves the amount of type information provided by an object (either zero or one).

Through the use of GetIDsOfNames() and Invoke(), it is possible to dynamically invoke a method, by knowing only its name. Before DCOM, IDispatch was the only way to implement remote method invocation. By using IDispatch, a client can directly invoke a method of an object, instead of retrieving an interface. This is called "late binding" (in contrast to the so-called "early binding" when using IUnknown), and it is the only possibility to access a component when a type library is not available. It requires two calls to the component; one to GetIDsOfNames() to retrieve a DISPID and the second to call the method, eventually passing parameters using the VARIANT data type.

Interface Identification and Registration

In Code 1 above, a universal unique identifier (UUID) was associated with the interface. An interface identifier (IID) is a 128-bit statistically generated number. Microsoft's development environments (such as Visual Studio) have functions to generate these values. They are also known as Globally Unique Identifier (GUID). The object itself (which contains one or more interfaces) is uniquely identified by its Class ID (CLSID), which is a number in the same format as UUID.

When retrieving interfaces through IUnkown, a client requests COM runtime environment to provide access by specifying the UUID. If using IDispatch, a client must first gain access to an object, which is achieved by specifying the component name and retrieving its CLSID (if CLSID was not known in advance). In both situations, the Registration process is central, allowing to maintain, in a kind of database, the UUID/interface/object and CLSID/object association. In some sense, this registration is similar to CORBA's Naming Service; its goal is to allow an interface to be located within an object implementing it.

In the beginning of the 1990s, it was enough to copy the DLL containing the component to the MS Windows installation directory. Nowadays, however, components must be registered in the Windows Registry to become useful. This registration is automatically done when using some development tools

© 2005 by CRC Press LLC

(such as Microsoft's) or when installing a new application. To manually register a component, tools such as regsvr32 or MMC (Microsoft Management Console) are available.

Type Libraries

A type library is a description of an interface in a format that can be easily parsed and read by any application or development environment via Windows system calls (Win32 functions). Microsoft decided to include this concept to its component environment to allow for the support of different programming languages, object-orientation, and to automatically find and run server upon client request. In a Visual Basic development environment, for instance, it is the existence of a type library that allows for the browsing of methods and attributes (Properties, in VB terms) of a component, independent of the language the component was written in. It also allows for compile-time syntax checking, because the VB environment (for instance) "knows" what it is inside the component. The "Properties Sheet" on any visual development tool is also an application of type library concept.

Type libraries are also in action during marshaling parameters when calling remote functions (COM invocation other than "in-process" mode). The COM runtime environment reads type information that also contains instructions on parameter data types. Having these instructions, COM is able to convert parameters for remote call.

Sometime ago, type libraries existed in a separate file with .TLB extension. Nowadays, this information is inside the component .DLL file, which eases component distribution because everything is inside a single file.

Strictly speaking, a type library is not required in COM technology, because "in-process" invocation can be done directly in some cases or the IDispatch interface can be used. But with COM+ and modern development environments, it became essential, which makes them, for all practical purposes, mandatory.

DCOM

DCOM is about remote method invocation. Every time a call to an object's method crosses the boundaries of a caller's process, there is a remote invocation. Therefore, it can happen inside a single machine, when the client and component are to run different processes, or when two machines are involved. This section provides some details of the mechanisms involved in a remote call, which is the same to say, details of DCOM.

DCOM general architecture is depicted in Figure 5.5.

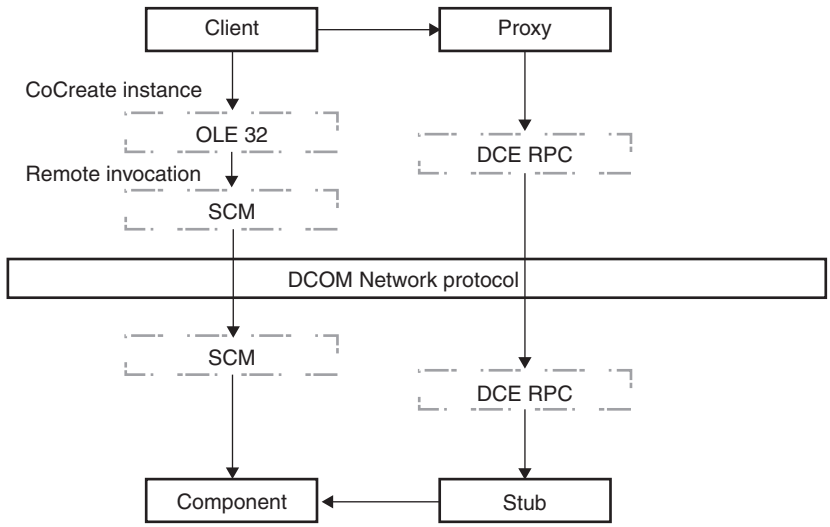

FIGURE 5.5 DCOM architecture (Microsoft, 1996).

© 2005 by CRC Press LLC

The basic mechanism, as mentioned before, is DCE RPC; a proxy object on client's side packs all arguments of a call (which is also known as "marshaling") and sends them (normally, via a TCP/IP socket) to the server. The DCOM network protocol controls this communication. Once at the server, the arguments are unpacked (unmarshaled) and passed to the component. Returned results follow the same path back to the client.

One of the major strengths of the COM architecture is to allow for location transparency. In other words, COM will select the best way a component will run, among the three server modes described above. Whenever possible, "in-process" is selected, because it is the fastest way; in this case, there is no remote method invocation (therefore, no proxies, no RPCs). This transparency is provided by COM's *CoCreateInstanceEx()* method,[4] which will first search the Registry for local DLLs implementing the required interface, then for a local process within client's machine and, finally, on remote machines. Technically, this last case is named as DCOM.

To be able to instantiate an object on a remote machine, COM libraries must know the server's network name and the required interface (CLSID). Once both are known, client's COM library contacts (via its local SCM, Service Control Manager) the remote SCM, through a well-known end-point TCP/IP port (normally, the standard DCE RPC port, number 145). The remote SCM instantiates the object dynamically allocating a port. Then, SCM responds to the client, informing the selected port. From this point, conversation (i.e., method calls) can be made directly from the client to component, without passing through SCM.

CLSID are normally given to the client as fixed data, as long as the interface ids are known in advance. To discover the server's network name, one of the following approaches must be followed:

1 An explicit parameter on CoCreateInstanceEx().
2 As a fixed configuration parameter within the Windows Registry or application's infrastructure (for instance, from a .INI file).
3 In a DCOM class store, which acts as an interface repository.

The first two situations are quite straightforward and require no further comments. The last approach has been possible (or, at least, has been directly supported by MS Windows) since the introduction of Windows 2000, and involves the use of the so-called Active Directory infrastructure to store activation-related information. Active Directory is responsible for holding all user-related information, such as login name, passwords, and others. This way, it behaves in a manner similar to the Naming Services in CORBA Architecture. This simplifies administration, because changes will automatically propagate to all clients.

DCOM also provides a solution for interface reference count, because a remote object must know when an instance has been released. In case of client crash or network failure, an instance must be de-referenced. DCOM provides a "pinging mechanism," which implies the server to "ping" (try contact) the client in a programmable time interval. Each time a certain number of "pings" are not responded to, the server assumes abnormal client termination and removes it from the reference list.

DCOM also defines a mechanism for asynchronous calls (Async DCOM), which is not recommended anymore, as discussed below.

5.5 COM+

There are two ways to understand COM+: either as an evolved COM version (therefore, a component model) or a component's runtime environment. Actually, it is both: because of this, several changes/enhancements were introduced in COM specification and also, it is a runtime environment supporting transactions, asynchronous messaging, and many other features. In this contribution, it will be treated as a runtime environment. The changes in COM specifications, therefore, will be separated from COM+ and considered as belonging to COM. Actually, the material discussed in the previous section also included some features only available after COM+ shipping.

[4]Actually, there are other COM functions which can be called; *CoCreateInstanceEx()* is just the more comfortable and used.

© 2005 by CRC Press LLC

As stated by (Brill, 2001),

COM + = COM – older, now unnecessary appendages
+ Event Notification
+ Object Pooling
+ Transactions
+ Queuing
+ Role-based security

Still, following (Brill, 2001), "COM+ is a fusion of traditional COM, MTS and MSMQ," where:

- Microsoft Transaction Server (MTS) enables two or more COM objects to participate in a transaction, adding the "2-phase commit" semantics to transactions.
- Microsoft Message Queueing (MSMQ) enables asynchronous (message-driven) calls between objects (COM only allows for synchronous calls). MSMQ implements guaranteed message delivering, by storing messages in a persistent storage (file, database) prior to sending and only removing after being received.

In the above, IIS, Microsoft's webserver, could also be included since it is a very frequent application server (i.e., the process within which a component runs) in the so-called "web architecture." In fact, since the introduction of Active Server Pages (ASP) with the IIS version 3.0, it became a "de facto" standard for the development of ASP pages activating COM components. An ASP page is a script that contains a mix of HTML tags (to display in a browser) and source code (normally, in a language derived from Visual Basic, called VBScript). In this way, an ASP page can format a screen to be sent to a web browser and do any kind of computational work, including database access. Including IIS in the COM+ definition makes even more sense if it is considered that Microsoft packed MTS within IIS 4.0, making them a single product. Starting with IIS 4.0, a number of IIS components could benefit from this merge, leading to a more component-based product.

Among other requirements, COM+ demands all components to be "in-process" (see the above discussion on COM server modes) and to have a type library. Therefore, a COM component must be "housed" within a process to be executed; normally, they will be within MTS or IIS.

As already mentioned, only topics related to Automation and Control on the shop-floor are discussed here to some extent. COM+ features more related to the upper levels of CIM pyramid and to data-centric systems are not covered, or mentioned.

Threads, Apartment, and Activities

A program is a file containing a piece of code compiled into binary (machine) language. A running program is called "process" and is the basic unit managed by an operating system. Nowadays, almost all modern operating systems (OS), including all Microsoft's OSs, starting with MS Windows 95,[5] offer support for "threads." A process is divided into different threads, each one representing a distinct flow in its computation and having its own memory space, although all threads share the same static memory space and code. Therefore, when an OS schedules a process to run, it selects one of its threads. A process, this way, is just a collective name for all the threads it contains and holds, constraints this collection of threads must deal with (for instance, the total memory available). In the days of single-threaded processes, a cooperative computation required some form of data sharing among processes; on the shop-floor (due to real-time constraints), it was normally accomplished by shared memory or semaphores. In a multi-threaded environment, global variables (static memory allocation) are visible to all threads, simplifying the development of applications. Special system calls allow for a thread start, stop, and the development of critical sections (where scheduling is prevented) for thread synchronization.

[5]Some readers may argue that MS Windows 3.11 supported multi-threaded, which is true. But scheduling was on developers' behalf, on a non-preemptive environment. Therefore, for practical (meaning: easy development) purposes, it was not there.

© 2005 by CRC Press LLC

Manual manipulation of threads, and especially of critical sections, is very error-prone and difficult. An error in thread synchronization may lead to race conditions where unexpected results may be obtained (for instance, one thread may alter the value of a variable controlling a loop in another thread, causing this loop to finish before it should do), due to the asynchronous nature of thread scheduling: a thread may be stopped for another one to run, at any time. COM+ incorporated the concept of "apartment" for easy development, although not allowing for a tailored schema. Apartment is a term used to describe groupings of related objects and threads aiming to protect COM objects not prepared to run in multi-threaded mode. The name apartment comes from the idea that a thread and some objects (the initial caller and all its callees) will "live" in one apartment. Apartment is just a concept; it does not map to any well-known operating system construct.

Three threading models are supported in COM+:

- Single-Thread Apartment (STA), when exactly one thread exists in one apartment.
- Multi-Threaded Apartment (MTA), when many different threads coexist in the same apartment. Objects must be thread-safe and, therefore, handle synchronization issues. In this case, invocation is exactly as an ordinary DCE-RPC.
- TNA or NTA (Thread Neutral Apartment), available starting with MS Windows 2000, when threads may enter an apartment momentarily, during a method call.

The desired thread model for a component is set by the component itself and can be chosen between:

- Apartment, which implies running only as STA.
- Free, to be handled as MTA even in cases when it could be handled as STA, being always subject to performance loss due to thread context switching .
- Neutral, which implies TNA (recommended if possible).
- Both, leaving the calling mode to decide among STA, MTA, or TNA. The name "both" came from the days when just two options were available.

The thread model is stored in the Registry beside other object information, because COM needs to know in which mode it initializes.

In STA, since just one thread exists in the apartment, all access is serialized. To accomplish this, a message queue receives all requests directed to the object. Message queues have been present in MS Windows architecture since its early days; at that time, every event (mouse move/click, keyboard hit, etc.) was (as still is) transformed in a Windows Message and queued, to be processed one at a time. This model is also applied to STA; during a call to a remote method, it is converted by COM into a Windows messages and queued. This clearly creates a huge performance penalty, as long as only one invocation can take place at a time. For large-scale (many users) or very fast systems, this will probably be unacceptable. Visual Basic until version 6 was only able to create components to run in the STA mode; C++ programmers do not have such limitations. STA is applicable to graphical interfaces (since all graphical components must run on this mode).

MTA works just like an ordinary DCE-RPC: a running process listens to requests on a determined port, waits for a remote client to connect, and makes a method call. A thread is then retrieved from a thread pool to deal with the request, on the apartment. When the thread pool is exhausted, a new thread is created. In this case, COM does not interfere. With MTA, there is no message loop, only RPC.

TNA is sometimes also called (Brill, 2001) a "rental mode," because during an invocation, assuming client and server are running in different threads, the called thread momentarily enters the caller's apartment. Therefore, the call can be made without context switching. Returning to the image of an apartment inhabited by objects and threads, TNA is just like an empty apartment where an object waits to be acted upon by a thread.

For concurrency control, COM+ introduces the idea of "logical thread" or *activity*. This idea came from a simple observation that there is only one root client. Therefore, from this perspective, there is a single running thread, even if the "physical" thread spans multiple threads, processes, and machines.

© 2005 by CRC Press LLC

Activities are particularly useful for MTA and TNA objects and maintain some resemblance to transactions, in the sense that normally a single transaction is involved when crossing various objects from a root client. An object may:

- DISABLE synchronization support, meaning that COM+ is told to ignore synchronization requirements.
- DOES_NOT_SUPPORT synchronization, preventing an object from participating in an activity.
- SUPPORT synchronization, when COM+ is instructed to share the activation context with the object if the object's creator had one, or will have no synchronization. It is the least applicable mode because of development complexity.
- REQUIRE synchronization, meaning an activity is shared with the creator's, or a new one is created if the creator had none.
- REQUIRE_NEW, when the object must have its own activity, different from the object's creator.

The example in Lowy (2001) makes the situation quite clear. Consider, for instance, the situation in Figure 5.6.

As depicted, Client_1 invokes Object_1 that, in turn, creates a new Object_2. If Object_2 is configured as "Required," a call from Client_2 will wait until the creation process is finished. On the other hand, if Object_2 is configured as "Requires New," Client_2 call is not blocked and Object_2 is capable of serving both requests at the same time.

Object Pooling

To avoid performance penalties due to (very) expensive processes of creating and destroying objects, COM+ provides *object pooling*. Therefore, before activating an object, it searches in the pool for a matching interface and returns it to the client, if found. After use, the object returns to the pool. Object lifetime can be configured using MMC.

To be pooled, an object must support the MTA or TNA threading model; therefore, Visual Basic 6 (and earlier) components cannot be pooled. Since the same object will be used in different activations, it must have no internal state (which is, anyway, the way objects are written using COM, as pure "function-oriented" components). If the object has to refer to external resources (database connections, for instance), it has to retrieve this information from the activation context.

Messaging and Asynchronous Calls

So far, components have been a "tight couple," since only client/server, synchronous calls were discussed. But COM+ also offers the possibility of asynchronous calls between components, using its Queued Components (QC), which rely on MSMQ product. MSMQ allows for:

- Guaranteed message delivery, if requested. In this delivery mode, messages are stored before sending on a persistent media (flat file, database) and are only removed when client receives it.

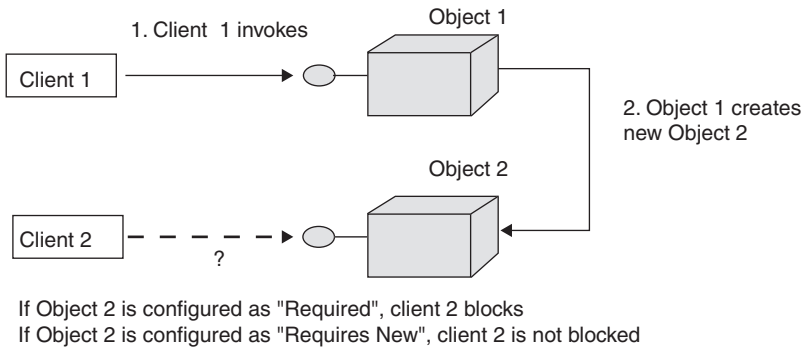

FIGURE 5.6 Synchronization.

© 2005 by CRC Press LLC

- Logging services, allowing messages to be stored for later review.
- Security, allowing permissions to be granted for specific queues to senders/receivers and also including message encryption, avoiding tampering.
- Distributed transactions, associating message sending/receiving with database transactions in a single, two-phase commit, transaction.

QC is just a set of few components, covering the MSMQ C API. Therefore, it is very straightforward to use. Message-oriented communication is based on *queues*. On QC, a queue is neither a fixed connection nor an asynchronous path between two components, or a directional path. Therefore, any component is allowed to send messages through a queue; similarly, any one can read messages from that queue. Queues always follow First-In, First-Out (FIFO) discipline. Queues are completely independent of applications that created them; once created, they will exist forever, unless destroyed by using MMC.

QC is also the basis for asynchronous calls. Any object can be reached via asynchronous call provided:

- Its interface only contains methods with input arguments among OLE automation data types and no output return.
- It is marked as "Queued" when registered via MMC.

When a "queued application" is registered, COM+ creates six queues, which can be seen via MMC, with names beginning with application name. A special queue, "<app name>_deadqueue," is also created and stores messages after a number of unsuccessful delivery retries, probably because of an internal error in the component.

Being able to handle asynchronous calls does not prevent a component from still continuing to be reached by synchronous, normal COM calls. The way a call is processed depends on how it was invoked by the client. If normal COM invocation is used, the call is processed via conventional RPC. To invoke a method asynchronously, a client must first retrieve a queue object pointing to the application queue. This may be accomplished by a single line of code; for instance, when writing a VB6 client, it should be coded as in code 2.

```
' assuming application name is MyAsyncApp implementing SomeInterface
Dim QC As MyAsyncApp.SomeInterface
Set    QC = GetObject    ("queue:ComputerName=somehost/new:MyAsynApp.
SomeInterface")
```

Code 2 Async invocation.

After GetObject() is called, any method can be called, as it occurs normally with COM invocation, as long as GetObject() returns a queue moniker that, for all practical purposes, acts as an interface. The above example also shows how to invoke remote objects asynchronously, by simply specifying *ComputerName* when calling GetObject(), which may be omitted when doing local calls.

Unlike conventional COM components, asynchronous calls require the application to be started from MMC manually or automatically, during system startup; Just-In-Time Activation (JITA) does not apply.

Events

COM+ supports component communication through events, implementing publish/subscribe (observer) design pattern (Gamma, 1995). This pattern is quite useful in Automation and Control, as shown in Blanco (2003). It results in a loosely coupled event (LCE) architecture. COM+ Events benefit from Queued Components, a set of messaging components based on the MSMQ product.[6]

[6]COM model also includes the so called Asynchronous COM, which allows about the same kind of functionality. But the limitations of its use are so hard at this time that it can be considered as a legacy feature and only be considered as an alternative for backward compatibility.

© 2005 by CRC Press LLC

In publish/subscribe, a client (subscriber) first calls a server (publisher), requesting to be enlisted to receive information, passing a callback interface (also known as *sink interface*). When new information is available, the server calls the client back through this sink interface.

The COM+ Event Model simplifies publish/subscribe development by placing the connection setup and event firing/callback action beyond the scope of the component. Therefore, a client who wants to receive events registers itself with COM+. Similarly, the publishing object sends events to COM+, which takes care of all callbacks. This is quite similar to the architecture "channel" concept in CORBA's Event Service (OMG, 2001).

An event is fired by the publisher using an *event class*, which is a COM+ implementation of the sink interface. Therefore, a publisher must instantiate the event class, and simply calls one (or more) of its methods. It is COM+'s job to actually make the event reach every subscriber. In its turn, a subscriber must implement this sink interface to be able to be called. Every event class and subscriber must be registered (as any COM component) within MMC. For event class, a special option is available, as shown in Figure 5.7.

Firing can be done synchronously or asynchronously, configurable from MMC. In the synchronous mode, if a subscriber blocks (for instance, because of a modal message box waiting for a user response), event firing also blocks. Therefore, events should be normally fired asynchronously.

Events can be filtered, to avoid waste of bandwidth and CPU cycles. Any event parameter may be used to filter the events a subscriber wants to receive in declarative form in the Properties tab of a subscriber in MMC. Besides subscriber filtering, COM+ also supports publisher filtering, which allows a publisher to decide which subscribers should actually receive an event. This can be accomplished by writing a COM component implementing the IPublisherFilter interface (or a similar interface). When such a filter is created, COM+ invokes the component before publishing. The filter has access to all subscribers and can decide upon which ones to publish to.

Transactions, Security, and additional COM+ features

Perhaps most pages written on COM+ discuss transactions and security. This is so because most systems developed around the world fall into this category. As stated before, these aspects are beyond the scope of this chapter.

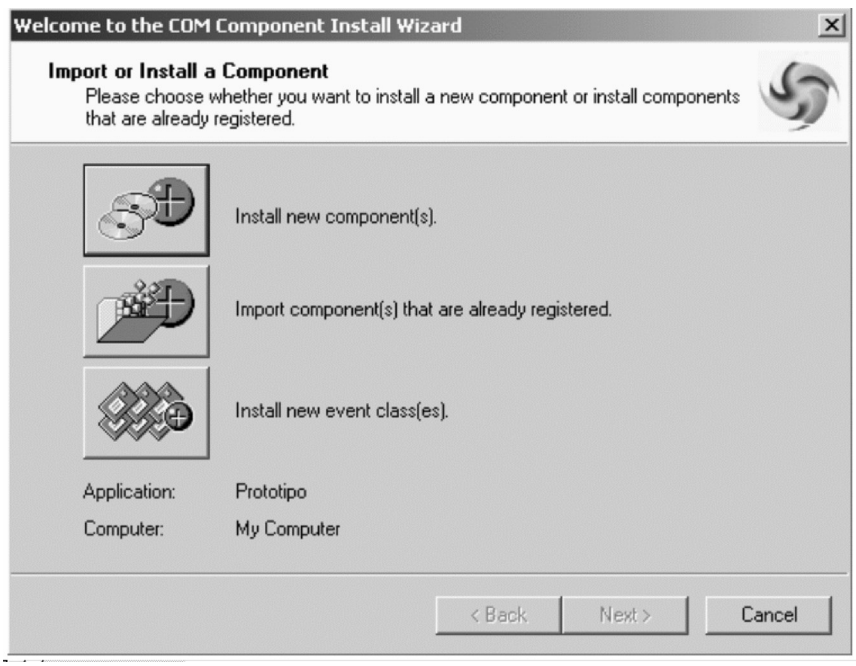

FIGURE 5.7 Registering an event class.

© 2005 by CRC Press LLC

In short, transactional control is about coordinating various Resource Managers (RMs) such as databases and queues to collaborate on a business transaction. The goal is to achieve Atomicity, Consistency, Isolation, Durability (ACID) properties. Transactional control is slightly more related to Atomicity, which implies a transaction is to be fully completed (i.e., all RMs were capable of termination of their work), or all its effects are canceled (i.e., all RMs are requested to roll back all changes already made). This is accomplished via a two-phase commit protocol, which has a:

- Phase 1 (preparation), when all RMs are solicited to do all checks and other work in preparation to complete a transaction. If any RM votes for a rollback, all others are signaled to roll back too.
- Phase 2 (commit), when all RMs are signaled to terminate their work, because all voted not to roll back. There is no going back at this point; changes are made permanent (which is the Durability in ACID).

To coordinate the two-phase commit protocol, Microsoft has been shipping DTC, since 1996.

With COM+, components may also act as RMs, being able to vote for a transaction commit or rollback, as a database does. This may be used if a violation on a business rule is detected: by voting for rollback, a component prevents changes from being committed.[7]

COM+ security services are tightly integrated into the MS Windows 2000 (and later) operating system, allowing for a fine-grained security control. It allows to associate *roles* with users (or groups of them) and then, to control their access to components, interfaces and even at the method level. COM+ security is declarative, meaning that it can be fully configured from the MMC's graphical interface, thus not demanding programming efforts. Also, it is detached from component implementation, passing this responsibility to people in charge of production systems.

Additional important (at least, to data-centric systems) COM+ features involve:

- COM+ Context, holding Transaction, Activity, Security, and Apartment information, shared among objects involved in a processing path started in a root client.
- Compensating Resource Manager (CRM), which facilitates the development of components to act as a Resource Manager (RM), at least as far as the transaction control is concerned.
- COM+ Catalog, which is a graphical interface for deploying, managing, and monitoring components. It is the Component Services part of MMC and is quite important because many COM+ features are within easy reach when using it.
- ActiveX Data Objects (ADO), which is an abstraction layer for data access, handling not only relational databases but also other data managers, such as a simple Excel spreadsheet. It is transaction-capable, object-oriented (as opposed to "SQL oriented," as ODBC-Open Database Connectivity). It follows a new vision for data access, generically known as OLE-DB.

5.6 .NET

.NET is the latest achievement in Microsoft's components technology. It not only includes a new component model but also it is a complete (and complex, comprehensive) runtime environment. In both cases, from the functional point of view, .NET is quite similar to COM+. Their goals are (Barnaby, 2002):

- Language independence: a component can be written in any (supported) programming language. In .NET, about 20 different languages are supported, because they are all compiled into an intermediate binary format interpreted by Common Language Runtime (CLR). It is interesting to note that Microsoft, Sun, and OMG component frameworks cover all the possibilities in this sense, as shown in Table 5.1.

[7]Although possible, starting a transaction to roll it back because of a simple error (such as a missing value on a mandatory field) is not a good implementation strategy because votes are only checked at the final of phase 1, when a lot of work on all RMs have been already done, causing avoidable resources comsumption.

© 2005 by CRC Press LLC

TABLE 5.1 Framework's Strategy with Respect to Independence

Framework	Language independence	Operation system independence
.NET	Supports about 20 different languages	Until now, only Microsoft Windows
Java	Just Java	Any OS where a JVM (Java Virtual Machine) is available
CORBA	Any language for which a binding exists	Any OS

As it can be seen from Table 5.1, Microsoft is closer to providing full language- and OS-independence than Java; it only takes a marketing decision.

- *Component interoperability*: since a common set of data types is supported by .NET, complete component interoperability is achieved. Even further, a component written in one language may even inherit from another, written in a different programming language.
- *Location transparency*: local (in-process) and remote (out-of-process) component access are identical, leaving details to a configuration tool.
- *Improved version control*: a new versioning scheme is available, solving a well-known problem in MS platforms (including COM+) when managing DLLs.

If they are similar, why to spend money in rewriting a new component framework? .NET provides a set of improvements over COM+, cleaning up years of technology adaptation and thus simplifying life for Microsoft and developers.

Runtime Environment

What are the basis for a component interoperability between programming languages? The .NET technology answer is a single set of data types, a single set of minimal programming language's features (or restrictions), a uniform runtime environment, and an improved (when compared to COM+) packing scheme. These characteristics are detailed below. Together, they provide a uniform, multi-programming language runtime environment.

Single Set of Data Types

For a component written in one language to call another one, written in a different language, there is a need to convert to/back parameters. Parameters must be in a programming language understandable data type. For instance, if a 16-bit (short) integer is passed from one language to a different one, which only supports 32-bit integers, "someone" must take care of a conversion. Java adopted the simplest solution: just one, single programming language — Java. Therefore, any component uses the same data types because they are Java data types. .NET, because of its goal to support multiple programming languages, decided to define and include a CTS (Common Type System), that is, a set of data types supported in all languages. This also provides a cross-language inheritance; for instance, a VB.NET[8] class may be derived from a C#[9] class.

One major achievement is the .NET Framework, which is a large set of about 3500 classes that can be inherited and therefore, extended. It is available for all .NET programming languages; it takes some time to get to know them, but it does speed up application development.

All classes within .NET Framework inherit from the same class, System.Object, which has the following methods:

- Equals(), allowing for comparison between objects.
- Finalize(), to perform cleanup operations before an object is automatically reclaimed; see discussion on garbage collection below.

[8]Visual Basic .NET (VB.NET) is a revision of Visual Basic, making it .NET-compatible. But it includes so many new features that it should be given a new, distinct name.

[9]C# (reads as "C sharp") is a new language, proposed by Microsoft, as a language intermediate between C++ and VB, in terms of simplicity.

© 2005 by CRC Press LLC

- GetHashCode(), which generates a number corresponding to some sort of manipulation of an object's attribute values.
- ToString(), to generate a human-readable string describing an instance of a class.

System.Object plays in .NET the same role as IUnknown and IDispatch in COM: as long as all objects inherit from it and it is a class, it can be dynamically interrogated by using the .NET Reflection API (simply put, a set of functions to determine which methods are inside the component and activate them) and loaded (as JITA, in COM+).

Set of a Minimal Programming Language's Features

To be able to run within .NET framework, a component must be written in a programming language complying with its characteristics. The Common Language Specification (CLS) determines which features must be present. CLS does not mind which keywords are used, just features such as inheritance. That is why Visual Basic (and all other MS programming languages) evolved into VB.NET (or a new .NET programming language).

CLS is actually a subset of CTS. All publicly available methods in a component must comply with CLS. But within a component, non-CLS compliant data types may be used with no risk. For instance, C# supports unsigned types, but VB.NET does not; unsigned types are CTS-compliant but not CLS-compliant.

Uniform Runtime Environment

The last element to achieve full component interoperability is the CLR. As stated by Barnaby (2002), "succinctly put, the CLR is an implementation of CTS," as long as it is an application execution engine and a class library built according to CTS.

All source code in any .NET-programming language is compiled into a platform-neutral code called Common Intermediate Language (CIL or MSIL or simply IL). The CIL code is interpreted by CLR. This approach is quite similar to Java's bytecode and JVM (Java Virtual Machine), but as old as computers.[10] The first time a part of the code is used, it is compiled into native code by a Just-In-Time (JIT) Compiler. Therefore, a user will probably experience a program speed-up after first execution of a sequence of commands.

CLR also introduces the notion of "managed code" and "unmanaged code." In "managed code," CLR runtime takes care of memory allocation/deallocation and security. A garbage collector, again similar to Java's, cleans up unused objects from memory. Modules ("assemblies," in .NET jargon) are loaded only when needed. Managed code frees a developer from many tasks but imposes some barriers. In situations when these barriers are not acceptable, CLR allows for unmanaged code, which allows for full access to memory and Win32 library. Unmanaged code is required for backward compatibility and in some applications where resource control must be in the developer's hands because of resource scarcity and speed.

Assemblies

With COM/DCOM/COM+, components had to be registered in the Registry to be known to an application: the "DLL hell," mainly because of inter-application dependence. Let us assume, for instance, that Application A uses version 1 of a component. As seen before, components are known by their UID. Now, a new application is installed, installing a new version of the same component. If the UID is retained, Application A may be broken. Briefly, component registration is machine-wide, but not exclusive to one application. Component update requires deregistration and reregistration, which, although supported by development tools (such as Visual Studio), is always annoying as it requires special scripts for installation on a production site.

.NET provides a new concept of Assemblies. Assemblies seem to be similar to DLL as long as they are packed into a file with a ".dll" extension. But they are quite different. Packing all types of information and metadata allows for an easy installation.

[10]Interpreters are quite frequent in computer's history: Basic and Pascal, for instance, are interpreted languages. But this has been proposed as a solution for platform interoperability since the earliest days in computer's history.

© 2005 by CRC Press LLC

Assemblies may be private or public. Therefore, a component may be packed to be used exclusively by a single application, or available to many different applications.

Private assemblies are stored within the "application tree file structure," that is, in the application's base directory, or some subdirectory. Public assemblies are stored in the Global Assembly Cache (GAC), which is normally the <BASE_WINDOWS_DIRETORY>\Assembly (c:\winnt\assembly). Opening this folder in MS Windows Explorer (over MS Windows 2000 or XP after installing .NET) is quite revealing; each component shows its name, type, version, culture (for internationalization), and public key token (which is part of the security mechanism in Assemblies, see below).

An application declares its dependencies in an XML file, giving a search path for components. Therefore, a much more flexible deployment mechanism may be used, allowing an application to have its own components, or share them among groups of applications, or even with all of them on the same computer. Changing from one option to another may be accomplished by changes in the XML file (or through the visual configuration editor inside Visual Studio .NET). Searching for the correct assembly is one of the key features for solving the "DLL hell"; it is known as "probing" in the .NET jargon.

An integral part of assemblies is its support for security and versioning. An application may be sure of the origin of a component if it requires an assembly with a *strong name* (or *shared name*). A strong name is a combination of a friendly name, culture information, version number, public key, and a digital signature. Because an assembly with a strong name is signed, an application can be sure of the originator. Even more, as long as it is ciphered, an application may be sure of the component's integrity. A "Trojan horse" virus would not be able to impersonate an assembly. Versioning support is also provided. An application may require a specific version (Major:Minor:Build:Revision), or a version range, adapted to a specific culture (for instance, in Portuguese). It is part of the probing mechanism to find a suitable component, that is, security and versioning restrictions are applied.

Application Domains

Operating Systems run processes. But from an application point of view, this abstraction is not adequate. An application may share the same process with another application, or may span across various processes. Therefore, starting and stopping an application (or configuring, resource allocation, and any other management action) require a new concept, which is called in .NET an *application domain*. An application domain is a kind of "logical" process that can be managed as a whole.

An application domain may contain many *contexts*, for sharing data among components, keeping objects with the same synchronization, and threading affinity requirements.

Specific classes within .NET framework allow manipulation of application domains and contexts. Both are used to define the *application boundary*, which plays a central role in the .NET remote invocation. It is somewhat natural that an application domain defines an application boundary. But contexts also may delimit application boundaries; an application may request a new context to be created and to execute one or more components within it. In this case, communication from one component (which is running in the default context) to another (running in this recently created context) also spans an application boundary. In this way, contexts have some correspondence to the Apartment concept in COM+.

Remote Invocation

Every time a component invokes another one crossing an application boundary, a remote invocation occurs. As discussed above, an application boundary exists

- between application domains,
- between objects in different contexts.

Unlike DCOM, to be able to be called from outside of an application boundary, a class must be constructed in a special way. .NET provides support for marshaling by value (MBV), when only data are passed to the remote side, and marshaling by reference (MBR), when a reference is passed to the remote side. When neither MBV nor MBR are involved, objects are called *agile* since the object may be directly accessed. In order to utilize MBV, all parameters must be able to be marked as *Serializable*, a synonym for

© 2005 by CRC Press LLC

marshaling. .NET provides means for annotation of *class attributes* such as this. For instance, in VB.NET, a developer will write a code as in code 3.

```
<Serializable>_
Public Class CustomerData
...
End Class
```

Code 3 Declaration of a Serializable class in VB.NET.

Normally, a Serializable class is just a ValueObject, that is, an object containing only attributes.

When invoking a remote method, a communication path is established; this is called *Channel*. The network transport protocol may be chosen between TCP or HTTP. Data are marshaled using Simple Object Access Protocol (SOAP), which is a remote invocation data format based on XML. Within a SOAP message, the following will be found:

- SOAP body, containing all information required to execute a method call, such as method name and parameters.
- SOAP header, specifying nonexecution-related aspects, such as security and transactional information.
- SOAP envelope, encapsulating the body and header.

In Figure 5.8, the Formatter is, normally, a SOAP formatter.

Table 5.2, based on Barnaby (2002), summarizes the existing options:

A server object may be called in Singleton or SingleCall modes. In the Singleton mode, a stateful object is created to service the request. Therefore, a successive call to the same object will reach the same instance. In SingleCall, an instance serves just a single call, that is, to service each call, a new instance is created; this is a stateless call. Instances are destroyed just after finishing a method processing. Of course, this could be a major penalty in performance since instantiation is an expensive process. The .NET framework provides an extensive set of configuration tags (and API calls) to allow a developer to control instance lifetime.

From the client's point of view, all this is not completely transparent. To gain access to a remote component, a client has to know

- hostname hosting the server application,
- type of channel being used (TCP or HTTP),

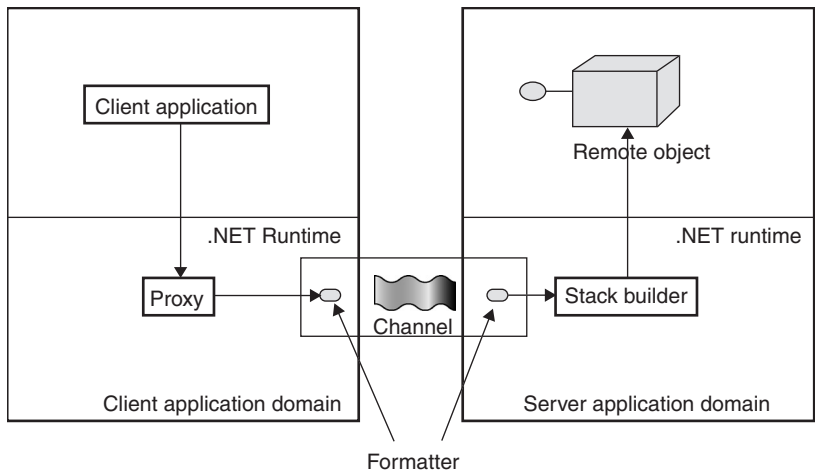

FIGURE 5.8 Remoting in .NET (based on Barnaby, 2002).

© 2005 by CRC Press LLC

TABLE 5.2 Options for Marshaling

Type	Base Class and Class Attributes	Description
Marshal by value	Marked as Serializable	This type is agile within a domain. But when transported across the domain boundary, it is serialized/deserialized
Marshal by Reference	Inherits from MarshalByRef Object; no class attributes needed	A proxy on client side is provided to remote access; therefore, all calls are executed within the application domain where it was originally created
Context bound	Inherits from ContextBound Object; no class attributes needed	A proxy to the object is always involved when crossing boundaries (both application and context); used in situations when a special handling is required (synchronization, for instance)
Not remotable	None of the above base classes or attributes	This type cannot be called outside domain but may be used in different contexts within a domain. Contexts hold a direct reference to them

- port number where the server is listening to incoming requests, and
- remote object URI.

All four values may be specified as an URL, such as
http://localhost:1702/MyURL.soap

In this case, the server object is called a *wellknown* object (or destination), because the client has all information for invocation.

Then, the client can:

- Use Activator.GetObject(), a method within .NET framework that returns a proxy to remote server giving component type and URL or
- Register a well-known end point by using RemotingConfiguration.RegisterWellKnown ClientType() and then simply instantiating objects following language conventions or
- Use its configuration file to declare the URL to a component. During initialization, CLR will register the component. This is probably the preferred method as long as a developer can write a program just following language conventions, providing the same level of location transparency as COM/DCOM.

It is also possible for a client to invoke a remote method without knowing the object's URI in a process called *client-activated object*. In this scenario, a client can either call RemotingConfiguration. RegisterActivatedClientType() or declare protocol/hostname/port values in a configuration file, tying to an object. After that, a developer simply uses the programming language convention to instantiate objects.

Asynchronous Invocation

Within .NET, asynchronous remote calls are completely client-side solution, that is, it has no impact on how the remote object is implemented. Therefore, asynchronous calls are available for all server objects.

Asynchronous calls are accomplished through the use of *delegates*. Delegates are sometimes described as type-safe function pointers. The key programming aspect to implement a delegate is to pass a function address A as an argument of another function B that can "call" A directly. It is a very common construction in C/C++ programs, sometimes known as a "jump table." Asynchronous calls infrastructure uses delegates either to set up a different thread to effectively call the remote method as well as to call back the client (when specified) after the completion of a remote call.

A delegate class has methods to:

- Start a remote invocation asynchronously (BeginInvoke()) eventually also specifying function parameters, callback function for remote call termination, and client-provided context information.
- Synchronize a remote call by waiting for its termination, thus allowing any returned results to be accessible to the client.

The entire remote call occurs asynchronously, including the overhead to marshal data. The major drawback of this approach is that it is a client-side solution; some developers not skilled with the dele-

© 2005 by CRC Press LLC

gates may find it hard to apply. These difficulties are somewhat removed if a callback interface is defined. In this case, the developer has to implement this interface, which is a relatively easy task. The drawbacks of this solution are the need for the client code to explicitly open a communication channel to listen to callbacks, and to make the call synchronous until the remote server is reached.

5.7 Performance

Since there is no standard for middleware performance measurement, a number of partial results may be collected to characterize COM/DCOM/COM+ and .NET performance. It is important to notice that performance is affected in so many ways that it is hard to completely define a test case and environment to conduct analysis.

Since all the technologies come from Microsoft, it seems to be fair to start with MS figures; Table 5.3 in Microsoft (1996) shows some of these.

Even though the results were obtained on relatively slow processors with limited main memory (Pentium@120MHz, 32Mbytes; Alpha@200MHz, 32Mbytes), the results show that the in-process activation is at least 10,000 times faster than a cross-process remote call. Also, cross-platform remote calls are at least 5 times slower than the cross-process activation.

In Adamopoulos (2000), a set of experiments with CORBA and COM/DCOM showed about the same performance for cross-process calls when transferring strings. This experiment also demonstrated that a single call transferring all strings is faster than multiple calls each transferring a single string, suggesting marshaling overhead as being minimal in process, and invocation costs being dominant. The same results were obtained when experimenting with remote calls.

For Automation and Control, Chisholm (1998) demonstrated OPC (which is based on COM) supplying more than 20,000 values per second to four simultaneous clients on a Pentium@233MHz. These figures, obtained on relatively slow processors with limited main memory, are quite important mainly because in Automation and Control this kind of machine is commonplace.

TABLE 5.3 Performance Figures

Parameter	4 bytes (Calls/sec)	50 bytes (Call/sec)
Pentium, in-process	~3.2 M	~3.2 M
Alpha, in-process	~2.8 M	~2.8 M
Pentium, cross-process	~2.300	~2.000
Alpha, cross-process	~1.900	~1.600
Alpha-to-Pentium remote	~400	~300

TABLE 5.4 COM/DCOM — CORBA Comparison (Adapted from Chung, 1997).

	COM/DCOM	CORBA
	Basic Programming architecture	
Common base class	IUnknown	CORBA::Object
Object class identifier	CLSID	Interface name
Interface identifier	IID, GUID	Interface name
Invocation (basic)	CoCreateInstance()	bind() (although not really CORBA-compliant)
Object handle	Interface pointer	Object reference
	Remoting Architecture	
Name to implementation mapping	Registry	Implementation Repository
Type information for methods	Type library	Interface Repository
Locate implementation	SCM	ORB
Activate implementation	SCM	OA (POA, BOA)
Client- and server-side stubs	Proxy, stub	Stub, skeleton
	Wire protocol architecture	
Marshaling data format	NDR	CDR
Object reference	OBJREF	IOR

5.8 COM/DCOM — CORBA Comparison

In Raj (1999), a detailed comparison of CORBA, DCOM, and Java/RMI is presented, by exploring an example application. His conclusion is that "…[both] provide mechanisms for transparent invocation and accessing of remote distributed objects… the approach that each of them take is more or less similar." The same conclusion appears in Chung (1997), which views this comparison in three different layers:

- the basic programming architecture layer,
- the remoting architecture, and
- the wire protocol architecture.

Table 5.4 summarizes their findings.

Acknowledgments

The authors wish to thank Victor Zamora, for his careful revision on the material and suggestions.

6.1 Overview

As technology evolved toward Object Orientation (OO), distributed computing models also progressed in that direction. By the end of the 1980s, a number of IT companies and individuals, mostly from Universities, founded a new association, the Object Management Group (OMG), devoted to the conception of a new standard for an object-oriented distributed computing framework. OMG is vendor-neutral and vendor-independent. It does not sell any products; its mission is to provide specifications that can be implemented into products.

The first result of this association was the establishment of standards for an object-oriented middleware architecture: the Object Management Architecture (OMA). OMA supplies a group of standards

© 2005 by CRC Press LLC

upon which the distributed applications can be developed, and consists of the following:

- definition of standards for remote method invocation (RMI) and object's life cycle control, known as Common Object Request Broker Architecture (CORBA);
- a set of standards defining services to objects, known as CORBAservices; and
- a set of standards defining services to aid application development, denominated CORBAfacilities.

OMG organization also includes a collection of working groups divided according to industry segment (Manufacturing, Medical, etc.), aiming at defining standard services specific for each industry. These groups are called Domain Technology Committee (DTC) and their work is, therefore, a highly valuable source of design ideas for professionals working on each industry segment.

This chapter provides an overview on CORBA, CORBAservices, and the work on DTCs related to manufacturing.

6.2 Scope

OMG's work is lengthy enough to provide material for a full collection of books, more so if distinct audiences (developers, application architects, managers, students, etc.) are considered. Therefore, a narrow focus is necessary due to space limitation.

A conceptual overview approach was considered as being appropriate. This chapter was written keeping in mind a technical audience: professionals and students familiar to programming (but not necessarily developers) and aware of object-orientation concepts. Only concepts are discussed; no source code examples are shown.

Moreover, considering the industrial area, which is the focus of this entire book, a further focus narrowing is necessary, since shop-floor IT demands are quite different from those on the upper levels of Computer Integrated Manufacturing (CIM) pyramid or Engineering departments. In this aspect, it has been decided to focus mainly on shop-floor needs.

Again due to space limitation, it has been decided to describe the technology itself and not its application. A large set of small- and large-scale CORBA applications are in use but they will not be described here.

Finally, OMG work is evolving over time; CORBA standards are up to their 3rd version. Therefore, all materials presented here tend to reflect current technology status, without efforts to show its evolution or trends. Fortunately, most concepts have been present since CORBA's 1st version and might be present in the future, making this decision the least impacting on chapter contents.

6.3 Some on the Past and Future of CORBA

The OMG was founded in Needham, MA, in 1989 as a nonprofit organization, by a group of 11 companies, with the mission of providing "a common architectural framework for object-oriented applications, based on widely available interface specifications." Currently, the OMG consortium includes approximately 800 members.

The work developed by the OMG focuses on establishing industry guidelines and detailed specifications for object management, creating standards that can accelerate the introduction of software components across all major hardware platforms and operating systems. One of the core lines of work inside OMG is the development and maintenance of the OMA, of which CORBA is a part.

The first CORBA version (1.0) was introduced in October 1991, and included the CORBA Object Model, the Interface Definition Language, and a core set of application programming interfaces (APIs) for communication with an ORB. At that time, it only included mapping for the C programming language. It was quickly followed by version 1.1 in February 1992, which clarified some ambiguities and defined the Basic Object Adapter (BOA) interface, and later by version 1.2 in December 1993. More details about the BOA will be given later on this chapter.

The next huge step in CORBA history was taken in 1996, with the introduction of CORBA 2.0, when many important improvements were made, as the ORB interoperability architecture (GIOP, IIOP, and DCE CIOP) and the initial reference resolver for client portability. This version added two new IDL

© 2005 by CRC Press LLC

language mappings — C++ and Smalltalk. Version 2.0 was then followed by version 2.1 in 1997 and 2.2 in February 1998, when the JAVA language mapping was introduced.

Since then, there were introductions of version 2.3 in 1999, version 2.4 in 2000 (when the notification service and the real-time CORBA were introduced), version 2.5 (introduction of fault tolerance) in September 2001, and version 2.6 in December 2001.

The next major CORBA release, version 3, was published in 2001. At the time this text was written, version 3.0.2 was approved and version 3.1 was to be voted. The major change introduced was the CORBA Component Model (CCM), which defines a container to transactional, secure, and persistence-aware components, providing a higher level of abstraction than the usage of independent CORBAservices. It is very similar to the container defined in Java's J2EE, which has close integration (Siegel, 2000).

Other efforts toward the development of framework for object interoperability have also been made during this period of CORBA evolution. One of the most relevant is the integration to Microsoft's COM/DCOM.

6.4 Architectural Concept: the OMA Architecture

One of the main results of OMG efforts was the definition of the OMA, of which CORBA is part. Basically, OMA provides a group of standards upon which applications can be developed. It defines the need for:

- an inter-component communication infrastructure (the ORB — Object Request Broker — function);
- a set of components offering basic services to other components (known as CORBAservices);
- a set of components offering basic services to applications (called as CORBAfacilities);
- a set of specialized components for a knowledge domain (such as Medicine or Manufacturing); and
- a set of application objects, forming the applications themselves.

The role of the CORBA architecture in the OMA is implementing the ORB function, providing the programmer with a standard mechanism for the definition of inter-components interfaces, as well as tools to make the implementation of these interfaces easy and language-independent.

In OMG (1996), the OMG presents its technical goals, terminology, and details the conceptual architecture upon which the specifications are defined. This guide also includes the OMG object model that defines the common semantic for the specification of an object's external characteristics in an implementation-independent manner and the OMA reference model.

In order to complement the OMA with detailed specifications of each of the reference model's components, the OMG has issued a series of Requests for Proposals (RFPs) and has thus established specifications for the CORBA architecture, CORBAservices, and CORBAfacilities.

In the reference model presented in Figure 6.1, the OMG identifies and characterizes the components, interfaces, and protocols that form the OMA, including the ORB.

The Object Request Broker, or ORB, the fundamental component of the CORBA architecture, consists of a software element whose purpose is to carry out the communication between objects. This is made possible through the availability of a series of capabilities, among them the capability of locating a remote object through its reference. An ORB is a mechanism through which objects can make requests and receive responses from each other, in a single computer or in a network. With the ORB, the client does not need to be aware of the mechanisms used to communicate with or activate an object, nor of its implementation details or physical location. The ORB is, therefore, the basis for building distributed applications and for the interoperability between applications in homogeneous or heterogeneous environments.

The reference model in Figure 6.1 also presents four categories of object interfaces:

- Object Services (CORBAservices) — interfaces for general services, with potential use in any distributed objects application.
- Common Facilities (CORBAfacilities) — interfaces for horizontal facilities (generic and reusable applications), applicable to most domains, and focused on helping the user with the implementation.
- Domain Interfaces — specific interfaces for each application domain, such as manufacturing, finance, medical, and telecommunications.
- Application Interfaces — nonstandard interfaces, specific for each different application.

© 2005 by CRC Press LLC

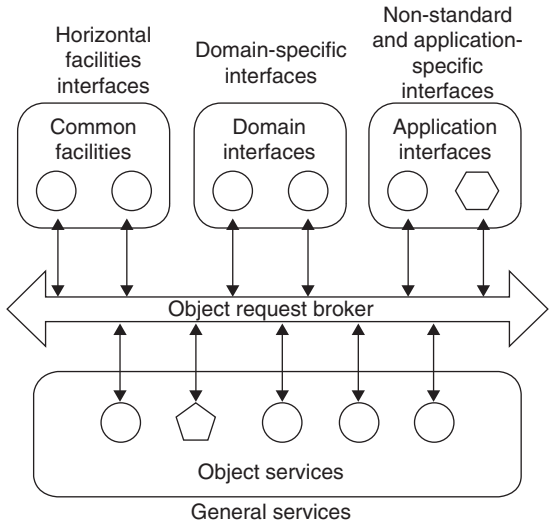

FIGURE 6.1 OMA reference model. (Adapted from OMG, 1997.)

Interfaces are at the heart of all OMA specifications and, in general, any work with components. In other words, to characterize a component's behavior, its interface (i.e., methods, arguments, returned values, and attributes) must be explicit. Semantics are not captured by interface definition. OMA includes the definition of a standard language for interface definition: OMG IDL (Interface Definition Language). IDLs were first introduced by Distributed Computing Environment (DCE) framework (OSF, 1995), proposed and managed by the Open Systems Foundation (OSF). OMG IDL extends OSF's, by adding object-oriented characteristics to it. OMG IDL is explained below (Gorton, 2000).

One of the characteristics of the OMA is that an application does not even have to be developed under the OO paradigm in order to be able to interact with the proposed architecture. It only needs to implement or support the interfaces defined by the OMG, as a way of being encapsulated in OMA-compliant objects.

6.5 Remote Method Invocation

IDL

IDL is a language to specify the interfaces of the CORBA objects, being responsible for the language independence of the CORBA standard. IDL is not a procedural language, that is, it can be used to define only interfaces, not implementations. The IDL can be compared to the header files used in C++ programming. A header file usually does not include classes implementation, being restricted to the interface description.

The IDL specification is responsible for assuring that the data are correctly exchanged between different programming languages. For example, IDL specifies the "long" data type, which is a 32-bit signed integer type, and that can be mapped to the "long" type defined in the C++ language or to an "int" type in JAVA.

Once all the interfaces defined in the CORBA architecture are described through IDL, they can be mapped to any programming language, that is, C++ servers can communicate with JAVA clients, which can communicate with COBOL servers and so on.

The IDL, as well as most programming languages, defines primitive types that include integer numbers, characters, floating point numbers, strings, boolean types, and constants, among others. Besides this, the primitive types can be aggregated in other types, such as "unions" and "structs."

Input and output parameters representation, methods, modules, attributes, inheritance, and some other language primitives are also defined by the IDL, as a way of creating a complete description of the interfaces defining an application.

© 2005 by CRC Press LLC

Once an IDL server file is compiled by the IDL precompilers included in any CORBA product, a series of classes will be automatically created, forming the basic infrastructure required for the communication of this server with the clients through the CORBA architecture. After this precompilation, the programmer can implement the code portions required for the server to work.

Stubs and Skeletons

In the same way as in other architectures, CORBA has the notion of client and server, being that any CORBA object can work in both ways. When an object is making services available to other objects, it is considered a server, and when an object is accessing other object's services, it is considered a client. Actually, CORBA differentiates a servant (an object implementation that provides the service) from server (a process where one or more servants will "live"). For simplicity, this text will use the term server.

In the client's implementation, the concept of stubs is used. A stub is a code part that allows a client to gain access to a server component. It is linked along with the client part of an application. Similarly, the skeletons are code parts that must be completed when a server is implemented. It is not necessary to manually write the stubs and skeletons codes, once they are automatically generated when the IDL interface is compiled (Figure 6.2).

When a client wishes to invoke a remote method, it issues a method call following its programming language convention. The stub is responsible for converting parameters into CORBA format and to communicate through the network with the server side. This parameter conversion is known as marshaling and is an important part of the language independence provided by CORBA. On the server side, the skeleton unmarshals parameters following the conventions of the language of the object implementation and actually invokes the method. Returned values follow the same way back to the client, being marshaled from an object's implementation language to CORBA language-independent format and, finally, to the client's programming language convention.

CORBA also supports dynamic creation and invocation of requests to objects, using an object's name, which is known as Dynamic Invocation Interface (DII).

Object References

In order to make the communication between objects easier, the CORBA architecture uses the notion of object references or Interoperable Object References (IORs). When a component of a given application needs to access a CORBA object, it initially obtains an IOR for this object, through which it will be able to use methods from this object. IORs are somewhat similar to pointers (or object references) in programming languages such as C++ and Java.

The most basic way of working with IORs is creating small text files with predefined names and writing the IORs in these files. When an object needs to locate a second object, it can open the text file and read the second object's IOR, and thus be able to interact with it. Unfortunately, for this method to work, every object interested in publishing its IOR must do it in a predefined location, in predefined files, which the other objects must be able to access. That is, the sever object must write its IOR in a shared file system known and accessible by the client. Sometimes, in small-to-medium systems, a webserver is used

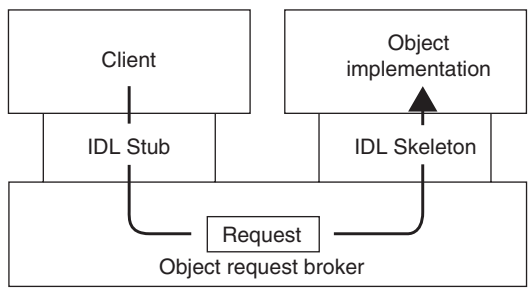

FIGURE 6.2 Request passing from a client to an object implementation. (Adapted from OMG, 2003.)

© 2005 by CRC Press LLC

to store IOR, making them available to clients through conventional HTTP access, as long as they can be stored in text files. This way, the shared file directory may be avoided; a client must only know the object's name and webserver IP address.

For large systems, both alternatives are not applicable. OMG thus defined the Naming Service, whose responsibility is the association of names to objects, through a process called Name Binding. The name bindings are always defined in Name Contexts, which are objects that have a group of name associations, so that each association is unique in a given context. Different names can be associated to the same object, in the same context, or in different contexts; but it is not mandatory that all objects are given names.

There are two basic actions possible in the Name Service. The first one is the association, (or binding, in the Name Service terminology), of a name to an object in a given name context; the second is locating (or resolving) a name, which is the action of identifying the object associated to a name in a context. Each name is always located inside a context, and there cannot be absolute names.

Once the context is an object like any other, it can also be associated to a name in a name context. This association of names to contexts has the effect of creating a name graph, in which contexts are nodes, and that makes possible the creation of composite names, in such a way that a sequence of names can reference an object. This composite names structure works in a manner analogous to the directory tree used by operating systems such as Windows or Unix, a clear analogy between contexts and directories being possible, and also between object names and files.

As all CORBA services defined by OMG, the Name Service is only specified through its interfaces. This means that OMG does not supply source codes to the software developers and vendors; only the interfaces are defined so that compatible solutions may be implemented by various vendors. By supplying IDLs and defining some basic implementation rules to be followed, OMG assures that companies interested in developing products based on the Name Service specification will do so by maintaining the standardization of the basic functions, of the modules' names, and of the methods' names, making the interoperability between different vendors possible.

Communication Protocols

ORBs usually communicate with each other using the Internet Inter-ORB Protocol (IIOP). The term "Internet" on IIOP was a concession to some of CORBA's specifiers, which wanted to reinforce its use with the World Wide Web; it actually means communication over TCP/IP. There are other protocols for inter-ORB communications, but IIOP is the most popular, given the popularity of the TCP/IP protocol. In any case, CORBA is protocol-independent, and could work with any other.

CORBA standard mandates at least the support to IIOP, leaving to implementers the option to implement other communication protocols (such as DCE, for instance, which has also been standardized).

The standard also mandates interoperability among ORBs through the use of IIOP. As shown in Figure 6.3, client and object implementation may be written to different ORBs, whose communication is guaranteed by CORBA inter-operability tests, a set of conformance tests any ORB must pass to be declared CORBA-compliant.

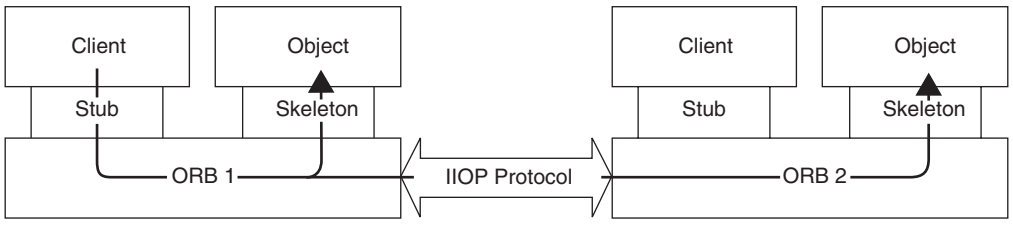

FIGURE 6.3 Remote method invocation using IIOP. (Adapted from OMG, 2003.)

© 2005 by CRC Press LLC

Object Adapters

The CORBA architecture also defines the BOA, which works as the interface between the objects and their ORBs, through the implementation of a series of methods for accessing the ORB functions, such as object activation or persistence.

In the CORBA terminology, the BOA is a pseudo-object, or an object created directly by the ORB, but that can be accessed directly by any other object. The BOA provides operations that the server objects in a system can access and also makes the interface with the ORB and the skeletons. On the other hand, this communication between the BOA, the ORB, and the skeletons is done by a series of private and proprietary interfaces, which means that the BOA is specific to each ORB implementation. This was a problem solved by OMG with the introduction of the Portable Object Adapter(POA), in version 2.2 of the CORBA architecture.

The BOA limitations existed because it had been underspecified when it was introduced in version 1.1. To solve the problem, OMG decided to completely rewrite the BOA specification, once the differences between real CORBA implementations and BOA specification were too numerous to reconcile.

So, instead of risking causing a large migration problem from the original BOA to the new adapter, OMG decided to leave the BOA the way it was and create a portable version: the POA. Nowadays, many CORBA implementations retain both adapters (BOA and POA), in order to maintain backward compatibility with their older systems and also be in conformance with the current CORBA specifications.

Asynchronous Method Invocation

So far, all remote method invocations have been synchronous, in the sense that a client blocks until the server executes. A standard CORBA call causes the execution of an operation by the server object, which is carried out in a synchronous manner and, for this operation to succeed, both the client object and the server object must be on-line and available. There are specific exceptions to be raised when this basic condition is not met.

On the other hand, synchronous method calls do not answer all the needs of a programmer or developer who is working on a distributed system. There are many situations when it is important to decouple the communication between the client and server objects, in order to improve the overall system performance (by making processing asynchronous), or due to particularities of the problem to be solved.

In order to promote the decoupling between client and server objects during data communication, OMG has defined the Event Service, which makes possible the asynchronous data transfer between objects. The Event Service defines two new roles for software objects: the Supplier and the Consumer.

The Supplier objects are those that generate events (that produce data), and the Consumer objects are those that process these events or data, which are passed to them by CORBA requests.

The communication between Suppliers and Consumers can take place in two different ways: through the Push communication model, or through the Pull model (See Figures 6.4 and 6.5). The Push model gives the Supplier the prerogative of initiating the event data transfer to the Consumer objects, which means that the Supplier is in charge of the communication initiative. On the other hand, the Pull model

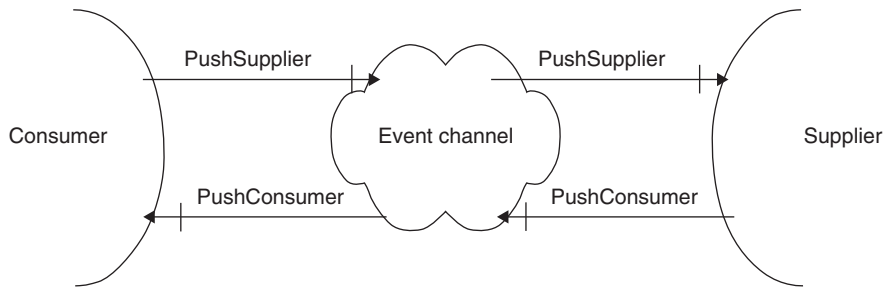

FIGURE 6.4 Push model communication. (Adapted from OMG, 1998.)

© 2005 by CRC Press LLC

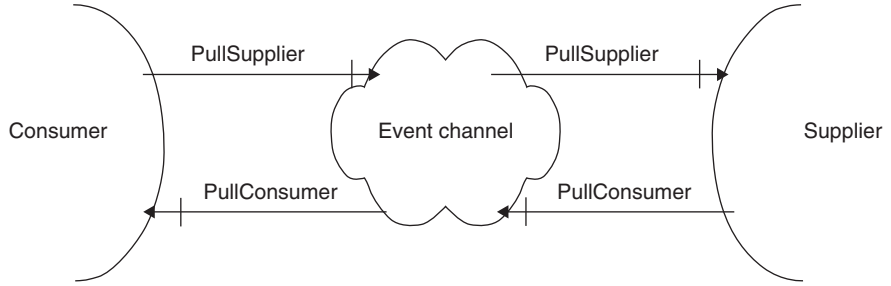

FIGURE 6.5 Pull model communication. (Adapted from OMG, 1998.)

gives the Consumer the ability to request data from the supplier at any given moment, and the consumer is in charge of the communication initiative.

The entire management of the data communication between Suppliers and Consumers as well as the request management are carried out by an object called Event Channel. The Event Channel is at the same time a Consumer and a Supplier, and is what makes the asynchronous data transfers possible. Every data exchange between the Consumer and the Supplier is made through the Event Channel, and never directly between them. The Channels are standard CORBA objects, and the communication between them uses common CORBA calls.

The process of creation of the communication mechanism by the Event Service is started with the instantiation of an Event Channel that supports the standard EventChannel interface, defined in the Event Service specification. This object basically supports three different operations: one operation that returns a Consumer Administrator object (or ConsumerAdmin), one operation that returns a Supplier Administrator (SupplierAdmin), and one operation that destroys the channel.

The administrators' role is to coordinate the addition of Consumers and Suppliers to the Event Channel. This is done through proxies, which are connectors used to link external objects (such as consumers and suppliers) to the channel, without direct contact between them.

This way, the linking process between a supplier application and the Event Channel takes place in two stages: first the event generator application receives a consumer proxy from the channel, through the Supplier Administrator, and then connects itself to this proxy. In the same way, the consumer application must first receive a supplier proxy from the channel and then connect itself to it, in order to gain access to the Event Channel.

As can be seen in Figure 6.6, OMG's specification defines the interfaces used for obtaining the consumer and the supplier proxies, in the Push and Pull communication models, resulting in a total of four different proxy interfaces to be implemented by the Event Service. There is also the event communication process using typed data, which implicates in the definition of a whole new structure, similar to the one shown above, with four more proxy interfaces. Every event communication is carried out through these proxies, so that the consumer and suppliers remain completely disconnected, and do not access each other's methods directly.

One example of applicability for the Event Service is the situation where a given system must provide a sensor reading to several different control panels, spread throughout a plant. Instead of having each panel reading the sensor individually, it is possible, using the Event Service, to create an Event Channel in which each panel is a Consumer, the system that reads the sensor is a Supplier, and the communication is made using the Push model. In this system, the Supplier only has to send the reading data to the channel, through a Consumer Proxy, and the channel will handle the distribution of the information to all Consumers. This example's architecture can be seen in Figure 6.7.

One of the features that can be noticed in this example, when it is compared to a standard CORBA call, is that it is asynchronous. The Supplier does not have to call methods in each Consumer to inform them of the new reading, being enough to send the data to the channel. This prevents potential problems, such as communication failure with the Consumer, which could cause the Supplier to hold until it received a

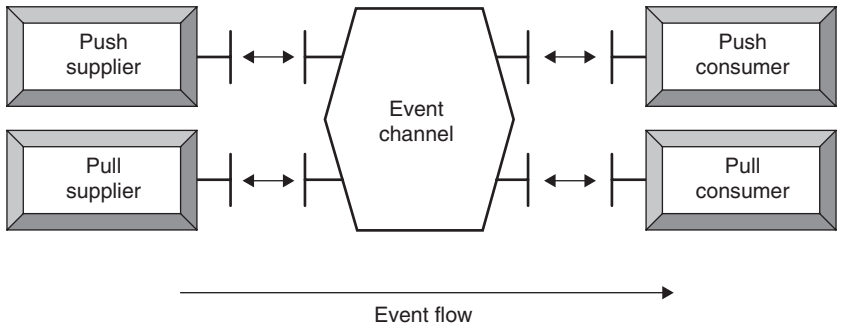

FIGURE 6.6 Untyped Event Channel Architecture, as defined by OMG. (Adapted from OMG, 2000.)

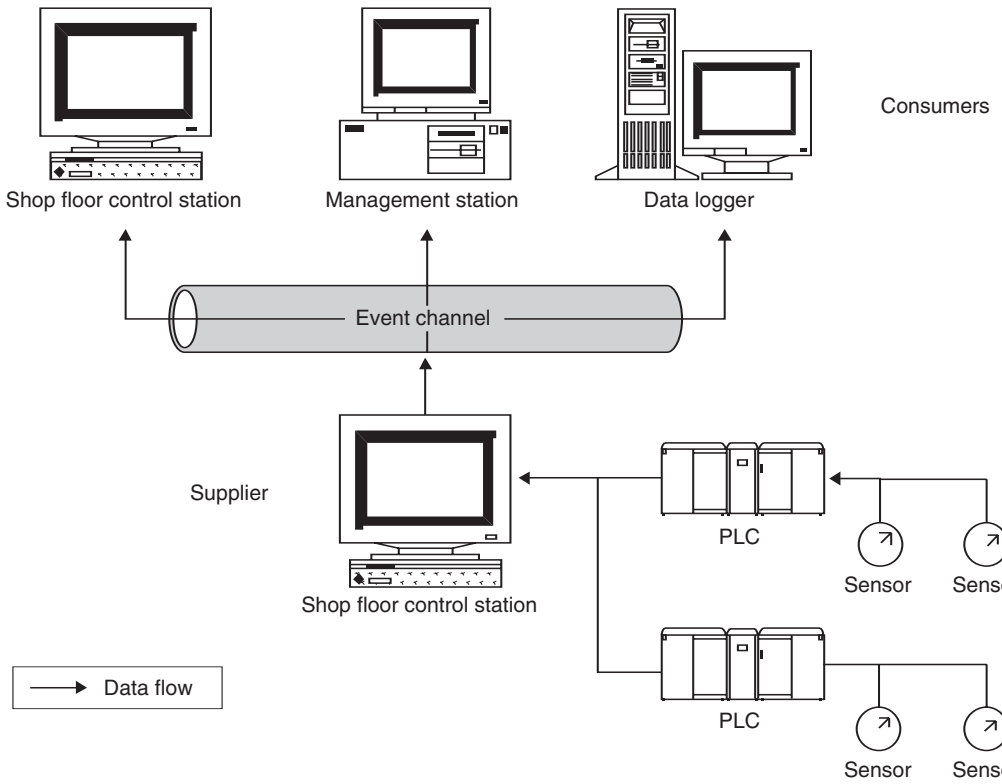

FIGURE 6.7 Example of a control system architecture using the Event Service.

reply (or until a timeout period expired), before it could go on and communicate to the next Consumer. In the original OMG specification for this service, it was not clear which technique should be used to control the event delivery, that is, to control the Quality of Service (QoS). This means that each vendor implementing an Event Service product is free to choose a different method, although all implementations must provide at least the "as quickly as possible" method. This way, it is really up to the vendor to decide what to do when a message cannot be immediately delivered, how to manage the event queue, and other issues inherent to the Event Service.

Although the Event Service is already a good contribution to the agility of the implementation of asynchronous communication between consumers and suppliers, there are situations when this service seems

© 2005 by CRC Press LLC

under-specified. Especially in an application with tight reliability requisites, as is the case of control systems and shop-floor supervision, there are some needs that cannot be ignored:

- The QoS, or the guarantee that events will be delivered to consumers according to a predefined priority, and that the system will be informed if it is impossible to deliver them in time.
- A filtering system, so that each client receives only the events that really matter to it. For example, a client who supervises the level of a tank may wish to receive the level reading constantly, when it changes more than a certain quantity, or only when it exceeds a maximum level. This considerably reduces the data traffic in the network, enhancing the overall network performance and reducing the processing load on the clients.
- The capability to transmit structured data, not just simple types, as it happens in the Event Service.

All these needs are addressed by the Notification Service, which is basically an extension to the Event Service. The main goal of the Notification Service is enhancing and refining the Event Service, introducing the concepts of filtering and configurability, according to different QoS requisites. The Notification Service's clients can request specific events associating data filters to the proxies they use to communicate to the Event Channels. These filters encapsulate restrictions that determine the events in which the client is interested, in such a way that the channel will only deliver events that meet the clients' interests. The Notification Service was designed to be completely compatible with the Event Service, supporting all interfaces defined by it. In other words, all the above concepts also apply to Notification Services.

6.6 CORBA Services

To make the development work easier, OMG created the Object Services, which consist of fundamental services that supply a base for application development. Object Services are basic elements for applications based on distributed objects, combining in different ways, attending needs such as object localization, persistency control, concurrency control, event treatment, and others. Object Services already adopted by OMG are in general called CORBAservices, and include the Naming, Event, Life Cycle, Persistent State, Transaction, Concurrency, Relationship, Externalization, Licensing, Property, Security, Notification, Query, Telecom, Trading, and Time services.

A minimum description of main CORBAservices is presented here, since it is a very lengthy subject.

Naming Service

This service aims at associating names to objects, using the name bindings. These associations are always defined in the so-called name contexts, which are objects that contain a group of name associations, each one being unique in a context. Different names can be associated to an object, in one same context or in different ones, but it is not mandatory that all the objects be assigned names.

Event and Notification Services

Event Service was described before, under Asynchronous Method Invocation, together with Notification Service. Both provide CORBA with asynchronous method invocation capabilities.

Collection Service

The Collection Service enables the support for grouping of objects and operations for the manipulation of the objects as a group. Queues, sets, bags, maps, and others can be collection types. Collections are foundation classes used in a broad range of applications.

The purpose of an Object Collection Service is to provide a uniform way to create and manipulate the most common collections generically.

© 2005 by CRC Press LLC

Concurrency Service

The objective of the Concurrency Service is to mediate concurrent access to an object so that it remains consistent when access is needed by more than one concurrently executing computation. The Concurrency Control Service supports both transactional and nontransactional modes of operation through multiple interfaces.

The Concurrency Service serializes clients, transactional and nontransactional. Thus, both kinds of objects may request access to an object at the same time, and the Concurrency Service will make sure that the integrity of both operations is maintained.

Externalization

The Externalization Service specification defines protocols and conventions for externalizing and internalizing objects. Externalizing an object is to record its state in a stream of data. Objects that support the appropriate interfaces and conventions can be externalized to a stream (be it in memory, on a disk, on the network, etc.) and then be internalized into a new object that may be in the same or in a different process.

Externalizing and subsequently internalizing an object is similar to copying the object. The copy operation results in the creation of a new object that is initiated from an existing object.

The Externalization Service is related to the Relationship Service and parallels the Life Cycle Service in defining some kinds of externalization protocols.

Licensing

This Service supports the management of software licenses. Licensing is the most common form used by suppliers to assure that their products are being used according to the contracts signed by the client.

The Licensing Service provides a mechanism for suppliers to control the use of their software and intellectual property as predicted by their customers requests and by their agreement.

Life Cycle

This Service defines services and conventions for actions like creating, deleting, copying, and moving objects. Following one of the main roles of CORBA, Life Cycle Service defines conventions that allow clients to perform life cycle operations on objects in different locations.

Persistent State Service

A datastore is a kind of entity that is responsible for the management of data, a set of files, or a schema in a relational database. This Service presents persistent information as storage objects in a particular storage place called "storage homes". Storage homes are themselves stored in datastores.

Property

Properties, as used in CORBA, are typed, named values dynamically associated with an object, outside of the type system. Examples of cases where the use of properties can become very useful are object classification (version, author, company, etc.) and usage count.

The Property Service implements objects supporting the PropertySet interface or the PropertySetDef interface.

Query

The need to make query operations on collections of objects is fulfilled by the Query Service. Queries are predicate-based and may return collections of objects. They can be specified using object derivatives of

© 2005 by CRC Press LLC

SQL or any other query language. Also, query does not only mean reading but also selection, insertion, updating, and deletion on collections of objects.

The Query Service returns collections of objects that may be selected from source collections given a selection criterion or produced by query evaluations based on the evaluation of a given predicate. The source and result collections may be typed.

Relationship

Objects do not exist in isolation; they are related to each other. The Relationship Service allows entities and relationships to be explicitly represented as CORBA objects. This service defines new objects to deal with a relationship that can be of an arbitrary degree. But the Relationship Services does not define a new type of system. Instead, it uses the IDL type systems to represent relationship and role types. A role represents a CORBA object in a relationship, which is created by passing a set of roles through a relationship factory.

Security

Security is an ever-rising concern of companies of all sizes. This security specification provides means for applications to provide protection against unauthorized access to information, security controls being bypassed, eavesdropping a communication line, and tampering with inter-object communication.

Telecom Log Service

The Telecom Log Service provided by this specification can be used in a pure CORBA environment as well as by TMN systems. This specification defines interfaces that provide logging of any type of event and querying of records based on constraint languages. Capabilities to form log networks for storing and forwarding events are also provided.

Time

The Time Service provides a means for a user to obtain current time together with an error estimate associated with it. Additionally, the specification also suggests that the service provide means to ascertain the order in which events occurred, to generate time-based events, and to compute the interval between two events.

Trading Objects Service

The OMG Trading Object Service aims at facilitating the offer and discovery of instances of services of particular types. A trader is an object through which other objects can advertise their capabilities and match their needs against what is advertised.

Transaction

The Transaction Service provides interfaces that allow multiple objects to cooperate to provide atomicity of a transaction. These interfaces enable the objects to maintain data integrity either by committing all changes or rolling them back in the event of a noncatastrophic failure.

Transaction Service's interfaces combine the transaction and object paradigms, the first being essential to the development of reliable distributed applications and the second providing the productivity and quality to application development.

6.7 Work on Verticals

OMG has established several Technology Committees, divided into three plenaries: the Architecture Board (AB), the Domain Technology Committee (DTC), and the Platform Technology Committee (PTC).

© 2005 by CRC Press LLC

The PTC focuses on infrastructure and modeling specifications, for example, the ORB, object services, protocols, IDL and its language mappings, etc. The DTC focuses on vertical market specifications, for example, finance, manufacturing, etc. The AB's responsibilities are to make sure that specifications developed by the other two plenaries are consistent with the OMG's architecture and existing suite of specifications.

The DTC is divided into many subgroups, usually called "verticals." The most related to industrial IT are Business Enterprise Integration; Consultation, Command, Control, Communications, and Intelligence; Manufacturing Technology and Industrial Systems; Space; Telecommunications; Transportation; Distributed Simulation; Super Distributed Objects; Systems Engineering; GIOP Tunneling over Bluetooth; Historical Data Access from Industrial Systems; SDO for PIM and PSM; XML Telemetric and Command Data Exchange; CAD (Computer Aided Design) Services; Data Access from Industrial Systems; Surveillance Manager; and Telecom Wireless CORBA.

From approved standards produced by these groups, it may be cited as more related to Manufacturing:

- CAD Services, addressing the interoperability between CAD/CAM/CAE systems from different vendors toward a Product Data Management (PDM) system.
- Data Acquisition from Industrial Systems (DAIS), providing support for real-time transfer of large amounts of data and closely related to OPC.
- GIOP tunneling over Bluetooth, specifying how CORBA should be used over wireless links.
- Historical Data Acquisition from Industrial Systems, defining a number of interfaces for a time-series data management facility.
- Laboratory Equipment Control Interface Specification, defining standard interfaces to integrate laboratory equipment.
- Telemetry and Telecommand Data, although devoted to spacecraft telemetry and telecommand, is also somewhat applicable to manufacturing.
- Utility Management Systems (UMS) Data Access Facility, providing interfaces for obtaining analysis data from a UMS.

The items in the list are increasing every day, as new specifications are produced and approved.

6.8 Performance

The study conducted by the Defense Information Systems Agency (DISA) known as "Defense Information Infrastructure Common Operating Environment" (DII COE) (OIS, 1999), conducted by Boeing Phantom Works on real-time CORBA implementations was released in 1999 but it is still considered one of the more important results on CORBA performance. It tested for performance HARDPack (Lockheed Martin), ORBexpress (Objective Interface), and TAO (Washington University). From the publicly available results, it is clear that ORBExpress closely follows raw sockets communication, which can be considered as a lower bound to performance, with TAO being about 3 times slower and HARDPack showing performance degradation with large packets. On a Sun Ultra 167MHz@256Mbytes running SunOS 2.6, ORBExpress has been capable of transferring up to 24 kbytes in less than 1 msec, with client and server processes running on the same computer.

In a more recent study, conducted by Lockheed Martin (Thaker, 2003), TAO and ORBExpress were both capable of delivering 16 kbytes in about 1.1 msec when running on an Ultra 1 170 MHz with Solaris 2.7, with the client and server running on the same computer. In the same study, results for other ORBs are also presented; for instance, Orbix took about 4 msec on the same computer to do an equivalent job.

6.9 Real-time CORBA

What are real-time systems? The answer to this question is not as obvious as it seems. For a citizen of a large city, for instance, real-time information about traffic conditions is that provided on the radio, which reflected the situation on a given avenue a couple of minutes before. On the other hand, for the PLC

© 2005 by CRC Press LLC

controlling specific industrial equipment, connected to a critical proximity sensor, real-time information is that which it receives from the sensor just milliseconds after the maximum capacity level of a given reservoir is reached. Therefore, real-time systems are not about speed and efficiency, but about meeting time constraints in applications where timing is as critical for success as the data itself.

Industrial control applications and SCADA systems are, in their very essence, real-time applications, where process-critical information often has to reach its destination in tenths or thousandths of a second.

For example, let us consider a robot manipulator that is required to pick a specific type of part from a conveyor belt. This robot can be connected to a machine vision system, which will provide the specific coordinates of the part on the belt at a given time. If any kind of significant delays are introduced in the process, the manipulator's movement can be compromised, and the operation will fail.

Although the data transfer in this example can be implemented through the use of standard CORBA calls between the machine vision system and the robot controller, the engineer developing this system would not have any way of assuring the system's reliability using only the standard CORBA specifications and services to do the job.

In order to fulfil this kind of need, OMG has released the Real-Time CORBA specification. Real-Time CORBA is an extension of the conventional CORBA specification designed specifically to support the functional aspects of Real-World time-based systems.

On the whole, it can be said that the main goal of Real-Time CORBA is to provide what OMG called "end-to-end predictability," that is, to provide the tools required to build predictable and deterministic CORBA applications. OMG tries to accomplish this goal by:

- Respecting thread priorities between clients and servers during CORBA calls.
- Limiting the duration of thread priorities inversions.
- Limiting the latencies of operation invocations.

It is important to note that the success of real-time data communication in a CORBA application does not depend solely on the application or the ORB capabilities, but in four major aspects of the system:

- The use of a real-time operating system (RTOS).
- The use of a real-time ORB.
- The network communication layer.
- The application itself.

The combination of these four prerequisites is essential for the real-time data transfer, and should not be neglected. If one of these conditions is not met, the system cannot be considered reliable for critical real-time activities.

There are basically two kinds of real-time requirements: soft real-time and hard real-time. Hard real-time applications are those where the resources must be managed to guarantee the constraints are met, all the time, and where missing a constraint is considered a failure to meet the system's requirements.

On the other hand, soft real-time are those applications where the time constraints may be missed infrequently or by a small amount (usually a percentage of the time constraint) or where occasional events may be skipped. In soft real-time applications, the resources must be managed to guarantee that the requirements are met, but not strictly "all the time," which, as a matter of fact, makes soft real-time systems even harder to define and manage than the hard real-time ones. The Real-Time CORBA specification spans these two variations of real-time systems.

An overview of the Real-Time CORBA extensions can be seen in Figure 6.8.

The entire Real-Time CORBA IDL is contained in two modules: *RTCORBA* and *RTPortableServer*, with the exception of only the new service contexts, which have been added to the IIOP module. The *RTCORBA*::*RTORB* interface is an extension of the ORB interface that handles the operations regarding the Real-Time ORB configuration and manages the instances of the other real-time IDL interfaces.

One of the key concepts necessary for the understanding of the Real-Time CORBA specification is the concept of thread scheduling, which the OMG uses for controlling the scheduling of activities. Basically, a thread can be seen as small parts of an activity, which are conducted at a single node of the distributed

© 2005 by CRC Press LLC

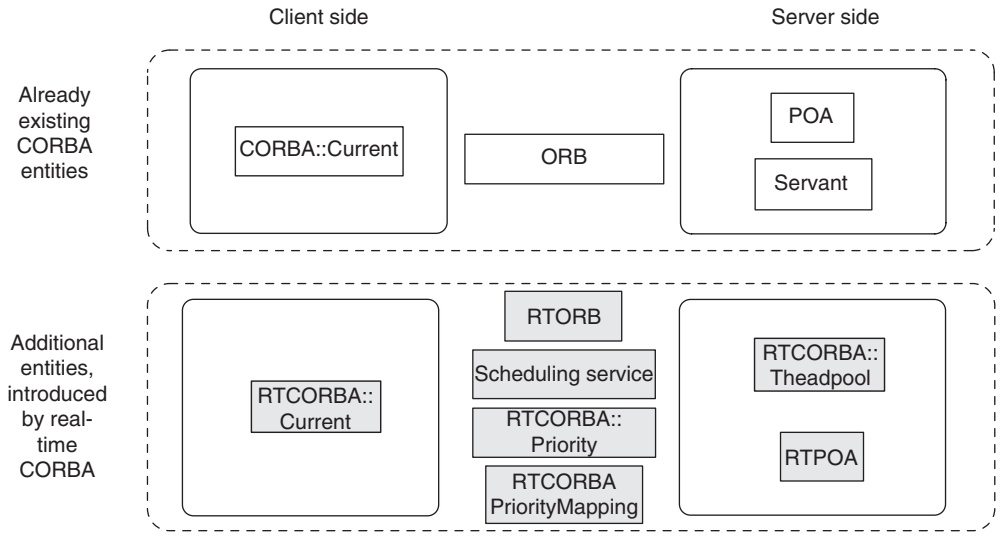

FIGURE 6.8 Real-Time CORBA Extensions. (Adapted from OMG, 2000a.)

objects network. The Real-Time CORBA specification defines interfaces that can be used to control the characteristics of the threads, enabling them to be scheduled, and therefore, allowing a system to control the scheduling of activities. These interfaces are *Threadpool* and *Current*.

Another part of the Real-Time CORBA specification that is quite important is the definition of the Real-Time CORBA *Priority* interface. Every Operating System available on the market has its own priority definition and handling mechanisms, but these mechanisms are not compatible between different OS. Thus, the OMG defined its own thread priority scheme, which overcomes the potential problems created by the utilization of different OSs in a distributed system. Therefore, any Real-Time CORBA application should always use the CORBA priority scheme, even if the same OS is used in all the network nodes. The access to the priority of a specific CORBA thread is achieved through the use of the *Current* interface.

Because of this standard priority scheme use, Real-Time CORBA applications must be able to map thread priorities into the native OS priority scheme. This is done through the *PriorityMapping* interface.

When one works with a shared-resources system, there are basically two different kinds of delays that can cause a thread to have its execution held up:

- Preemption — when a task has its execution delayed by the execution of a higher priority task.
- Blocking, or Priority Inversion — when a task is delayed by the execution of a lower priority task.

One of the goals of the Real-Time CORBA specifications is to minimize the occurrence of priority inversions, and one of the mechanisms used to do so is the propagation of the activity priority from the client to the server. In fact, Real-Time CORBA supports two different priority models:

- Client-Propagated Priority Model — when the server honors the priority of the invocation that had been set by a client.
- Server-Declared Priority Model — when the server handles requests at a priority assigned on the server side.

On the whole, Real-Time CORBA provides tools for the management and configuration of three basic types of resources in a distributed objects system: processor, communication, and memory.

At the processor level, Real-Time CORBA provides the mechanisms of thread pools, priority models, portable priorities, and priority banding. At the communication level, it provides mechanisms for priorities banding, protocol policies, and explicit binding. Finally, at the memory level, the mechanism supplied is the request buffering.

© 2005 by CRC Press LLC

6.10 MinimumCORBA

For systems with limited resources, like embedded controllers, intelligent sensors, and many others, CORBA might just be too large to fit into the memory space provided. For situations like these, where the application possibly does not require the full set of features provided by the CORBA definition, a reduced version of CORBA was specified. This reduced version is called "MinimumCORBA." MinimumCORBA is, in fact, a subset of the CORBA specification, with all the basic features included but with some of the nonessential ones removed. These omitted features can be implemented by the application when needed (OMG, 2002b).

The features cut off in minimumCORBA represent, in fact, a trade-off between usability and resources conservation. Bearing in mind compatibility between CORBA and minimumCORBA, all the IDL features are included in minimumCORBA. So, an application written with CORBA is fully compatible with another written with minimumCORBA. This is a highly desired feature, as there is no need to review or rewrite any application previously written to add some new component like an embedded controller or some new or upgraded sensor.

In short, minimumCORBA is CORBA without DII and its related interfaces, such as Dynamic Skeleton Interface (DSI) and the Interface Repository. It also does not include DCE ESIOP, COM/CORBA Interworking, and Interceptors. As for language mappings, the full mapping must be supported, except for the omitted core objects related to the above items.

6.11 Product Availability

There are a number of suppliers of CORBA ORBs. This section will list some of the software available for CORBA developers. Many of the implementations listed here are freeware, shareware, or free software.

Orbix, by IONA

Orbix is a commercial ORB, supporting Java and C++ mappings, being CORBA 2.5 compliant with some CORBA 3.0 features. It runs on Windows, Linux, and various Unix.

Devoted to the corporate market segment, it includes Naming, Transaction, Security, and Event Services, besides load balancing and fault tolerance capabilities.

Visibroker, by Inprise

This is a CORBA 2.5 compliant product, supporting Java and C++ mapping. Also devoted to the corporate market, it includes clustering and load balancing, portable interceptors, POA, objects-by-value, and RMI-over-IIOP for better Java interoperability. It implements Naming, Transaction, and Notification Services and is available on Windows, Linux, and various Unix.

Inprise also offers Visibroker-RT, a CORBA for real-time, embedded systems. It is offered in two versions, a full CORBA implementation and the Minimum CORBA subset, both with RT CORBA extensions.

The ACE ORB (TAO)

TAO is an open-source, high-performance, real-time implementation of CORBA that provides efficient, predictable, and scalable quality of service (QoS) end-to-end. At the time of this writing, TAO is CORBA 2.3 compliant.

It provides C++ language mapping, in which the generated code closely follows the C++ mapping specified in the latest C++ mapping for CORBA 2.3. TAO supports development in a number of different Operating Systems: many flavors of Unix, Linux, and Windows NT, as well as some real-time operating systems such as Lynx, PSOS, and VxWorks. TAO also supports some embedded operating systems like Windows CE.

© 2005 by CRC Press LLC

TAO also provides the implementation of a number of CORBAservices:

- A/V Streams Service,
- Concurrency Service,
- Event Service,
- Real-time Event Service,
- LifeCycle Service,
- Load Balancing Service,
- Logging Service,
- Naming Service,
- Property Service,
- Scheduling Service,
- Security Service,
- Trading Service,
- Time Service, and
- Notification Service.

It also implements the SSLIOP Pluggable Protocol. TAO's copyright license makes it perpetually and irrevocably an open-source free software, and it can be found on the website: http://www.cs.wustl.edu/~schmidt/TAO.html.

ORBacus

ORBacus is a fully CORBA-compliant ORB that is distributed as a source code. It is a robust, full-featured object request broker with a proven record and enterprise-class features.

Orbacus provides complete C++ and Java language mappings, a simple configuration and bootstrapping, small fooprint, and, at the time of this writing, is CORBA 2.4 compliant. ORBacus also supports some of the features in the CORBA 3 standard, including Portable Interceptors.

It supports the AIX, Tru64, HP-UX, Linux, Solaris, Irix, and Windows NT/2000/XP platforms. ORBacus offers a 30-day free evaluation, and is also free for use, with full support, in application development being offered in a distributed computing course that requires CORBA.

The Naming Service, Event Service, Property Service, and Time Service are included in the package.

Orbacus' site is http://www.orbacus.com.

omniORB

The omniORB is a robust high-performance CORBA ORB with C++ and Python language mappings. It is freely available under the terms of the GNU Lesser General Public License (for the libraries) and the GNU General Public License (for the tools). It is one of the only three ORBs to be awarded the Open Group's Open Brand for CORBA.

omniORB version 4.0 adheres to version 2.6 of the CORBA specification. It is fully multithreaded. It has support for Windows NT/XP/95/98, Linux, Solaris, HP-UX, Irix, Digital Unix, AIX, OpenVMS, NextStep Reliant Unix, Phar Lap's Real-time OS, SCO Unixware, Mac OS X, and others.

omniORB supports CORBA 2.6 DynAny interfaces, TypeCode, and type ANY, GIOP, and IIOP 1.0, 1.1, and 1.2, wchar, wstring and code set negotiation, bidirectional GIOP, and others. It also provides included support for the Naming Service and is fully interoperable with other CORBA ORBs.

The omniORB project is hosted at http://omniorb.sourceforge.net/.

jacORB

The jacORB is a high-performance, fully multithreaded ORB with an IDL compiler that supports OMG IDL/Java language mapping revision 2.3. It has native IIOP, GIOP 1.2, and Bidirectional GIOP. CORBA 2.3 specification is supported.

© 2005 by CRC Press LLC

jacORB uses the GNU Lesser General Public License, which means that it is free even if one wishes to sell a product that uses its libraries.

It requires a Java VM with version 1.1 or better, and it should be possible to run jacORB in any operating system with a suitable Virtual Machine. It has been tested on Windows 95/98/NT/2000/XP, Linux, and Solaris; but reports show that jacORB also runs on other Unix flavors and MacOS X.

jacORB supplies CORBA Naming Services, COSS Event Service, Transaction Service Collection, Concurrency, and Trading Services. It should be fully interoperable with other ORB implementations through the IIOP. Portable Object Adapter is supported and some GUI tools like POAMonitor and NameManager are provided, which allow users to inspect their object adapters and browse the Naming Service.

Dynamic Invocation Interface (DII) and Dynamic Skeleton Interface (DSI) and Dynamic Management of Anys (DynAny) are also some features provided by jacORB 1.4.1.

The software and documentation can be found on http://www.jacorb.org.

MICO

The acronym MICO expands as "MICO is Corba." The intention of this project is to provide a freely available and fully compliant implementation of the CORBA standard. MICO has become quite popular as an OpenSource project and is widely used for different purposes. It has recently been branded as CORBA compliant by the Open Group.

MICO is currently tested on Solaris, AIX, Linux, Digital Unix, HP-UX, Ultrix, and Windows 95/NT. Reports indicating that it also works on FreeBSD, Irix, OS/2 DG/UX, and LynxOS have been received by the supplier.

The software is fully CORBA 2.3 compliant, and support Dynamic Invocation Interface (DII), Dynamic Skeleton Interface (DSI), Interface Repository (IR), IIOP as native protocol, IIOP over SSL, and DynAny, among others.

MICO supports IDL to C++ mapping, and supports the following CORBA services:

- Interoperable Naming Service
- Trading Service
- Event Service
- Relationship Service
- Property Service
- Time Service and
- Security Service.

MICO is currently under the GNU General Public License, and can be found at http://www.mico.org.

VBOrb

VBOrb is an Object Request Broker, written entirely in Visual Basic 5. With VBOrb, it is possible to write CORBA Visual Basic clients and servers.

VBOrb can be used instead of a COM-CORBA-Bridge, to access Enterprise Java Beans(EJBs), or to remote control a Microsoft program by using Visual Basic for Applications(VBA). VBOrb comes with an IDL to VB compiler called IDL2VB. The compiler is written in Java.

VBOrb supplies the Naming Service and is distributed under the GNU General Public License. The software can be obtained at: http://home.t-online.de/home/Martin.Both/vborb.html.

ORBit

There are currently two versions of ORBit in use: the original "stable" ORBit and the new ORBit2. ORBit is an implementation of CORBA which is used in the GNOME project, an open-source project aimed at

© 2005 by CRC Press LLC

implementing a windowing interface for Linux. Active development is done for ORBit2, being a clean reimplementation from scratch. The old ORBit code is no longer maintained.

ORBit, the original version, is CORBA 2.2-compliant and has a number of language mappings. ORBit2 is a CORBA 2.4-compliant Object Request Broker (ORB) featuring mature C, C++, and Python bindings. Bindings (in various degrees of completeness) are also available for Perl, Lisp, Pascal, Ruby, and TCL; others are under development.

It supports POA, DII, DSI, TypeCode, Any, IR, and IIOP. Optional features including INS and threading are available.

ORBit2 is engineered for the desktop workstation environment, with a focus on performance, low resource usage, and security. The core is written in C and runs under Linux, Windows, and many flavors of Unix.

ORBit and ORBit2 support the following CORBA services:

- Concurrency Service
- Event Service
- Naming Service and
- Transaction Service.

ORBit is distributed under the GNU Public License and GNU Lesser Public License (libraries), and its homepage can be found at http://www.gnome.org/projects/ORBit2; but a number of other sites can be found with consistent documentation about the software.

e*ORB

According to the supplier, OpenFusion, e*ORB (tm) is the smallest and fastest Object Request Broker in the world and has the smallest footprint. It supports C, C++, Java, and Ada mappings. One of e*ORB's most prominent characteristics is its support for Real-time and embedded systems.

e*ORB Java edition was the first Java ORB to be ported to operating systems such as VxWorks, Palm OS, EPOC, and Windows CE. Today, e*ORB empowers embedded systems ranging from driver information systems to battle-tank simulations and optical switches.

It is supported on a wide range of platforms including Lynx, embedded and desktop Linux, Solaris, HP-UX, Windows, VxWorks, Integrity, Stratus VOS, and Palm OS.

Three CORBA services are included with e*ORB:

- Naming Service,
- Notification Service, and
- Logging Service.

The software is licensed and downloads are provided for evaluation free of charge for 30 days. During evaluation, customers are also entitled to 30 days of free support. The e*ORB site can be found at: http://www.prismtechnologies.com

Other Products

A good resource for becoming acquainted with some free CORBA products is the OMG website. OMG maintains a list of links for many free CORBA implementations at: http://www.omg.org/technology/corba/corbadownloads.htm

7.5 Intermediate Components
7.6 Summary

Robert Tolksdorf
Freie Universität Berlin

7.1 Introduction

The Web is a network-based information system in which a huge number of components interwork. The main classes of these are Web servers that have and deliver information, Web clients that request information, and intermediate components that help to make the overall system more efficient. In this chapter, we review these components and their functionalities.

7.2 The Architecture of the Web

The Web is a network-based information system where information is delivered by Web servers to Web clients on request. Components involved in this system can be classified into the following three categories:

1. *Web servers* have information and make it available on request. They are accessed by TCP connections on the IP address of the machine they run on and the port they are configured to listen to. On that connection, they communicate with the Hypertext Transfer Protocol HTTP.
2. *Web clients* request information from specific servers by issuing a request following the HTTP. The information received is then further processed according to the kind of client. The most well-known kind of Web clients are Web browsers that display the information transferred from the server to a human user. The most important "invisible" kind of Web clients are *Crawlers* that retrieve information from Web servers to feed it into indexed full-text databases that are the core of Web search engines.
3. *Intermediate components* transform requests or information. One important kind of such components is formed by *proxies* who act on behalf of the actual client, for example, because it is behind a firewall and should not be visible outside. The other important kind of intermediate components are *caches* that also act as proxies but store information retrieved and answer further requests for it without having to contact the actual Web server.

© 2005 by CRC Press LLC

Figure 7.1 shows a configuration of such components. There are two Web servers: one offers some specific information and the other one hosts a Web search engine. There is a traditional Web browser as a client, which is configured to use a proxy to access the corporate Web server and to contact the search engine directly. Close to the search engine, a Web crawler retrieves some information from the corporate Web server that will be fed to the full text index of the search engine on which searches are performed later. All components run on different machines connected via IP. They communicate with HTTP to transfer requests and responses on information.

Figure 7.1 shows a very small excerpt of the real structure of the Web. The Web Server Survey of Netcraft (available at http://www.netcraft.com/Survey) counted 35,424,956 Websites in January 2003. The HTTP service is available on a substantial fraction of the named computers on the Internet — these were counted as 171,638,297 in the January 2003 edition of the Internet Domain Survey of the Internet Software Consortium (available at http://www.isc.org/ds/WWW-200301). The number of clients cannot be counted. However, the number of people having Internet access can give an indication of this. The Global Internet Statistics survey of Global Reach (available at http://www.glreach.com/globstats) estimates the size of the worldwide online population in September 2002 as 619 million people.

7.3 Web Servers

Web servers are the source of information in the Web. They are, in general, passive in that they deliver the information they have on request to clients.

Historically, the first Web page on a server was http://nxoc01. cern.ch/ hypertext /WWW/TheProject. html. The server ran at the European Organization for Nuclear Research (CERN) where the Web project was invented. The page mentioned contained the description of this project. The first server program available to the public was httpd developed at the CERN by Ari Luotonen, Henrik Frystyk Nielsen, and Tim Berners-Lee. It is still available at http://www.w3.org/Daemon. It soon found a more successful rival with the NCSA (National Center for Supercomputing Applications) HTTPd. Today, the most used Web server is Apache (see http://www.apache.org). It ranks first in the Netcraft Web Server Survey (http://www.netcraft.com/survey), with an estimated share of about 62% in January 2003 before the Microsoft product family of Internet-Information-Server with a share of about 27% of all servers.

General Operation

The identification of content on the Web is done by URLs. For HTTP communication, they have the format *http://<Servers IP Address>/<Path to information>*. An example URL is `http://www.w3.org/Protocols/Activity.html`, which identifies the HTML page `Protocols/Activity.html` on the server `www.w3.org`. This Web page is stored in the Web servers file system in the form it is delivered to the client. Therefore, it is called *static content*. Another example is `http://www.google.com/search?q=server`, which addresses the script search on the

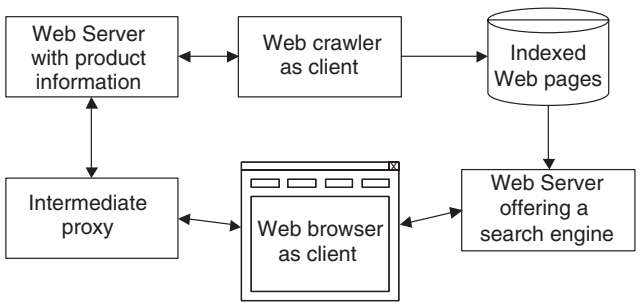

FIGURE 7.1 Components in the Web.

© 2005 by CRC Press LLC

server www.google.com and passes a parameter string q=server to it. The information returned from the server is generated fresh with each request; therefore, we speak of *dynamic content* in this case.

The resolution of the servers address is part of the standard TCP usage by any client. The resolution of the path information to a specific chunk of data is up to the server. It may map it into some location in a local file system, or to the execution of some programs on the servers' machine.

Web servers in general consist of several subcomponents. Among their duties are the following:

Interfacing with the network: Web servers speak by definition HTTP for communication with clients. HTTP interaction is initiated by contacting the default port 80 on a machine with TCP as the transport protocol. Since Web servers can be configured to accept connections on a different port and since HTTP can be directed to any port, this is actually just a default definition.

A Web server has to set up the standard interface for the respective IP communication, which means to listen on port 80, to accept connections, and to perform the standard HTTP communication over the resulting communication socket.

Mapping of static content to the local file system: Web servers have access to some local file system, which is the persistent storage for the static contents. How the path to information from the URL is mapped to a path in the file system is up to the server and its configuration. http://www.w3.org/Protocols/Activity.html could lead to the delivery of the file /htdocs/Protocols/Activity.html, /import/htdocs/staticcontent/Protocols/Activity.html, or ~auser/.public_html/Protocols/Activity.html. The mapping could also map to different filenames, for example, to c:\Protocols\Activity.htm. In the extreme case, it is not necessary to access a file system at all — a server could execute some network access or have static hard-coded HTML pages as constants in its program.

Mapping of dynamic content by execution of programs: The servers' configuration determines whether a URL denotes static or dynamic content. An example configuration could state that —after performing the static mapping — all files in the directory cgi-bin and ending in .cgi are programs to be executed to generate dynamic content. The server then has to interface the standard input and standard output channels of the programs with the incoming and outgoing network connection and to start the program. A most important side issue of this operation are security aspects, for example, under what user account the program runs and what permissions it has.

Coordination of the components: Web servers must be able to serve multiple requests at a time. Sequential processing is necessary for the acceptance of TCP connections on port 80. All other activities of a server can in principle be executed concurrently in different threads. Managing this degree of concurrency needs coordination activities. These have to take care of shared writable resources, for example, log files, deal with processes started by dynamic resources, or optimize the degree of concurrency.

Dynamic Content

The static content offered by a server is generated by authoring Web pages in advance. This is usually supported by editors for individual pages, by programs that help to handle the complete structure of a site, or by advanced content management systems.

Dynamic content is the basis for interaction on the Web — any forms that accept user input have to be processed on the server. Conceptually, the generation of the page that answers to the form input is the goal of the server. In practice, of course, side effects such as storing inputs in a database or triggering the delivery of some items purchased with the form is the actual goal of this generation of dynamic content.

Figure 7.2 shows a minimal script that generates dynamic content. We can assume that it is accessible by the (imaginary) URL http://www.foo.ba/cgi-bin/serverdate.cgi. We also assume that the server runs on a UNIX system that recognizes such a script as executable content. When a request for /cgi-bin/serverdate.cgi reaches the server www.foo.ba, it executes that script.

The echo instructions in this script simply write the following string to the standard output. The line echo `/usr/bin/date` invokes the program /usr/bin/date — which results in the current system date of the server — and forwards its result to the standard output.

© 2005 by CRC Press LLC

```
#!/bin/sh
echo "Content-type: text/html"
echo
echo "<html> <head> <title>Date here</title> </head> <body>"
echo "The current date here:<b>"
echo `/usr/bin/date`
echo "</b>. Thanks for using this service. </body> </html>"
```

FIGURE 7.2 A sample script.

```
Content-type: text/html

<html> <head> <title>Date here</title> </head> <body>
The current date here: <b>
Sun Dec 29 20:54:41 2002
</b>. Thanks for using this service. </body> </html>
```

FIGURE 7.3 The output of the script.

The Web server sends all output of the script to the Web client in its response, resulting in an answer as in Figure 7.3.

The generated content always contains the date of its creation. For interactive Web sites, it is necessary to process input typed by the user in forms with scripts. The *Common Gateway Interface* (CGI) (see http://www.w3.org/CGI) defines a mechanism to pass these data to scripts. The core idea is to use environment variables to communicate this information. The Web server sets a specific set of about 20 variables and then calls the script (which is often also called "CGI program"). An example variable is `REMOTE_ADDR`, which contains the Internet number from which a client sent the HTTP request. More important is `QUERY_STRING`, which contains the form-input to be processed.

Figure 7.4 shows the flow of information in the processing of a CGI request. After filling out a form, the client encodes input data in the URL and sends it as part of its request to the server. The server identifies `phone.cgi` as a script and places the information received from the client into environment variables according to the CGI mechanism. The CGI program processes these data, for example, by querying a database accordingly. The results received are then placed in an HTML page, which is communicated to the server by the standard output of the CGI program. The server passes the generated HTML page to the client, which displays it as the result of the request to the server.

Many Web-Servers offer another mechanism to include dynamic content in Web pages, the so-called *Server Side Includes*. The basic idea is that the server scans the Web-pages to be delivered for a set of special tags. These tags are then replaced by dynamic content by the server. The set of these tags depends on the Web server used.

For most Web servers, the SSI Tags are actually HTML comments of the form

<!--#*directive attribute*$_1$="*value*$_1$" *attribut*$_2$="*value*$_2$"-->.

This makes the approach compatible with all Web servers: if SSI are not parsed and replaced they appear as HTML comments and are ignored by clients.

Figure 7.5 shows an example use of SSI: the regular HTML code includes one SSI tag. It contains the directive `flastmod`. This tag is replaced by the Web server with the date of the last modification of a file within the Web server's file system. Its name is given in the attribute `file`. In the case that the attribute has an empty value — as in the example — the modification date of the file that contains the SSI directive is taken.

7.4 Web Clients

Web servers are accessed by programs, which converse in HTTP and interact with the server accordingly. Only at first glance, all clients are Web browsers. There are number of components in the Web that are not intended for user interaction, such as proxies and caches. We provide an overview on them in the following.

</div>
```

FIGURE 7.5 The page with SSIs before and after processing by the server.

Web Browsers

Web browsers are what makes the Web usable — they retrieve information and display it. The success of the Web is due to two mutual reinforcing developments — the availability of more and more information on growing numbers of Web servers and the availability of better browsers as clients.

Historically, the first Web browser was written in 1990 on a NeXT machine by Tim Berners–Lee, who keeps a description including a screen shot at http://www.w3.org/People/Berners-Lee/WorldWideWeb.html. The first widespread client application was the Mosaic browser written by Marc Andreessen and Eric Bina at NCSA. It was available for a number of Unix platforms. Andreessen soon commercialized the application by cofounding Netscape and developing the browser with the same name. The rest is history — after a long time of dominating the browser market, Netscape was outnumbered by the installations of Microsoft's Internet Explorer. Today, the Internet Explorer is the by far the most used Web browser.

A Web browser consists of multiple components that fulfill at least the following functionalities:

Accepting user inputs: A Web browser is a program with a GUI that accepts user inputs like mouse-clicks, menu selection, or keyboard input. The browser has to interpret these inputs, for example, to determine on which link a user has clicked, what bookmark was selected from a menu, or which URL was typed in. Processing this input can affect the current display, affect the browser's state, or lead to a network access.

Retrieving information from servers: When a URL is determined, the respective Web server has to be contacted, which means extracting the server's IP address from the URL and to initiate a HTTP connection with it. Then, the client has to extract the path to information and generate the respective HTTP request. The answer from the Web server has to be read and stored in some internal data format. Then, the network connection has to be closed. The browser has to be able to react properly to the various response-codes as defined in HTTP, for example, by retrieving redirected URL from another server or by asking the user for necessary authentication credentials and retrying the access. The browser also has to scan the retrieved HTML code for further embedded data-like images and retrieve these also from the network.

© 2005 by CRC Press LLC

Rendering and displaying information: A Web page has to be rendered by the browser, which means to associate the HTML elements with some display style, for example, that headlines with the <h1>-Tag are displayed in a very large font-size and boldfaced. The style can be determined by the HTML standard, by a style specification with the Cascading Style Sheets language (http://www.w3.org/Style/ CSS), or be browser-specific. Device specific abilities also have to be taken into account for rendering. Then, the whole display has to be formatted. The main parameter here is the current width of the browser window and any scaling levels selected. Then, the rendered page has to be displayed in a window according to the windowing and graphic system found on the machine. After this, user inputs are again accepted.

Coordination of activities: Web browsers are usually able to offer multiple windows to the user. This implies that multiple interactions with the network can take place concurrently. Also, embedded elements in a page can be retrieved in parallel. The management of this concurrency needs coordination, which takes care of thread management and optimization of network usage, for example, by limiting the number of concurrent network accesses or ensuring that resources are retrieved only once and then reused.

Management of the users' interaction environment: The activity of browsing the Web is usually supported by some interaction environment that is specific for the user. It includes a set of preferred Web server addresses, the bookmarks or favorites, a user history, the storage of data entered info Web forms and its automatic usage in further forms, account information for Web passwords, functionalities to export Web information to local programs, etc. The variety of functions is large and so is the effort spent on them. Since the basic network access and rendering of information is quite standardized, these user-centered functionalities leave room for browser vendors to come up with unique product features.

Support functionalities: Web information is not limited to HTML and some standard graphic formats. There is a variety of — often proprietary — further formats, for example, for audio. Web browsers usually support a wide variety of such formats and offer an interface for extensions with so-called plug-ins that are able to render further formats. Modern Web browsers also include a set of further functionalities that support the user in other Internet functionalities as well. Usually, a Web browser also includes a client for Netnews following the NNTP protocol and email following POP3, IMAP, and SMTP protocols. Finally, client-side activity is supported by scripting languages like JavaScript and execution environments like Java or ActiveX.

Other Clients

It is not necessary that Web servers are accessed by Web browsers only. Any program that obeys the HTTP can retrieve information from a Web server. Examples are Web site copy programs that retrieve the contents of some Web site by traversing all links starting from some entry site. The content is then stored on a local disk and available for usage even if no network connection is available. More important are, however, so-called *Web crawlers* that are the basis for any search service on the Web like Google or AltaVista.

Historically, one of the first was the WebCrawler (see http://www.ncsa.uiuc.edu/SDG/IT94/Proceedings/Searching/pinkerton/WebCrawler.html). It used the same principles as today's search engines. However, in 1994, the Web became significantly smaller — WebCrawler indexed about 50000 pages. As of Spring 2003, the largest Web search engine is Google, with more than 3 billion pages indexed.

A Web search engine is usually a full text index of Web pages on which queries can be placed. The technology of these engines differs in the way they determine the similarity between the query and the contents of the index and the way they order the results.

But the full text index has to be filled with contents retrieved from the Web. Since the Web is extremely large, this task has to be automated. Web crawlers are clients that automatically traverse the Web and feed the retrieved information into a full text index. They operate according to the following generic steps:

1. Initialize a list of URLs to retrieve.
2. Take a URL from the list and perform a test whether it should be retrieved. This tests whether the URL has already been visited, or the crawler could be configured to focus only on URLs from some specific Internet domains.
3. Retrieve the information referenced by the URL using HTTP.

© 2005 by CRC Press LLC

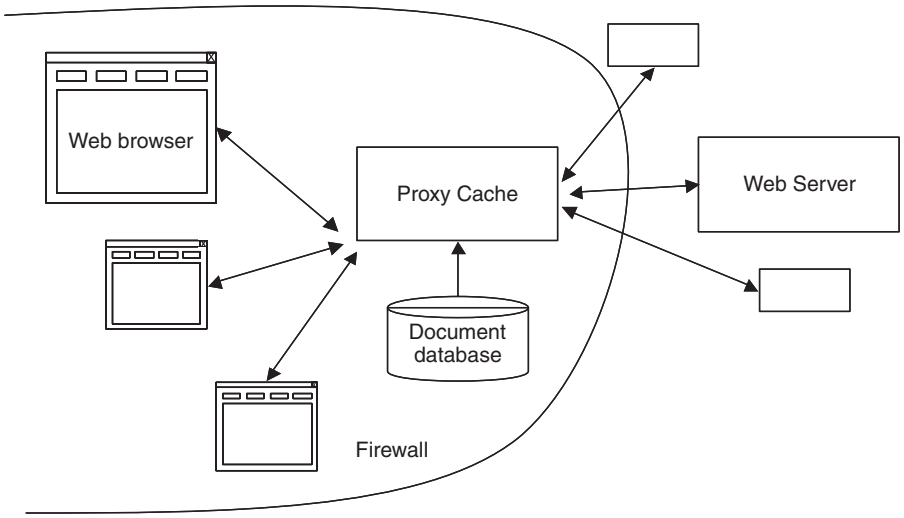

FIGURE 7.6 Browsers connected to servers via a proxy cache.

4. Extract any references from the information (for HTML pages, e.g., the references from the tags `<a>`, `<link>`, `<meta>`, `<img>`, `<object>`, and `<frameset>`) and put it into the URL list.
5. Extract all contents from the retrieved information as text and enter it into the full text index.
6. Extract any metainformation available like authorship, size, date written, etc. and store it in some database.
7. Repeat the process starting with step 2.

This basic process still defines the algorithm used by search engines. However, today, better strategies for selecting the next URL to follow exist; information can be extracted from more file types aside from HTML, and more metadata are retained.

7.5 Intermediate Components

Browsers and crawlers communicate directly with Web servers. However, there are also components that act in between clients and browsers. The most important ones are proxies and caches discussed in this section. Historically, the CERN httpd server was also able to act as a cache. Today, many Web servers offer the cache functionality either integrated or as configurable modules. A popular stand-alone cache program is the Squid proxy cache available at http://www.squid-cache.org.

The direct connection between Web clients and servers is not always possible or advisable. For example, in a corporate network, clients should not be fully exposed to the outside world due to security reasons. All Internet traffic will be routed through a firewall, which is the single and central interface between the — both IP based — LAN and WAN. It could be advisable to hide the internal network usage from the outside world.

A solution to this is to establish a *proxy* that resembles the origin of all Web accesses to servers but actually only forwards requests by clients in the LAN and directs answers to them. A client is configured to access a proxy at a fixed address with its request. The proxy program forwards the request to the actual Web server and retrieves results from there. The results are then forwarded to the original client. This configuration has the consequence that the actual client is never exposed to the outside world in the Internet as a WAN. All traffic is directed through the proxy to whom special security measures can be applied.

Since the proxy is used by all LAN clients, it can be extended to offer an additional functionality. As a *cache,* it can store all information retrieved indexed by the URL used. Any future accesses for the same URL can then be satisfied from that cache without having to contact the actual server. The result is the reduction of WAN usage and lower network latency due to the avoidance of WAN connections to servers.

© 2005 by CRC Press LLC

As a side effect, the overall traffic in the WAN and the load to Web servers are reduced. In practice, proxy and cache functionality is combined in a single program leading to a *proxy cache*.

Figure 7.6 shows a configuration where a proxy cache is located behind a firewall. It is contacted by several browsers and in part satisfies requests from a database of documents. The proxy cache contacts Web servers to retrieve documents not in the store. After retrieval, they are stored and then delivered to the clients asking for them.

7.6 Summary

The Web is conceptually a simple client–server system with clearly defined interfaces. The main components in the Web are clients that access Web servers by HTTP to retrieve information. Mainly that information is displayed to users by a browser, and often it is also used to build search engines. Intermediate components help in optimizing the performance of the components. The most important of these components are proxy caches.

About the Author

Robert Tolksdorf is professor of computer science at the Freie Universität Berlin, heading the group on network-based information systems NBI (http://nbi.inf.fu-berlin.de). His research focuses include the study and development of languages, models, and systems that guide the coordination of activities in networked systems, the study, application, and evaluation of XML-technologies for network-based information systems, among others, and the study and application of Semantic Web technologies, and the use of novel models for the coordination of agent societies on a large scale, especially those models based on Swarm Intelligence. Tolksdorf authored several journal articles, four books on Internet and coordination technologies, and about 90 refereed publications, invited book contributions, and research reports. He is a member of the IEEE Computer Society, the ACM, and the German Informatics Society, where he chairs the special interest group on multimedia.

8.3 Script Languages
Common Gateway Interface — CGI • Perl • PHP • JavaScript
8.4 Web Services

8.1 Introduction

The development of Internet programming languages was mainly driven by users' needs. Since Tim Berners Lee introduced the first version of the Hyper Text Markup Language (HTML) [9], various Internet programming languages have been developed to meet the demands of the Internet community. At the beginning, the community had to get along with no programming language at all for 20 years. Nowadays, it is hard to find the best and most suitable Internet programming language.

The most popular language on the Web is of course HTML, a markup language. Markup languages are interpreted by the Web browser and are not termed as programming languages. They consist of tags and values, whereby tags declare how to interpret the enclosed value. The main disadvantage of HTML is the miscellaneous content and layout information. This was the main reason for the development of the eXtensible Markup Language (XML). XML [8] has, in contrast to HTML, no predefined tags. Hence, the structure of an XML document can be defined by the developer. The layout of the page will be defined in a separate style file.

A main result of the Web hype was the change of classical software engineering toward a new discipline termed Web engineering. Tools, methods, and data descriptions have been adapted to develop Web Applications more efficiently. Often, Web engineering is described as different from and more complex than traditional software engineering [2]. Web engineering has to deal with the development of Web-based systems and applications. Therefore, it typically has to handle conditions of Web-based systems [4]: rapid growth of the requirements and the continual change of the content. The systems also have to be built as scalable and maintainable because such functionality cannot be added later. In [5], Web engineering is described as the outcome of the convergence process between software engineering and hypertext systems. Until now, Web engineering has been coined, on the one hand, by traditional hypertext-oriented information systems and, on the other, by application-driven e-commerce systems. To overcome these issues, Web engineering and its programming languages attempt to integrate databases and middleware systems, and even use software engineering methods such as the Unified Modeling Language (UML) to design Web systems [1].

© 2005 by CRC Press LLC

The major difficulty in finding a common Internet programming language derives from the diversity of Internet architecture. The traditional client–server structure is heavily influenced by the client type for example, personal computer, personal digital assistant, or mobile phone. The service developer has to keep in mind the devices and the possible bandwidth that the client may use to connect. The business logic often remains the same and only the presentation has to be adapted. Users demand to see their data only in different views. Figure 8.1 shows the Enterprise Application.

The integration (EAI) approach focuses on the integration of different applications by means of connectors[1] [3]. The user integration is defined in a separate layer, which allows to serve several types of user devices and interfaces. At some point, it will be possible to even integrate new user interfaces with as yet unknown technologies. The EAI layer is responsible for the integration of the different applications needed for the service, for examaple, user data or order information. Through EAI, it is possible to combine legacy applications with new technologies and make them accessible via the Internet.

We will now describe the most popular Internet programming languages and their main fields of application. Every description will include a small example to outline the advantages and differences.

8.2 Java

In 1990, Sun Microsystems launched a project under the code name "green project" to develop base technologies for the consumer market. These so-called "set-top-boxes" were planned to be programmable hardware components for households. The goal was to transmit small programs via TV channels for easier update of the functionality of household devices. The result was a portable, network-compatible operating system, and a flexible programming language named Object Application Kernel (OAK). At the same time, the Web began to grow in importance, and with this hype the breakthrough of the language named Java began.

Java [10] is an object-oriented programming language based on the concepts of C and C++. Object-oriented concepts have been implemented more effectively in comparison to C++. The memory management and handling of object references are much simpler, which has the drawback of machine-intimate programming not being possible.

One main advantage of Java is the platform independence. In a first step, the source code is compiled into a platform-independent byte code. This byte code will be interpreted by a Java Virtual Machine (JVM) in a second step. The JVM itself is platform dependent, which means that a JVM has to exist for different target platforms and several operating systems (see Figure 8.2). This portability has the disadvantage of lacking in performance, compared to a compiled program. A conditional corrective is the

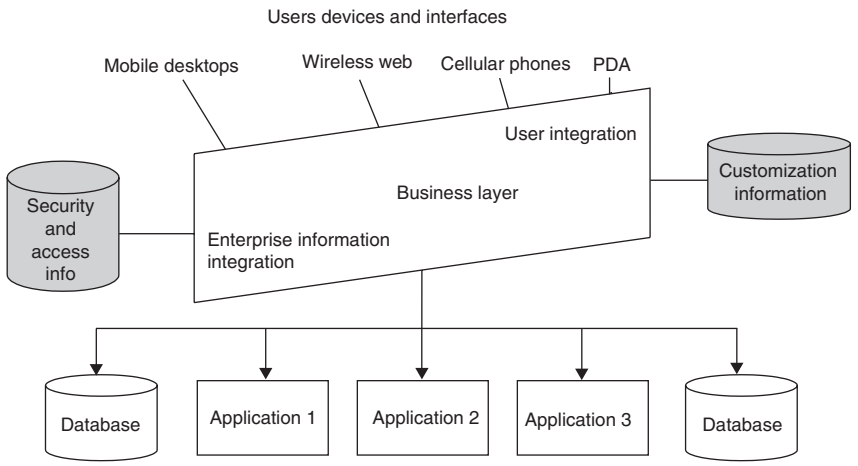

FIGURE 8.1 Enterprise Application Integration Based on [3].

© 2005 by CRC Press LLC

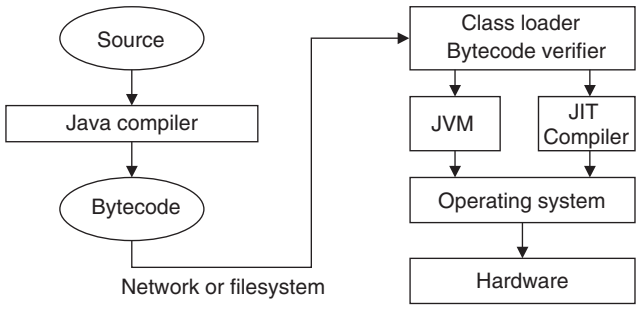

FIGURE 8.2 Design of the Java Compiler.

so-called "Just-in-Time" (JIT) Compiler, which transforms the byte code by the first execution into a platform - and operating system-dependent machine code. During the next processing of this code segment, the machine code can be executed directly by the CPU.

Portable and distributed systems are particularly susceptible to security problems. The security concept of Java is described by using the metaphor of the "Sandbox." The sandbox guarantees that an untrustworthy application cannot gain access to system resources. Therefore, Java implemented a four-level security concept:

- Java itself avoids many problems, for example, no pointers available.
- Verification of byte code during interpretation.
- Dynamic loading of classes is connected with security examinations. Additionally, the runtime environment uses separate name spaces for local classes and classes from the network.
- Access to local resources and network resources is restricted and only possible by means of additional actions. (certification)

The following characteristics of Java — not only as a programming language, but in the sense of the total concept — are to be particularly emphasized:

- Automatic memory management (Garbage Collection).
- Integrated multi-threading allows parallel processing.
- Robustness by explicit declarations, no type casting, and no explicit references (pointers).
- Dynamic loading and binding of classes also over the Internet.

Java offers several options of integration as Internet programming language:

Java-Applications are stand-alone applications without restrictions. In combination with the Java Runtime Environment, they form an operational program.

Java-Applets are special Java programs that can be interpreted directly from the virtual machine of a Web browser. They make Web pages more functional for the client side.

Java-Servlets are Java programs for server-side applications that are using the Common Gateway Interface (CGI). This interface is provided by the Web server and allows to call the Java servlets.

Java Server Pages — JSP are an enhancement of Java servlets with the aim of separating layout information and business logic.

JavaBeans are reusable software components that can be manipulated visually in a builder tool.

Enterprise Java Beans form a framework architecture for component-based and distributed business applications development.

Applets

A Java applet contains classes that can be executed directly by a Web browser. They are embedded in HTML pages and therefore always come with a graphical user interface. Applets are subject to severe

© 2005 by CRC Press LLC

restrictions in order to ensure security: access to local resources, and to the network is not permitted. It is possible only to connect to the host server of the applet.

These restrictions can be eased on the client side by means of signed applets. However, this seems to be of importance only for applications in the intranet, since an applet developer has to be in possession of a system structure on the client side. Example 1 shows a simple applet as well as the possibility of embedding it into an HTML page.

```
import java.applet.Applet;
import java.awt.Graphics;
public class HelloWorld extends Applet {
      public void paint(Graphics g) {
            g.drawString("Hello world!", 50, 25);
      }
}
<html>
<head>
<title>A Simple Program</title>
</head>
<body>
      <p>Here is the output of my program:
      <applet code="HelloWorld.class"
            align="baseline"
            width="150"
            height="25">
      </applet>
      </p>
</body>
</html>
```

Example 1. Simple Java Applet — HelloWorld.java

The upper part shows the applet class, which contains a single method to draw the output. Below is the corresponding HTML file to embed the applet by means of the applet tags. Additional parameters to position the applet are provided.

Java Servlets

Java servlets are modules to extend Web servers or application servers that hold appropriate interfaces ready (Java servlet API). They have no user interface and basically serve as alternatives for CGI scripts. While loading, the servlet is initialized, configuration data are loaded, and possible auxiliary threads are started. The servlet is removed from the environment only by the garbage collector; up to then, it operates on the request–response paradigm.

```
public class SimpleServlet extends HttpServlet
{
public void doGet (HttpServletRequest request, HttpServletResponse
response) throws ServletException, IOException {
            PrintWriter out;
            String title = "Simple Servlet Output";
            // set content type and other response header fields
```

© 2005 by CRC Press LLC

```
            response.setContentType("text/html");
            // write the data of the response
            out = response.getWriter();
            out.println("<HTML><HEAD><TITLE>" + title );
            out.println("</TITLE></HEAD><BODY>");
            out.println("<H1>" + title + "</H1>");
            out.println("<P>This is output from SimpleServlet.");
            out.println("</BODY></HTML>");
            out.close();
      }
}
```

Example 2. A Simple Java Servlet

As Example 2 shows, the HTML code is directly included in the Java program. Special methods (e.g., doGet) act as entry points to the servlet. The output is written to "standard out" (stdout) and is sent to the client via the Web server.

Java Server Pages — JSP

Java Server Pages (JSP) have developed from Java servlets. They follow the approach of separating the business functionality from the layout information. Normally, the generated layout is pure HTML. Hence, JSP are based on HTML tags and include calls to JavaBeans, which contain the business logic. The JSP are complied into Java servlets with the first call of the page. By means of this approach, it is possible for the Web designer to focus on the layout and for the application developer to focus on the business implementation.

Figure 8.3 shows the JSP architecture. A Web server needs to include an extension to execute the JSP. By the first call, the JSP engine translates the page into a servlet, which will be executed by the servlet engine of the Web server. The HTML output of the servlet will be transferred as an HTTP response to the client.

Example 3 shows the JSP file in extracts in the upper part and below the corresponding Java class. The HTML page consists of wild cards that allow the reference to a Java class.

```
<HTML>
<%@ page language="java" import="Clock" %>
<jsp:useBean id="clock" class="Clock" />
      ...
      Today is the <%= clock.getData() %>
</HTML>
import java.util.*;
public class Clock {
      public String getDate() {
            return new Date();
      }
}
```

Example 3. Simple Java Server Page

8.3 Script Languages

While applications developed with common programming languages have to be compiled before runtime, programs developed with script languages, called scripts, are interpreted at runtime by appropriate

© 2005 by CRC Press LLC

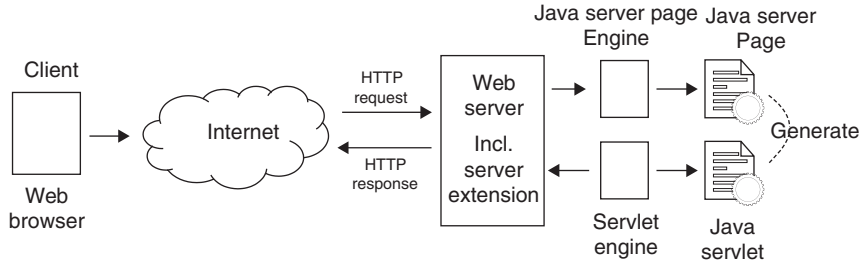

FIGURE 8.3 JSP Architecture.

interpreters. The script itself can contain several lines of commands like a common batch file and may be processed automatically by the interpreter.

Nowadays, many scripting languages are available, and can be divided into server-side scripting (Perl, PHP, etc.) and client-side scripting languages (e.g., JavaScript), depending on where the interpreter processes the script.

In general, scripts can be used to create dynamic Web pages and interactive applications on the World Wide Web. Thereby, scripts may be embedded into HTML pages or may serve as stand-alone Web applications and mostly obtain data from databases or legacy systems via well-defined interfaces. Server-side scripting can be used in the areas of information systems, e-commerce, and for monitoring as well as for loosely coupled steering purposes in the automation systems domain.

Common Gateway Interface — CGI

The Common Gateway Interface (CGI) itself is not an Internet programming language. Referring to [11,12] it is a standard for external gateway programs to interface with information servers such as Hyper Text Transfer Protocol (HTTP) servers. HTTP [6] is used as the protocol between Web clients and Web servers. The disadvantage of the HTTP protocol is its stateless character, which lets the connection between client and server become lost after the connection is closed. Therefore, a separate session handling has to be implemented to overcome these deficiencies. A CGI program, on the other hand, is executed at runtime, and can therefore generate dynamic information. An HTTP server is often used as a gateway to legacy information systems, for example, an existing software system or an existing database application. The Common Gateway Interface is an agreement between HTTP server developers on how to integrate such gateway scripts and programs. It is typically used in conjunction with HTML forms to build dynamic database-based Web applications. The CGI specification is currently maintained by the NCSA Software Development Group [12] and is available in version 1.1, or CGI/1.1. Further revisions of this protocol are guaranteed to be backward compatible.

Figure 8.4 shows the basic architecture of CGI to enhance an existing Web server in order to create a dynamic Web content. The CGI interpreter can vary from a simple shell to more powerful and comfortable interpreters like PHP or Perl, and is chosen in the first lines of the CGI script. Server and interpreter, respective the CGI script, can communicate in four major ways: environment variables, command line, standard input, or standard output.

There are two HTTP methods that can be used to access a certain CGI service: the GET and POST method. Depending on which method is used, the script will receive encoded data of HTML forms from clients:

- *GET method*: The CGI script receives the encoded data in an environment variable.
- *POST method*: The CGI script receives the encoded data directly over "stdin," and can calculate its length.

© 2005 by CRC Press LLC

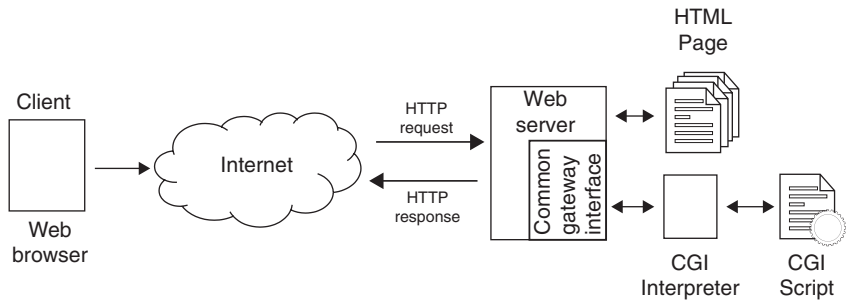

FIGURE 8.4 Web server using Common Gateway Interface.

The results of the CGI script are written to standard output and redirected by the Web server to the inquiring client.

Perl

As mentioned before, the CGI mechanism allows the use of miscellaneous interpreters for parsing and executing scripts. One of these interpreters is Perl, an acronym for "Practical Extraction and Report Language." The corresponding scripts are named Perl-scripts. While Perl was initially developed for UNIX platforms, there are nowadays various interpreters for platforms like Linux, Unix, VMS, OS/2, Macintosh, and all Windows variants in existence. Hence, Perl scripts can be used on all of these systems without making any changes to the scripts.

Perl created, written, developed, and maintained by Larry Wall was initially a language for processing text. In the current version of Perl, features like sophisticated pattern matching capabilities, straightforward I/O, and flexible syntax are included. In fact, by borrowing heavily from C, sed, awk, and the Unix shells, Perl has become the language of choice for many I/O, file processing and management, process management, database administration, client/server programming, and system administration tasks for Web-based information systems [13].

Perl is an ideal choice for small solutions. Example 4 shows a script that sends an email and writes an HTML message to standard output if the script is executed directly in a shell by typing "`perl SendMail.pl`" on the command line. If the script is called by a Web server, the HTML output is delivered to the Web client. The first line of the script is a comment line and is used to denote the script as Perl script and to define the interpreter application (`perl`) that should process the script.

Perl is available for free. One of the numerous sites where Perl packages can be downloaded is the Comprehensive Perl Archive Network (CPAN) [14].

PHP

PHP, a project of the Apache Software Foundation, is a widely used general-purpose scripting language especially suited for Web development and can be embedded into HTML documents. This, of course, is a major difference from Perl. Various Web servers can use PHP in the form of the CGI mechanism or by extending the Web server with a PHP module if performance optimization is important. Figure 8.5 shows both configurations.

Most of the following descriptions can be found in [15]. PHP can be used on all major operating systems, including Linux, many Unix variants (including HP-UX, Solaris, and OpenBSD), Microsoft Windows, Mac OS X, RISC OS, and probably others as well. PHP also supports today's most popular Web servers like Apache, Microsoft Internet Information Server, Netscape, and iPlanet. For the majority of these servers, PHP can be integrated as a module or as a normal CGI processor.

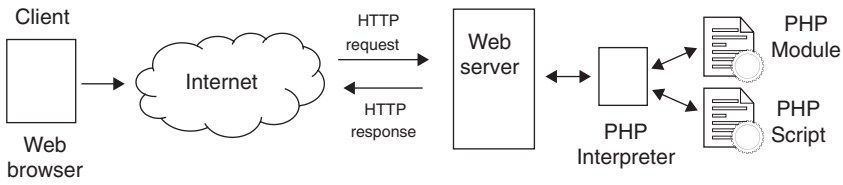

FIGURE 8.5 Web server using PHP.

```
#!/usr/bin/perl
use CGI; $cgi=new CGI(); print $cgi->header;
$from=$cgi->param('Sender'); $mailtext=$cgi->param('Mail text'); $sub-
ject=$cgi->param('Subject'); $to='john@doe.com';
send($to, $from, $mailtext, $subject);
print "<HTML><FONT Face=Arial><B>Your Mail was sent.</B><BR>";
print "further text ...<BR></HTML>";
sub send {
my ($to, $from, $mailtext, $subject) = @_;
use Net::SMTP;
my $smtp = new Net::SMTP("smtp.somewhere.com");
$smtp->mail();
$smtp->to($to);                                    #Addressee
$smtp->data();
$smtp->datasend("From: $from\n");                  #Sender
$smtp->datasend("Subject: $subj\n");               #Subject
$smtp->datasend("\n");                             #Close heading
$smtp->datasend($mailtext);                        #E-Mail text
$smtp->dataend();
$smtp->quit();
}
```

Example 4. Simple Perl Script — SendMail.pl

PHP is mainly focused on creating dynamic Web pages, also known as server-side scripting. The main fields of operation are: collecting form data, generating dynamic page content, or sending and receiving cookies.

There are three main fields where PHP scripts are used:

- *Server-side scripting*: This is the common use for PHP. There have to be three parts to activate PHP scripts: the PHP parser (server module), a Web server, and a Web browser. The browser accesses the script via the Web server and receives the output.
- *Command-line scripting*: In this field, a PHP script can run without any server or browser. Only the PHP parser is needed. This type of usage is suitable for scripts regularly executed automatically, for example, text processing.
- *Writing client-side GUI applications*: A not very widespread approach with PHP is the implementation of window applications. By including the PHP-GTK (Graphical Toolkit) package, PHP allows to include some advanced features even for cross-platform programming.

One of the advantages of PHP is its support for a wide range of databases, for example, Oracle, dBase, mySQL, Microsoft SQL, Sybase, and all ODBC databases. PHP allows to develop database-based Web application at a high speed.

PHP can also communicate with other services using protocols such as Lightweight Directory Access Protocol (LDAP), E-mail protocols, and many others. It is even possible to open raw network sockets and

© 2005 by CRC Press LLC

PHP has support for the WDDX complex data exchange between virtually all Web programming languages. With respect to interconnection, PHP supports instantaneous access of Java objects and use them transparently as PHP objects, in addition to using a CORBA extension to access remote objects. PHP has extremely useful text processing features, for example, for parsing XML documents. It supports the Simple API for XML (SAX) and Document Object Model (DOM) standards.

Example 5 shows a PHP script sending a query to a database and returning the results in the form of an HTML table. The PHP code is embedded in the HTML pages and is processed on the server after calling. It will be replaced by the result of the database query. Thus, the client receives a pure HTML page without PHP code. As the example shows, PHP allows easy integration of a database and thus provides a flexible solution for Web-based database applications.

The file will be normally invoked via a common Web browser.

```
<HTML>
<HEAD>
      ...
</HEAD>
<BODY>
<H1>List of Persons orderd by age:
<TABLE> <TR><TD><b>Lastname</TD><TD><b>Firstname</TD><TD><b>Age</TD><TR>
<?php
// open a connection to a MYSQL database
$link=mysql_connect("localhost","Username","Password");
           or die("Could not connect:" . mysql_error());
// select database
mysql_select_db("DB-Name",$link);
// query persons (ordered by age) from database
$query="select firstname,lastname,age from person order by age,last-
name,firstname asc";
$result = mysql_query($query,$link);
$num = mysql_numrows($result);
// print table of persons
for ($i=0; $i<$num; $i++){
      $row=mysql_fetch_array($result);
      echo
"<TR><TD>$row[lastname]</TD><TD>$row[firstname]</TD><TD>>$row[age]</TD></
TR>;
}
mysql_close($link);
?>
</TABLE>
</BODY>
</HTML>
```

Example 5. Simple PHP Script — Database-Access.php

JavaScript

JavaScript is a client-side script language, which was introduced by Netscape in 1995. It is independent from HTML and has been defined to support HTML developers to optimize their Web pages. JavaScript has nothing in common with the programming language Java.

© 2005 by CRC Press LLC

JavaScript can either be embedded in HTML pages or in a separate file and can only be referenced. The JavaScript code is interpreted during runtime by means of an interpreter software included in the Web browser. It is executed in a "Sandbox" to restrict the possibilities and to ensure security on the client side. It is, for example, not possible to access files out of a JavaScript.

JavaScript does not replace server-side programs, for example, cgi-based programs. It can be used for small calculations, input checks, etc. in HTML files. Example 6 shows a Java Script for the calculation of a square. The function is embedded in the HTML page and executed on the client side after the button "Calculate square" is pressed.

```
<html>
      <head><title>Simple JavaScript</title>
      <script type="text/javascript">
            <!--
            function square() {
         var Result = document.Form.Input.value *
         document.Form.Input.value;
         alert("The Square of " + document.Form.Input.value + " = " +
         Result);
            }
            //-->
      </script>
      </head>
      <body>
            <form name="Form" action="">
                  <input type="text" name="Input" size="3">
              <input type="button" value="Calculate square"
              onClick="square()">
            </form>
      </body>
</html>
```

Example 6. Java Script Example

8.4 Web Services

A new trend throughout the Internet is brought about by Web services. Today's Web is designed for human interaction and is a very successful system in domains like information sharing, distributed content library, Business to Customer (B2C) e-commerce, and nonautomated business-to-business (B2B) interactions. The reasons are the few standards (HTTP and HTML) and a shallow interaction model (only few assumptions made about computing platforms). The result is the ubiquity of the Web where existing applications in various internet programming languages work together.

Open, automated B2B e-commerce, business process integration, resource sharing, or distributed computing are some examples. While an *ad hoc* solution could be used to realize application-to-application (A2A) interaction with HTML forms on top of existing standards, the goal for the future is to enable systematic A2A interaction on the Web.

"Web Services" is an effort to build such a distributed computing platform. According to Gartner Group Inc., Web services will capture substantial attention in 2002, and by 2004 Web services will dominate deployment of new application solutions. According to the W3C, the definition of Web services is [7]:

© 2005 by CRC Press LLC

"A Web service is a software system identified by a URI, whose public interfaces and bindings are defined and described using XML. Its definition can be discovered by other software systems. These systems may then interact with the Web service in a manner prescribed by its definition, using XML based messages conveyed by internet protocols."

A rough outline is shown in Figure 8.6 and in more detail in Figure 8.7.

The goal is to enable universal interoperability, widespread adoption, and ubiquity by enabling an Internetscaled dynamic binding, efficiently supporting both open (Web) and constrained environments, using the following standards to build a Web service:

- Simple Object Access Protocol (SOAP) [16].
- Web Service Description Language (WSDL) [17].
- Universal Description, Discovery, and Integration (UDDI) [18].

The Web service's architecture can be divided into three parts: Service Provider, Service Registry, and Service Customer. The Service Provider publishes services via the Service Registry, and the Service Customer (a person or a program) searches this registry for an appropriate service (Figure 8.8). Web service applications can be seen as encapsulated, loosely coupled Web "components" that can be dynamically connected.

The Web service technology stack, shown in Figure 8.8, is based on the TCP/IP stack and supports, in addition to the network and transport layers, a packaging, a description, and a discovery layer. The discovery layer provides a mechanism to fetch the description of the services (UDDI) provided, the

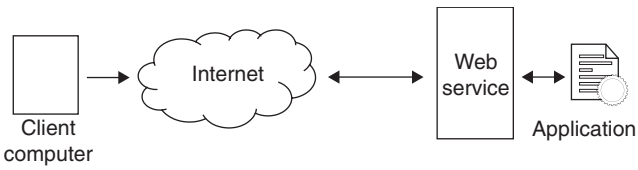

FIGURE 8.6 Web service outline.

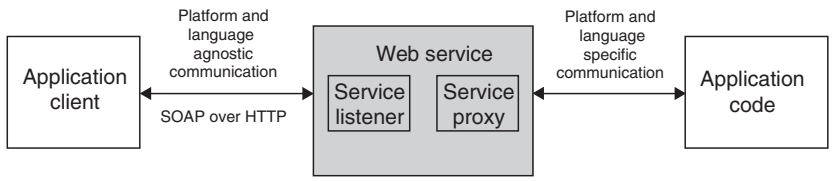

FIGURE 8.7 Web service in more detail.

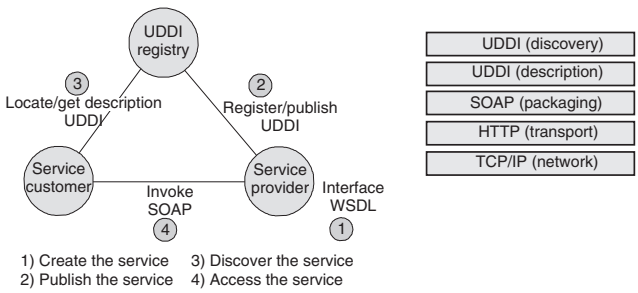

FIGURE 8.8 Web Service Architecture and Technology Stack.

© 2005 by CRC Press LLC

description layer provides a description of services for the customer (WSDL), and the packaging layer provides packaging of the data to serialize it (HTML, SOAP). This layering system helps to guarantee platform neutrality.

Finally, some notes on the technologies involved:

- The SOAP is a lightweight and simple XML-based protocol to allow the exchange of structured and typed information across the Web. It is a standardized Packaging Protocol in the form of an XML application; therefore, XML schemas and XML namespaces can be applied.
- The WSDL is a powerful means for service developers to describe their services. A WSDL description can be used to describe which type of message can be exchanged, how messages are related, and how SOAP messages are exchanged.
- The UDDI standard was designed for building repository-based registry services for the lookup of Web services. It defines how to publish a business information.

The Web Service approach allows either new applications or existing applications (legacy applications) to be accessed via the Internet based on standard protocols. XML is the base technology for the description of the Web services and for the data exchange protocols.

Internet Still Image and Video Formats

Guido Heising
University of Applied Sciences TFH Berlin

Kai Uwe Barthel
University of Applied Sciences for Technology and Business Berlin

9.1 Digital Images
Need for Compression • Image Format Features • Image Compression Principle
9.2 Video Formats
Video Compression Principle • Internet Video Applications • Video Coding Standards, Quasistandards, and File Formats

Nowadays, it is hard to find a website without images. Even buttons and layout elements of a website consist of small bitmaps. The use of images in the internet has become possible as there are sophisticated compression algorithms to keep the sizes of the images as small as possible. Video clips are still rarely found on typical websites; but the usage of video is increasing. However — opposed to still images — up to now, there is no commonly accepted video coding standard that has been incorporated into web-browsing applications. In addition, the bandwidth that is required for the transmission of high-quality videos—larger than the size of a matchbox — is still too high for most users having access to the internet with moderate bandwidth only (e.g., a modem).

This chapter introduces some basic facts about images and videos. It explains the essential ideas of image and video compression techniques. Standards and quasistandards are described, and their features will be discussed.

9.1 Digital Images

When images like photos or graphics are digitized (e.g., using a scanner), the color and the brightness information of the original image is converted into discrete digital picture elements — the *pixels*. There are two parameters — the *color depth* and the *image resolution* — that control how the analog image information is converted into the digital image data (Figure 9.1).

Due to the fact that our eyes use three kinds of cells for color perception, all colors can be described using three components or channels. Thus, the information that has to be stored for each pixel consists of three values to describe the color components R, G, and B (red, green, and blue). There is a standard sRGB color space that is used by many scanners and other devices. If a different color space is to be used, this information can be described in an *ICC-profile* from the *international color consortium*. This color profile should be joined to the image data. For *grayscale images* (like black and white photos), only one channel for the brightness information is needed. The number of bits that are assigned to a pixel is called the *color depth* and is measured in *bits per pixel* or *bits per channel*. Most computer graphic adapters use a display mode called *True Color*, which uses 8 bits per channel, which corresponds to 24 bits per pixel.

© 2005 by CRC Press LLC

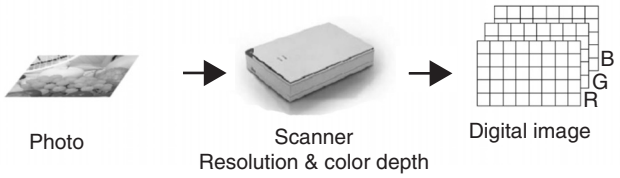

FIGURE 9.1 The resolution and the color depth control the quality and the size of the digitized image.

In this mode, 16.7 million different colors can be described or displayed, which is more than sufficient for typical digital images to be shown on computer monitors. In the prepress domain, four-channel images, Cyan, Magenta, Yellow, and black (CMYK), are used for printing purposes. Other image types like medical images might need a higher color depth such as 12 or 16 bits per channel. A simple fax image uses only 1 bit per pixel to distinguish between black and white. If an image has only a limited number of different colors (up to 256 colors), the RGB-values colors are stored in a lookup table (LUT). In this *palletized image,* every pixel color can be described by an index referring the color from the LUT entry.

By selecting a *resolution,* the scanning device is instructed on how many samples (pixels) are to be generated. The unit for resolution is *dpi,* which stands for *dots per inch*. Typical values for scanning resolutions are in the range between 50 and 1200 dpi. If the resolution is chosen to be a high value, then the quality will be very good as even the finest details of the image can be captured. However, the amount of digital data generated will also be quite high. The pixel number of the image is given by the product of length and width — both multiplied by the dpi number. To obtain the total number of bits for this image, the pixel number has to be multiplied by the color depth.

Websites are viewed by many different users on different computer screens that have dissimilar resolutions. The actual resolution of a monitor depends on the number of pixels that can be displayed and the dimensions of the screen (measured in cm or inch). Typical computer systems have a monitor resolution of approximately 100 dpi. This should be taken into account if images are to be displayed on a website. There is no use displaying an image having more pixels than the area on the screen in which it is displayed. This may seem obvious; however, many web pages can be found that use very large images. Browsers can scale images to any size; however, they do not use sophisticated scaling or interpolation techniques, so that the best visual results are obtained if every pixel will be used only once nonscaled.

Need for Compression

A typical photo (10 cm × 15 cm) scanned at a resolution of 100 dpi in true color (24 bits per pixel) will result in an uncompressed file size of 680 kB (393 rows × 590 columns = 231,870 pixels × 3 Bytes). Using the fastest available modem with a bandwidth of 56,000 bits/sec, this image would need 100 sec to be transmitted. If we were talking about a video clip of this size, even with a reduced frame rate of 10 fps (frames per second), a compression factor of 1000 would be needed for the 56k modem. Typical videos have frame rates of 25 (PAL) or 29.97 (NTSC); the dimension of digitized video in pixels is 720 × 576 pixels for PAL DV, and 720 × 480 for NTSC DV.

These examples show how important it is to use highly efficient image compression techniques. When talking about compression, three different modes should be distinguished: *lossless compression* does a perfect preservation of the image, and every pixel is unchanged in every bit. For typical images (photos), even the best algorithms are not able to achieve a compression factor higher than two to three. "Visual lossless" compression is a term that was introduced by the industry trying to tell their customers that their compression technique is almost perfect. However, there is no exact definition for visual lossless; usually, it means that encoding errors are not noticeable to a typical viewing person. Whether encoding errors may be perceived depends very much on the viewing conditions and how much the viewer is trained. Typical compression factors range between 3 and 10. Then, there is *lossy compression*, mostly used in the Internet due to the need for very small file sizes. A lossy compressed image may look different compared

© 2005 by CRC Press LLC

to the original; however, the quality is still acceptable. Needless to say that quality requirements are different in different circumstances. Typical compression factors are in the range from 10 to 100.

Once a compression standard has been established, new improved ideas or algorithms cannot be incorporated. However, as only the decoding part is standardized, there is always room for optimizations on the coder side, as long as the decoder can still decode the compressed data. After a standard has been settled, it usually takes some years until optimal coding settings are determined. This is particularly true for video compression, as there are too many different parameter settings possible. This also means that there are JPEGs and MPEGs of similar size but of different quality. It actually depends on the capability/quality of the coder used, and how well an image or video is compressed.

Image Format Features

If images are to be used in the internet, several aspects have to be considered: there are hundreds of image file formats, compressed and uncompressed; however, standard browsers only support three of them. These supported image types are *Compuserve GIF* [1], *Portable Network Graphics* (PNG) [2], and the *JPEG-standard* from the *Joint Picture Expert Group* [3]. Often, image file formats provide different encoding modes such as support for different color spaces, the choice between lossy and lossless compression, and different transparency modes. However, not all modes of these image file formats are supported by all web browsers. For example, the original JPEG standard knew more than 20 different encoding modes, but only two of them are supported by standard browsers and common image viewing applications. For example, there is a lossless JPEG compressing mode, which cannot be used in the Internet. Image file formats other than the three mentioned above can only be used if appropriate plugins are installed or a special applet image viewer is used.

However, none of the three image formats — GIF, PNG, or JPEG — is suitable for all purposes. They differ in the type of color spaces supported and other modes. Table 9.1 compares the main features of these image file formats.

TABLE 9.1 Comparison of Features of Internet Image File Formats

	Image format

■□=supported by image format, but problems with some web browsers
*) Today JPEG is outperformed by newer & better algorithms like JPEG2000, which has no browser support yet.
**) GIF images allow one out of the possible 256 colors to be fully transparent. PNG has a much higher level of transparency support.

© 2005 by CRC Press LLC

One important distinction is the *support for different color modes. Bitonal images* or palletized images with a reduced number of colors are only supported by GIF and PNG. These images could, however, be converted into RGB images and then stored as JPEG, but this would make these images larger than necessary. JPEG should be used for natural photographic images. The professional device-independent *Lab color space* is not supported by any of the three formats. Four-channel CMYK images can be stored as JPEG, but these images should not be used in the Internet, as browsers cannot display them.

Other distinctions between features are the available *compression mode* and the *support for additional (meta) data* or *special transmission* abilities. JPEG always performs a lossy compression, the desired quality can be controlled by a quality factor. GIF and PNG use lossless compression only. However, some tools can modify the image data to ease subsequent lossless compression.

Compression efficiency has been permanently improved over the last few years. JPEG does a very good compression job; but naturally there are far better schemes by now.

All three formats have support for *progressive* (sometimes called interlaced) *transmission* of the image data, such that a reduced resolution version of the image may be seen before the entire data have been transmitted. Usually, the file size increases by a few percent when using this progressive option. However, some browsers ignore this feature and only display the image if all data have been transmitted.

Meta data like the author, copyright information, etc. become more and more important. Only JPEG supports the *IPTC standard for metadata*; PNG allows some annotations and comments. Usually, browsers cannot display this extra information.

Transparency or an alpha channel describes whether the pixels of an image are fully or partially transparent. GIF images allow one out of the possible 256 colors to be fully transparent. PNG has a much higher level of transparency support, but has very reduced browser support. Transparency support is needed if the background of a website is changed very often. In order to avoid transparency information, the transparent image can be overlaid on the background image/color. The resulting merged image can then be stored with no transparency even using JPEG.

JPEG and PNG have limited *ICC-profile* support, which is ignored by most browsers.

For huge images like maps or aerial views, a *random access* to small fractions of an image would be very desirable. However, none of the described formats has support for this. Usually, many different small images are held on the server, which are then dynamically selected.

The new compression standard *JPEG2000* [4] has support for most of the above-mentioned features and it also outperforms these formats in coding efficiency. To date, there is no browser support for this new powerful standard.

The choice of a particular image file format should be based on the following aspects:

- *For photographic images,* JPEG is the right choice, if a lossy representation can be tolerated. If not, PNG (24 bit mode) should be used for lossless transmission.
- *Nonnatural images* with only a few colors should be compressed to GIF or PNG (8-bit mode). It should be noted that the PNG format does not have any patent restrictions, as opposed to GIF.
- *Animated images* have to be saved as GIF. There is an animated version of PNG called MNG, however, without support from any browser.
- *Images with transparency* need to be stored as GIF or PNG, while PNG has a much higher level of transparency support; but unfortunately is not supported by all browsers. (At *http://entropymine.com/jason/testbed/pngtrans/,* a PNG transparency test web page can be found.)

As mentioned before, there are several coding tools that can differ significantly in encoding quality. PNG allows different filter settings that affect the compressed file size. Optimal compression depends on a suitable choice of the filter type for PNG and the usage of a high-quality encoding tool in the case of a JPEG image.

Image Compression Principle

The core idea of image compression is to remove any *redundancy* or correlation present within the image. Redundancy is all the data, that are not important to the information. Consequently, it can be removed by the coder, whereas at the decoder these data are reconstructed and added back to the image.

© 2005 by CRC Press LLC

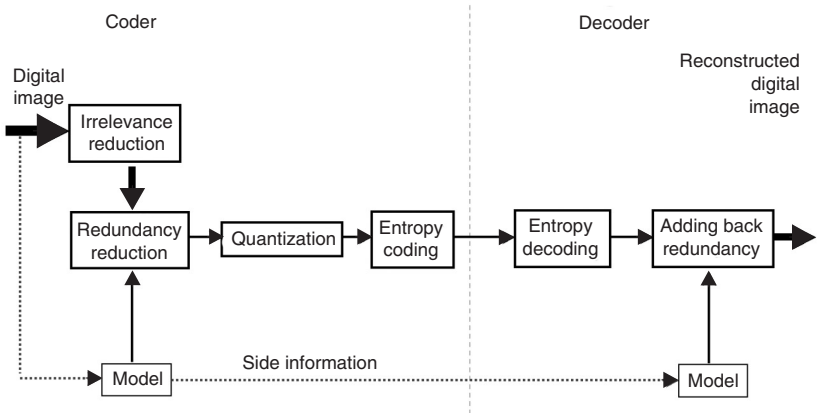

FIGURE 9.2 Block diagram of an (image) compression scheme.

The basic idea of image compression is shown in Figure 9.2. In the first step, all *irrelevant information* is discarded. This might be a very high color depth, which is not needed or a very large image, which is scaled down first before it is compressed and transmitted.

The next step is to remove the redundancy of the image data. The efficiency of a coder depends on how good this redundancy is discovered and removed. Actually, a *model* describes the idea as to how the redundancy can be exploited.

Models have become more and more elaborate over time. A very simple model could use the fact that most pixel values do not change abruptly. The value of the previously transmitted pixel can be used as a guess (a *prediction*) for the next pixel value. Now only the prediction error has to be transmitted or stored. If it is possible to store this prediction error more effectively than the original pixel data (with fewer bits), then there is compression. A more sophisticated model might use a better adaptive predictor taking into account more surrounding pixels. The model for JPEG compression uses the fact that it is more effective to describe an image block through a superposition of suitable basic blocks instead of transmitting it pixel by pixel.

If this model (how to remove the redundancy) is known both to the coder and the decoder, there is no need to transmit the model data. However, if the image data are analyzed first to adapt the model to the particular image, then some extra data (the *side information*) have to be transmitted to the decoder as well in order to guarantee that the same model is used at the coder and decoder sides.

After the redundancy reduction in the next step, the remaining data can be further simplified by using a *quantization* process, which basically performs some sort of rounding. If a quantization is performed, this is the point where the compression gets lossy, since the decoder is not able to reverse the rounding. This is the main parameter for controlling the compression factor.

As an example, let us assume that the pixel values of an 8-bit gray channel are to be coded. Using a quantizer consisting of 2^6=64 equal distributed values over the input range of 2^8=256 gray values, the input values can be rounded to the closest value of {2,6,10,…,254}. If only 2^4=16 output values are allowed, the input values can be rounded to {8,24,40,…,248}. In the first case, 6 bits/pixel are necessary, which results in a compression factor of 8/6=1,33, whereas only 4 bits/pixel are used in the latter case leading to a compression factor of 8/4=2. Needless to say that the losses, the *quantization errors*, introduced in the latter case are larger and the reconstruction quality will be worse.

Finally, the quantized data have to be transmitted or stored in an efficient way: *entropy encoding* tries to assign short codes (bit patterns) to frequent symbols, whereas rare symbols do get longer codes (more bits). Thus, by employing a *variable length code* (*VLC*), the average code word length will be reduced compared to using a *fixed length code* (*FLC*) as assumed in the above example.

© 2005 by CRC Press LLC

At the decoder, all the steps are performed in the reverse order to reconstruct the decoded image, which leads to an approximation of the original image in the case of lossy coding or an identical version in the case of lossless coding.

The principle of *predictive coding* — also known as Differential Pulse Code Modulation (**DPCM**) — has already been roughly described in the previous section. A very sophisticated coder using DPCM is the relatively new JPEG lossless (*JPEG-LS*) standard also known as *LOCO*; however, there is no browser support for this. Some other image coding approaches, especially those used by the Internet image formats, shall be explained in the next part of this chapter.

Run length coding is one of the simplest image coding approaches — particularly efficient for images with a limited number of colors. Instead of repeating identical pixel values over and over, the value is reported only once, followed by the quantity of pixels of the same color (Figure 9.3). As an example, "red, red, red, blue, blue, blue, blue, …" could be transmitted as "(red, 3); (blue,4); …." This approach is in part in the *Microsoft* **BMP** file format.

Lempel-Ziv-Welch (LZW) is the patented coding algorithm used for the GIF format. It is similar to the techniques used for ZIP or COMPRESS. LZW is a sophisticated lossless compression method, which analyzes the data and searches for repeating patterns within the (image) data. A library is built up during the encoding process. If a new pattern occurs in the data, this pattern will be added to the library at the coder and decoder as well. If the same pattern occurs again, then the library index can be used to describe this pattern. If LZW sees "012012," it is a clever-enough algorithm to spot the trend of alternating symbols and replace each instance with a shorter code for the index, thereby compressing the information.

GIF compression does a line scan of the image data, thus only exploiting the horizontal redundancy. PNG compression can use prediction techniques (called compression filters) to exploit vertical redundancy as well. In addition, it uses a patent-free version for the actual compression.

JPEG coding splits the image into blocks of 8×8 pixels. Every block is then transformed using the *discrete cosine transform* (DCT), which results in energy compaction within the block. This approach corresponds to the idea that instead of describing the block on a pixel-by-pixel basis (Figure 9.4, left), it is more efficient to perform a weighted overlay of only a few well-chosen basis block patterns, which will generate an identical or similar block. The fixed set of basis blocks consists of 64 different cosine-shaped patterns of varying frequency, which is known at the coder and decoder sides. Thus, only the weights (DCT coefficients) have to be coded. Any quality can be achieved from a highly compressed coarse approximation up to a visual lossless representation by selecting the precision (quantizer) of the weights of these blocks. In the example shown in Figure 9.4 on the right, a high precision is chosen, which leads to an almost lossless representation of the small block in the top right position.

The lower the contrast of a basis block, shown in the example, the closer the weight to zero and the lower the importance of that respective basis block. Therefore, one can further reduce the bit rate by coding only the n largest weights of an image block out of 64. The quality of the reconstructed block often is still quite high, as can be derived from Figure 9.5 for n=16. There is one exception from the above-stated rule as there is one basis block that does not show a contrast but in most cases does have a large weight. This is the left-most block in Figure 9.5. It represents the mean or DC value of the image block [5].

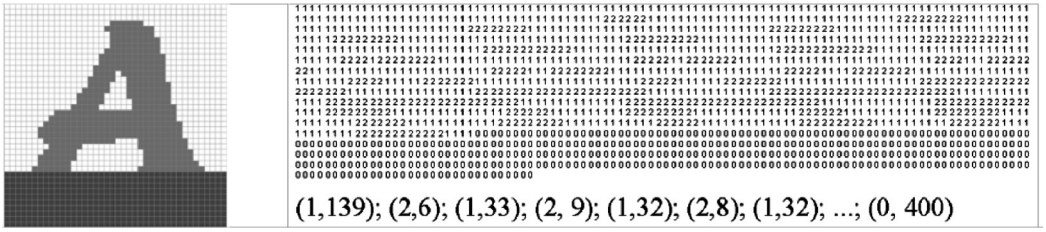

FIGURE 9.3 Run length coding; indices are grouped and described as value followed by the number of occurrences.

© 2005 by CRC Press LLC

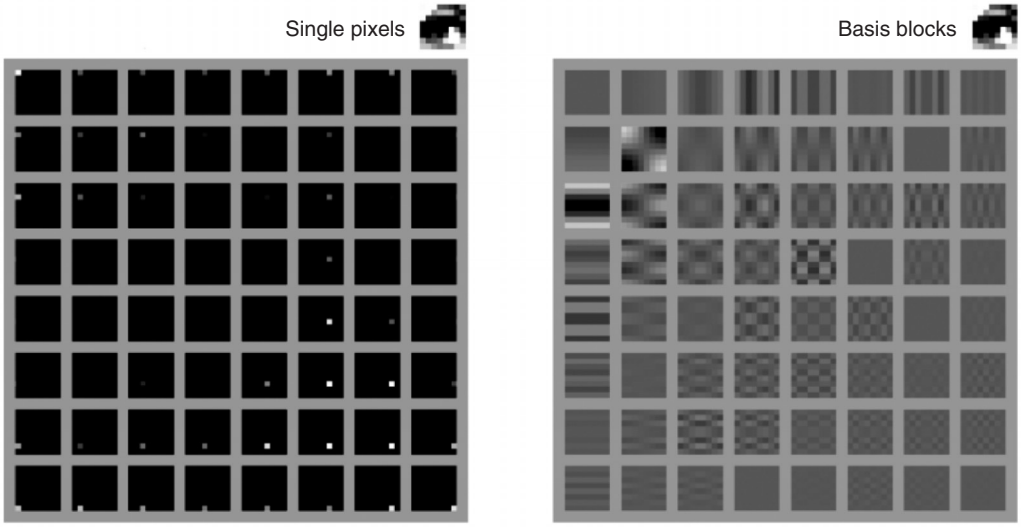

FIGURE 9.4 JPEG; instead of a description by pixels (left) image blocks are approximate by overlaid basis blocks.

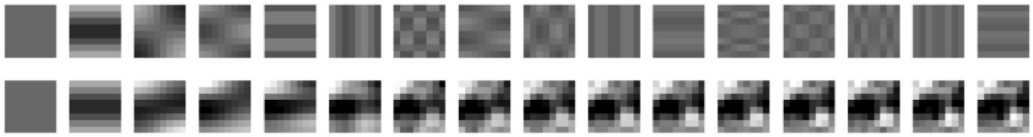

FIGURE 9.5 JPEG; The successive overlay of basis blocks (shown in the upper line) can produce better and better approximations of any image block (shown below).

The DCT approach is very efficient as far as coding of natural images is concerned as in most cases the spatial variation of the image signal is rather smooth. Thus, only a small number of the basis blocks will be required for the approximation, most probably those blocks in the top left corner of Figure 9.4, which represent lower frequencies.

One major disadvantage of the block-based DCT scheme should be mentioned as it is often recognized in decoded images, that is, the so-called *blocking artifacts*. These annoying artificial block structures are related to the choice of a high compression ratio, which led to a poor approximation of the image blocks. This is due to a strong rounding or the omission of DCT coefficients. In JPEG2000, overlapping basis blocks are used to reduce the blocking artifacts. The DCT blocks of size 8×8 are replaced by overlapping blocks of different sizes based on a *wavelet transform*, leading to visually improved decoded images without any blocking artifacts.

9.2 Video Formats

Accessing video via the Internet will become more and more popular as the bandwidths of the Internet connections will increase and the means for acquisition and processing of video data are already highly available on the consumer market. Camcorders, web cams, and graphics cards with a TV tuner or video-in adapter are the devices most commonly used by consumers for bringing video into the computer. The camcorder can be connected to the computer via FireWire (IEEE 1394) for transferring the video and associated audio data. The very popular *DV format* is often used in digital camcorders. Its compression scheme is based on JPEG but with some modifications to better adapt to video signals.

At this stage, one problem may arise, which is associated to *interlaced video formats*, like PAL or NTSC [6]. Please note that the terms *interlaced* and *progressive* have a different meaning in the context

© 2005 by CRC Press LLC

of video formats than in the context of bit stream organization and transmission as introduced in the image formats section. The interlaced video formats are designed for displaying video on a TV in fields instead of full frames. There are two alternating fields: *odd* and *even fields*. An odd (even) field consists of all odd (even) numbered rows of a full frame; but odd and even fields are captured and displayed at different time instances. The advantage is that instead of having a full frame rate of 25 Hz for PAL (29.97 Hz for NTSC), a 50 Hz field rate (59.94 Hz for NTSC) is achieved without increasing the bit rate or bandwidth. Thereby, flickering is reduced. Since computer monitors are designed to display *progressive video formats*, that is, full frames, displaying interlaced video can introduce severe artifacts. This is especially the case if two neighboring fields are combined by simply copying the respective lines to a full frame in the presence of motion as the position of a moving object will not coincide in the combined odd and even fields.

One simple way to overcome this problem is to perform an *interlaced to progressive format conversion* also known as *deinterlacing,* which reduces the temporal and spatial video resolutions.

For example, the PAL DV interlaced format with 720 × 576 full frame pixels consisting of 720 × 288 pixels each for the odd and the even fields can be converted into a full frame with 360 × 288 pixels at 25 Hz. This can be easily achieved by omitting one field type and omitting the missing lines in the other fields as well while reducing the number of pixels of every line by a factor of two.

Obviously, the quality of the converted video is lower, but it is good enough for most of the Internet applications. However, the amount of video data is still quite large.

A video sequence in *Common Intermediate Format* (CIF) has 352 × 288 = 101,376 pixel/frame and 101,376 pixel/frame × 25 frame/s = 2,534,400 pixel/s and 2,534,400 pixel/s × 1.5 byte/pixel = 3,801,600 byte/s.

Please note that the number of pixels per line is reduced by 8 to cut off dark areas of a PAL signal at left and right image borders. In addition, the CIF video format, which is standardized by the International Telecommunication Union (ITU), requires only 1.5 byte/pixel on average. This is due to the fact that the CIF format is not based on the RGB color format but on the *YUV color format*. It consists of a luminance component Y and two chrominance components U and V, each of which can be computed by a linear combination of the RGB components:

$$Y = 0.299R + 0.587G + 0.114\,B,\ U = B - Y \text{ and } V = R - Y$$

This is the common video color format for the transmission and coding of PAL systems; the weighting factors for computing the NTSC or SECAM chrominance components are slightly different [6]. There are two main reasons for utilizing the YUV format: one historical and one related to the human visual perception. The first popular video application was the TV broadcast of monochrome video. Later, when color TV was introduced the analog color TV signal was broadcasted in a *composite video format*, in which the luminance and the two chrominance components were multiplexed in order to make the signal compatible with the monochrome TV systems. In addition, it was realized that the human eye is less sensitive to spatial variations of the chrominance than of the luminance. Thus, the signal bandwidth can be reduced by separating chrominance from luminance and transmitting only a band-limited chrominance, resulting in a hardly visible reduction of the video quality. The CIF format employs the so-called *4:2:0 format*, where the number of chrominance values in each of the two components is reduced by a factor of two in both the vertical and the horizontal directions. This leads on average to one U and one V value for four pixels and to the above-mentioned total of 1.5 byte/pixel when using a color depth of 8 bits per channel.

Since the amount of raw data of the CIF format is still too high for Internet applications, the video resolution can be further reduced and compression should be employed. The *Quarter CIF format* (QCIF) was standardized mainly for videophone-like applications and is well suited for most Internet video applications. It has only half of the resolution of a CIF frame in horizontal and vertical directions (176×144) and a raw data rate of 995,400 byte/s at 25 Hz. For Internet applications, the frame rate is often reduced to 8.33 or even 5 frames/sec (fps). If an advanced video compression scheme like MPEG-4 is additionally applied, the bit rate can be decreased to less than 8 kbyte/s.

Video Compression Principle

In principle, JPEG, like every other image compression scheme, can be used for coding of motion videos as well, simply by coding every video frame separately. This approach is simple but not as efficient as it could be. In addition, some flickering artifacts can be introduced when displaying a moving sequence of images, although individual pictures do not show an annoying artifact. This is due to the coding artifacts related to the quantization process that changes from frame to frame. These artifacts are especially visible at lower bit rates. To achieve better compression, the temporal correlations between consecutive frames have to be exploited.

The most commonly used approach is to perform a *temporal prediction* of the pixels of the current frame to be coded x (Figure 9.6b) out of a previous frame y (Figure 9.6a), subtract the corresponding pixels of the predicted frame from the current frame, and encode the difference frame e (Figure 9.6c) in a JPEG-like manner by transform coding. The difference frame shown in the example of Figure 9.6c is often referred to as the *prediction error frame* in which the mid-gray pixels reflect areas with a low prediction error and the dark and light pixels show areas with large errors. The advantage of coding the prediction error frame instead of the original is that there are normally large areas having only small errors. This will result in only a few, if any, nonzero coefficients after the transform and quantization stages that have to be encoded.

A comparison of frames x and y shows that the image content has moved to the bottom right due to a camera pan. This leads to strong errors in the prediction error frame in textured regions and at object borders, which in turn increases the bit rate required in these areas.

A *motion compensated prediction* is often applied to further reduce the prediction error. This can be achieved by subdividing the current frame into regular, nonoverlapping blocks and finding a corresponding block in the previous frame, which describes each block of the current frame as well as possible. These blocks are then copied for the prediction of the current frame (Figure 9.7). Figure 9.6d shows that motion-compensated prediction leads to less prediction errors. Only those areas of frame x that have new content cannot be predicted properly, for example, at the bottom of the frame.

For every block, a suitable *motion vector* has to be determined during a *motion estimation* process. This vector describes the relative translational motion of the block and has to be coded as additional side information. The quality of an encoder is highly dependent on the way the motion estimation is performed. As this process is generally very time consuming, most encoders allow motion vectors of lower quality,

FIGURE 9.6 Temporal prediction of a video frame with and without motion compensation: (a) previous frame y, (b) current frame x, (c) prediction error frame, $e = x - y$ (d) prediction error frame after motion compensation.

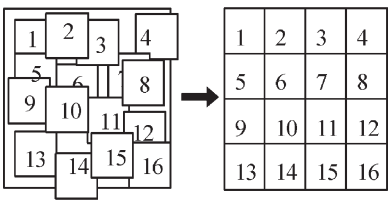

FIGURE 9.7 Motion-compensated temporal prediction of a video frame.

© 2005 by CRC Press LLC

which result in a lower coding efficiency but faster encoding. Fortunately, the decoder does not have to perform the motion search, which reduces the computational complexity considerably.

To enable the encoder to control the video quality at the decoder side, both the encoder and decoder have to perform the prediction equally. Thus, the last decoded frame instead of the original has to be used for prediction, since the decoder does not have the original frame.

This implies that the encoder also consists of a decoder, which feeds back the last decoded frame, including the coding artifacts to predict the current frame. This *coding loop* has a strong impact on the characteristics of the video coding scheme.

- *Coding efficiency*, that is, the visual quality at a given bit rate is much increased. Therefore, almost 100% of the efficient video codecs on the market are based on this scheme.
- Coding artifacts of the previous frame are introduced into the current frame, which is not necessarily a disadvantage. Compared to the separate encoding of the frames, the artifacts are temporarily more correlated, thus reducing the annoying *flickering artifacts*.
- If transmission errors occur, which affect the quality of a frame, these *errors* will be *propagated* to the following frames.
- Since the decoding of a frame depends on the previous frames, there is no *instantaneous access* to the frames in a sequence.

The coding loop introduces a trade-off between coding efficiency and error robustness. The design of a video codec will stress one or the other characteristic depending on the kind of video application.

The frames that are coded by prediction from a previous frame are called *P-frames*. Obviously, the first frame of a sequence has to be coded without prediction. Therefore, it is called intra or *I-frame*, because only information available within this frame is used for coding. A P-frame can be predicted from an I-frame or another P-frame as can be seen in Figure 9.8, where the arrows indicate the prediction direction. There is one other frame type, namely a *B-frame*, which is not predicted from one but from two frames. In most codecs, a *bidirectional prediction* is made from one previous and one following frame, which can further reduce the bit rate. B-frames introduce an additional delay as the following P-frame has to be acquisitioned, coded, and decoded prior to coding the current B-frame coding. Thus, B-frames are not employed in delay-sensitive applications such as video communication.

Further I-frames will be inserted, for example, one per second, to allow for starting the decoding process at more or less arbitrary time instances of the sequence. All frames depending on one I-frame are often grouped into a *group of pictures* GOP structure.

Internet Video Applications

For most of the Internet video applications, the two main problems related to transmission via the Internet are that the available average network bit rate is too low and that some of the video packets do not arrive timely enough to be displayed. The first problem has an impact on all Internet video applications and can be reduced by video codecs with improved coding efficiency. The second problem addresses only those Internet applications where simultaneous transmission and display of video is required, that is, for *live video* reception and *video streaming*. This is a more serious problem, because losing one packet containing, for example, a P-frame means that all following frames of a GOP cannot be decoded. Here, very sophisticated techniques have to be combined to achieve a properly working system. These techniques might fall within the following categories: video buffer management, coder control, feed back,

FIGURE 9.8 Possible frame types in a video codec.

© 2005 by CRC Press LLC

scalable coding, quality of service, streaming and real-time protocols, and error concealment. For more detailed information on this topic, the reader is referred to [6].

A very common technique to improve the error robustness of video a stream for transmission over band-limited channels is to use a *rate-control*. The rate-control controls the encoder coding options in order to achieve at least on average a *constant target bit rate* (CBR). Without rate-control, a constant quality at a *variable bit rate* (VBR) is achieved. Large fluctuations of the amount of bits per frame can occur due to the content of the images, the variations thereof over time and the chosen frame type. An I-frame may need a bit amount 10 times higher than that of a P-frame. The rate-control can influence the bit rate by changing the accuracy of the quantization, which affects the picture quality as well, or by *frame-skipping*. By skipping input frames at the encoder side, the bit rate and temporal resolution will be reduced. The missing frames are substituted at the decoder side by repeating the respective previous frame.

Some encoders provide a *2-pass coding* as an optional feature to better adapt to a target bit rate. In a first pass, the sequence is coded and the required bit amounts per frame for the chosen encoder parameters are evaluated. In the second pass, the actual coding is done with a corrected encoder setting.

In the following, we will concentrate on the more simple application of *video downloading* and successive decoding. For downloading of preencoded video, encoding time and delay are generally not important factors. The main objective is achieving a high coding efficiency in order to allow small video file sizes and a reasonable video quality. Thus, the GOP structure similar to Figure 9.8 including B-frames can be used. An exhaustive but time-consuming motion search can be chosen and also the variable bit rate mode since it often leads to better visual results.

Video Coding Standards, Quasistandards, and File Formats

First of all, a distinction has to be made between the *coding scheme* and the *file format* containing the bit stream. There are file formats that allow compression with a variety of different coding schemes. In addition, a single file may contain more than one video and audio track. Currently, there are more or less four popular internet video formats on the market, that is, *MPEG* (*.mpg), *Windows Media Video* (*.wmv, *.wm), *Real Video* (*.rm), and *QuickTime* (*.mov). The first three have their own video coding scheme and file format, whereas *Apple's QuickTime* format is basically a file format that can be used with several codecs. This is also true for the *Windows AVI* format (*.avi). A tag in the header of the file indicates the used compression scheme. Therefore, it might happen that a *player* cannot decode an AVI file found in the web, since the corresponding decoder is not installed in the player. Thus, the availability of players for the respective format is an important aspect for choosing an appropriate video format. Players for the four formats mentioned above are widely installed and can be downloaded for free at [7–9]. There are several players for the MPEG format, but it can also be played with the *WindowsMediaPlayer*.

In the following, some characteristics of the most popular video formats are given.

Motion JPEG, an extension of the JPEG standard, is a simple but not very efficient scheme for video compression since every frame is stored as an I-frame. The very popular *DV format* is based on motion JPEG but with some slide modifications to better adapt to video signals. It is rarely used for Internet applications.

The different *MPEG formats* have been developed by the ISO Moving Picture Experts Group mainly for video and audio compression, storage, and transmission. There is a file format specified for each version. All MPEG video coding standards are based on motion-compensated prediction and the GOP structure.

MPEG-1 is well suited for compression of progressive video in CIF format at rates of 1–1.5 Mbit/s, including audio. For audio compression, the very popular MPEG-1 layer3 scheme can be used, which is also known as *MP3*. It has been used for storing video on CD-ROM at a quality comparable to an analog consumer VCR.

MPEG-2 has been derived from MPEG-1 but with improved performance and additional features for coding interlaced video at higher bit rates (4–15 Mbit/s) and qualities. It is widely used, for example, for DVD and Digital Video Broadcast (DVB).

Both formats are more appropriate for high bit rates, but can operate at lower bit rates as well; thus, they are used as an Internet video format for downloading.

© 2005 by CRC Press LLC

MPEG-4 is much better suited as an Internet format as it has been especially designed for low bit rates, although it covers a wide range of bit rates (8 kbit/s–1200 Mbit/s), video resolutions, and qualities [10]. Furthermore, it allows to encode arbitrarily shaped video objects, 2D- and 3D-scenes composed of natural and synthetic still image, video, and audio content. Binary format for scenes (**BIFS**) has been specified for the scene description. It was derived from VRML but allows compression of the scene description, user interaction, and streaming. An introduction to the MPEG-4 multimedia standard can be found in [6,11]. Since the MPEG-4 standard is rather new, up to now only rectangular videos compressed by MPEG-4 can be found on the Internet.

A new video coding standard with a much better coding efficiency has been standardized in 2003. It is a joint development of the ITU-T and MPEG, the *H.264* | *MPEG-4 AVC* advanced video coding standard. Although being part of MPEG-4 it is not backward compatible with MPEG-4, in comparison to MPEG-4 and MPEG-2, the bit rate at the same visual quality can be further reduced by about 40% and 63%, respectively [12]. Unfortunately, the complexity, especially at the encoder, is largely increased. Due to the good performance, this coding scheme will probably become very popular.

For the *Windows Media Video format,* the *Windows Media Encoder* is available [7]. Since this coding scheme is a proprietary standard of *Microsoft* and the used coding techniques are currently hidden, it can only be decoded by the *Windows Media Player*. But as *Microsoft* participated in the development of MPEG-4 AVC, some of its efficient new features might have gone in the latest Media Encoder. At least its coding efficiency is now better than that of the (older) MPEG-4. The latest *Windows Media* file format can also include video compressed with other codecs such as MPEG-4.

The situation for the *Real Video format* is quite similar [8]. The video coding scheme is hidden; encoding can be performed using *RealSystem Producer* and decoding can only be done by *RealPlayer*. This is the dominant format for streaming applications. It provides slightly better qualities at low bit rates compared to the competitors. In addition, it supports more platforms than *Windows Media* and *QuickTime*, not only Windows and Mac OS but also Linux and Unix. The latest *RealMedia* file format can also include video compressed with other codecs such as MPEG-4.

Apple's *QuickTime format* is capable of carrying media data other than pure audio and video as well [9]. Animations, graphics, texts, and even 360° virtual reality scenes can be stored in *QuickTime* format. That is the main reason why MPEG has based the MPEG-4 file format on *QuickTime*. *Apple's QuickTime Pro* package provides a variety of different video codecs. Formerly, *Sorenson Video* was often chosen as the preferred video codec, but this may change since the latest version of *QuickTime* supports MPEG-4 video.

Please note that the above-mentioned qualities of the video codecs only reflect the situation at the beginning of the year 2003. Every new release of a codec can lead to large improvements. On the other hand, one should be aware of the fact that standardized coding schemes, like MPEG-4, are public and the format will not change. Proprietary standards will change, and future players may not support older versions.

10.1 Introduction to Web Services

Web services are one of the major hypes in today's Internet world. But what is so special about Web services? To answer this question, let us look at two definitions. The first one gives a statement about the problems that Web services promised to solve in their beginning late 2000 [3].

> "A Web service is a collection of functions that are packaged as a single entity and published to the network for use by other programs. Web services are building blocks for creating open distributed systems, and allow companies and individuals to quickly and cheaply make their digital assets available worldwide."

Companies that want to make their "digital assets" available to other companies, to customers, or to roaming employees need a new paradigm for the creation of open distributed systems. They need new kinds of "open interfaces" or standards for specific business domains and they need a better infrastructure for the development, operation, and usage of distributed systems. In short, Web services promised to simplify the syntactical and semantically interworking of programs in a distributed and heterogeneous environment that is operated by different, autonomous companies. Let us now look at the current definition from the W3C [6]:

> "A Web service is a software system identified by a uniform resource identifier URI, whose public interfaces and bindings are defined and described using XML. Its definition can be discovered by other software systems. These systems may then interact with the Web service in a manner prescribed by its definition, using XML based messages conveyed by Internet protocols."

This more technical definition restricts the definition and usage of Web services to the application of XML-based techniques [11]. The definition of the syntax and semantics of a Web service is restricted to the abilities of XML; they are invoked by conveying XML messages by Internet protocols. The most important conclusions from this definition are the following. First, Web services try to solve both the problems mentioned above with the application of XML. Thus, anybody who wants to advertise a new

© 2005 by CRC Press LLC

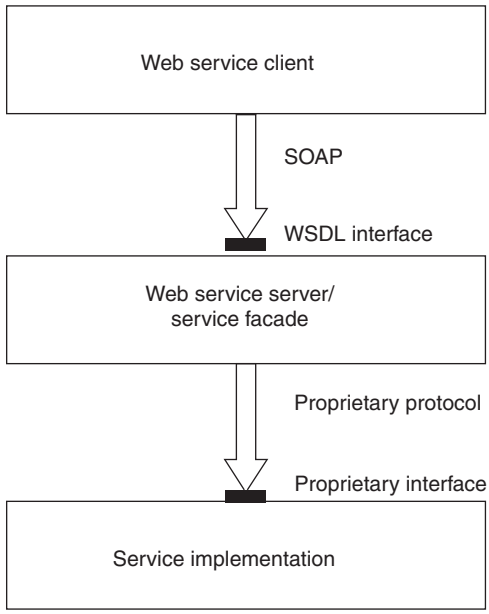

FIGURE 10.1 Constituent parts of a Web service configuration.

Web service or who wants to use an existing Web service has to deal with XML. Second Web service technology provides means for the specification of interfaces and bindings as well as for the exchange of messages. They do not provide any assistance for the implementation of the software system behind the Web service. Web services are an interface technology, not an implementation technology (See Figure 10.1).

Third, the Web service architecture describes three phases

- the provider advertises the existence and contact information in some registry,
- the client looks up the service in a registry, and
- the client contacts and invokes the service.

The means for these three phases, WSDL for the service description, UDDI for the advertisement, and SOAP for the invocation, will be investigated in the following sections.

10.2 Introduction to WSDL and UDDI

The Web service description language WSDL [8] allows the expression of all the information that is necessary to specify the signature of a Web service as well as the binding information to an instance of the service. WSDL defines an XML schema for the description of services. The outer <definitions> element encloses all parts of the service definition. Its attributes specify the XML namespaces used in the specification. The target namespace distinguishes the definitions in this template from definitions in other documents. Additional namespace declarations facilitate the identification of types and elements with the same name, but from different embedded schemas or imported documents. The <definitions> section contains the following information (See Figure 10.2):

- First, the <definitions> element itself has two attributes: the optional *name* is of the XML type *noncolonized name* (NCName), and the optional *targetNamspace* is of the XML type *anyURI*. It is important to consider that the type system for the definition of WSDL is the XML schema Part 2 [11] and that an understanding of the WSDL specification is impossible without knowledge of XML schema.
- <import>ed (associated) XML namespaces that refer to externally defined parts of the Web service definition.

© 2005 by CRC Press LLC

- <types>: the service-specific data types.
  The <types> element encloses data type definitions that are relevant for the exchanged messages. WSDL uses the XML Schema as the canonical type system. The role of this element is to contain an XML <schema> element.
- <message>: the elements of the signatures of the supported messages consist of:
  - the name of the request message (<message name = ...>);
  - the names and types of the input parameters. Each parameter is denoted as a <part> of the <message> :
    <part name = paramName element = paramType> or
    <part name = paramName type = paramType>
    The notion of an *element* refers directly to a similar term in the definition of an XML schema. The notion of a *type* refers to an XSD *simpleType* or *complexType*. The values of both attributes have to be expressed in the form of so-called XML *qualified names* (QName).
  - the name of the response message (<message name = ...>);
  - the names and types of the return parameters:
    <part name = paramName element = paramType> or
    <part name = paramName type = paramType>
- <portType>: the signatures of the provided operations, consisting of:
  - The name of the <operation> and the names of the appropriate request and response <message>s. Operation overloading is possible; thus, operation names do not have to be unique.
  - The order of the parameters.

A port type is a named set of abstract operations and the abstract messages involved. The *name* attribute provides a unique name among all port types defined within the enclosing WSDL document. The WSDL 1.1 specification comprises four different communication patterns called *transmission primitives* that an endpoint can support. Until now it is not clear whether future WSDL specifications will support all these transmission primitives.

- *One-way*: The endpoint *receives* a request message but returns no response.
- *Request–response*: The endpoint *receives* a request message and *sends* a correlated response message. This primitive can be used to model RPC semantics.

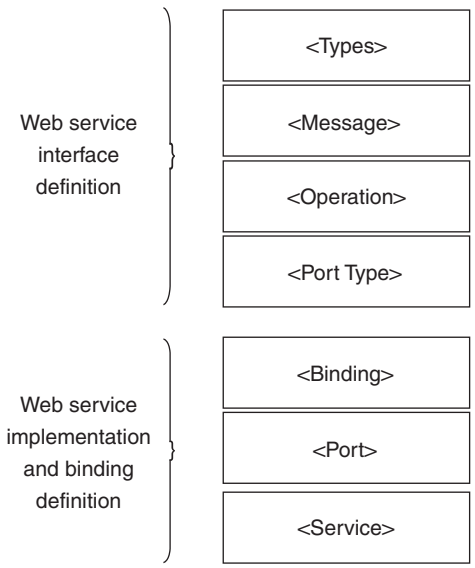

FIGURE 10.2 Sections of a WSDL description.

© 2005 by CRC Press LLC

- *Solicit–response*: The endpoint *sends* a response message, and *receives* a correlated request message. This primitive can be used to model callbacks.
- *Notification*: The endpoint *sends* a response message. This primitive can be used to model notifications in the Web service world.

- <binding>: the specification of:
  - the protocol,
  - the encoding rules, and
  - the supported <operations>

for a particular instance of a <portType> called <port> or *endpoint*. Web services use so-called *extensibility elements* to specify the message format and the used encoding rules. The WSDL specification states

> "that it is unreasonable to expect a single type system grammar can be used to describe all abstract types present and future. WSDL allows type systems to be added via extensibility elements."

The binding extensibility elements are used to specify the concrete grammar for the input, output, and fault messages. Peroperation binding information as well as perbinding information may also be specified. For detailed information on the WSDL–SOAP binding, refer to section "SOAP binding in WSDL."

- <port>: the combination of a <binding> with a network address.
- <service>: a collection of <port>s.

WSDL Specification of a Sample Web Service

To clarify this fundamental definition, let us look at a simple calculator service. The service provides two operations. The first one is called *Add*. It returns the sum of two integer arguments. The second one is called *Compute*. It considers a data structure containing an operator and two integer arguments as an input parameter and returns the result of the operation.

It has to be mentioned that the generated WSDL differs from tool to tool. Thus, all the given examples have to be considered as one of several possible syntactical representations of the specification of the same calculator service.(See Fig. 10.3)

The WSDL file contains a top-level <definitions> element. This element defines the imported and exported namespaces used in the rest of the file. Here, the references to XML schema definitions, the WSDL–SOAP binding-related schema definitions, and the WSDL schema definition itself can be found.

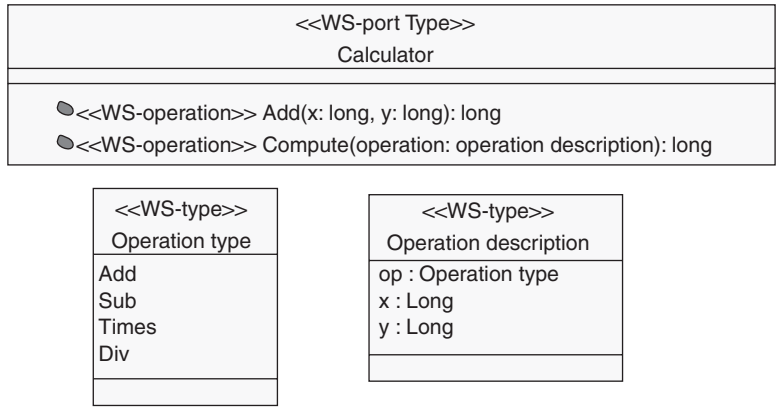

FIGURE 10.3 Specification of a sample Web service.

© 2005 by CRC Press LLC

```
<?xml version="1.0" encoding="UTF-8"?>
<definitions
      name="Calculator"
      targetNamespace="http://www.myorg.org/Calculator.wsdl"
      xmlns="http://schemas.xmlsoap.org/wsdl/"
      xmlns:soapbind="http://schemas.xmlsoap.org/wsdl/soap/"
      xmlns:tns="http://www.myorg.org/Calculator.wsdl"
      xmlns:xsd="http://www.w3.org/2001/XMLSchema"
      xmlns:xsd1="http://www.myorg.org/Calculator.xsd">
...
</definitions>
```

The data type describing the operation is mapped to the <types> section and defined as an XML schema:

```
<types>
      <xsd:schema
                  targetNamespace="http://www.myorg.org/Calculator.xsd"
                  xmlns:xsd1="http://www.myorg.org/Calculator.xsd"
                  xmlns:xsd="http://www.w3.org/2001/XMLSchema">
...
            <xsd:simpleType name="Calculator.OperationType">
                  <xsd:restriction base="xsd:string">
                        <xsd:enumeration value="add"/>
                        <xsd:enumeration value="sub"/>
                        <xsd:enumeration value="times"/>
                        <xsd:enumeration value="div"/>
                  </xsd:restriction>
            </xsd:simpleType>
            <xsd:complexType name="Calculator.OperationDescription">
                  <xsd:sequence>
                        <xsd:element maxOccurs="1" minOccurs="1"
                              name="op" nillable="true"
                              type="xsd1:Calculator.OperationType"/>
                        <xsd:element maxOccurs="1" minOccurs="1" name="x"
                              type="xsd:int"/>
                        <xsd:element maxOccurs="1" minOccurs="1" name="y"
                              type="xsd:int"/>
                        </xsd:sequence>
            </xsd:complexType>
      </xsd:schema>
</types>
```

© 2005 by CRC Press LLC

The request and reply messages of the operations are mapped to the <message> section:

```
<message name="Add">
      <part name="x" type="xsd:int"/>
      <part name="y" type="xsd:int"/>
</message>
<message name="AddResponse">
      <part name="AddReturn" type="xsd:int"/>
</message>
<message name="Compute">
      <part name="operation" type="xsd1:Calculator.OperationDescription"/>
</message>
<message name="ComputeResponse">
      <part name="ComputeReturn" type="xsd:int"/>
</message>
```

The signatures of the two operations "Add" and "Compute" are a part of the <portType> section:

```
<portType name="Calculator">
      <operation name="Add" parameterOrder="x y">
            <input message="tns:Add"/>
            <output message="tns:AddResponse"/>
      </operation>
...
</portType>
```

The <binding> section defines that the operations are used in an RPC-like style and that SOAP via HTTP is used as the communication protocol:

```
<binding name="CalculatorBinding" type="tns:Calculator">
      <soapbind:binding style="rpc"
            transport="http://schemas.xmlsoap.org/soap/http"/>
      <operation name="Add">
            <soapbind:operation soapAction="Calculator#Add"/>
            <input>
                  <soapbind:body
                  encodingStyle="http://schemas.xmlsoap.org/soap/
                  encoding/"
                  namespace="Calculator" use="encoded"/>
            </input>
            <output>
                  <soapbind:body
                  encodingStyle="http://schemas.xmlsoap.org/soap/
                  encoding/"
                  namespace="Calculator" use="encoded"/>
            </output>
      </operation>
...
</binding>
```

© 2005 by CRC Press LLC

Finally, the <service> section defines that the calculator service can be accessed at the given URL:

```
<service name="Calculator">
      <port binding="tns:CalculatorBinding" name="Calculator">
            <soapbind:address
                  location="http://myHost:8080/serviceDir/Calculator"/>
      </port>
</service>
```

Do not panic after looking at all these XML definitions. Neither for the definition nor for the advertisement or usage of a Web service its WSDL file has to be created by hand. As a programmer, you will specify the "proprietary" interface shown in Figure 10.1 in your preferred language like Java, C#, or CORBA IDL. Afterwards, some tools will take your specification as input and generate the interface-related parts of the WSDL. When one deploys the implementation of the service, that means when one starts it and makes it accessible by other programs, again some tools will generate the binding-related parts of the WSDL (see Figure 10.4).

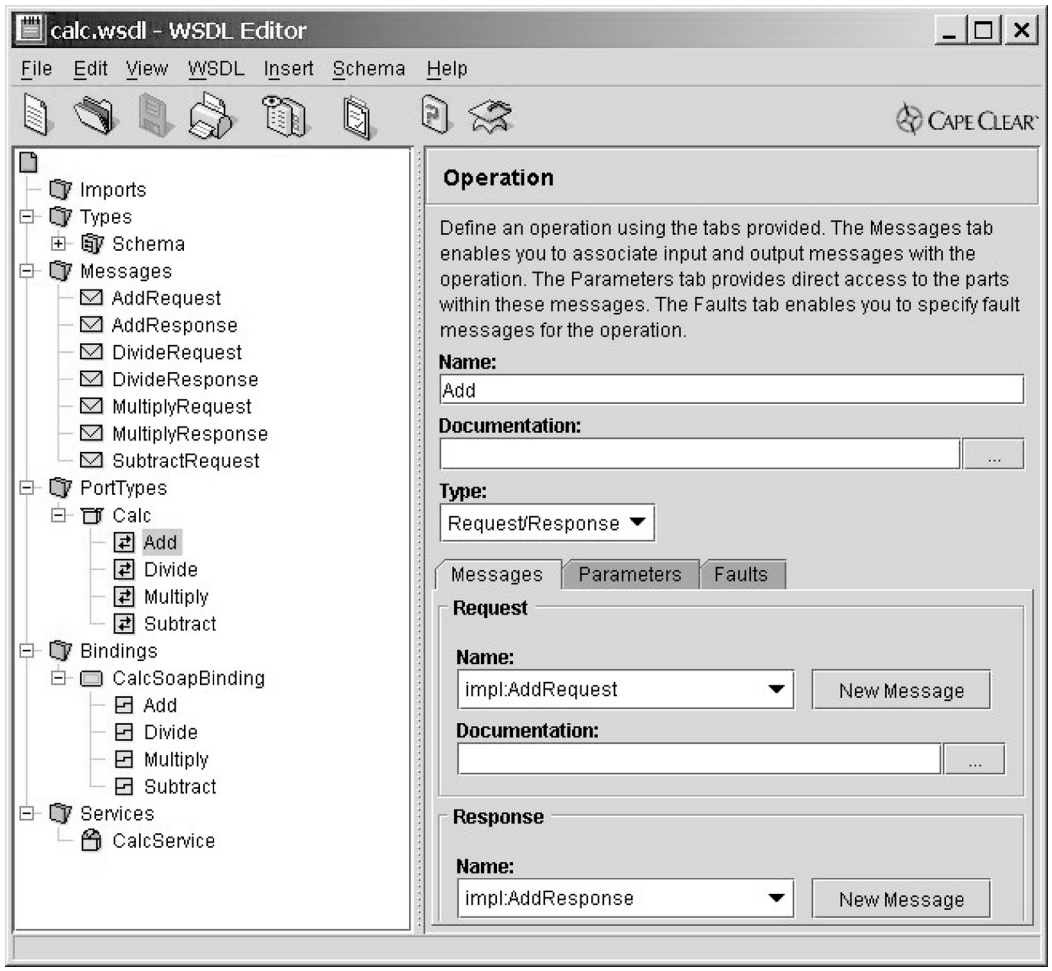

FIGURE 10.4 The sample WSDL shown in a WSDL editor [7].

The UDDI Web Service Registry

Assume now, you have implemented and deployed your Web service and that some tools have generated a WSDL description of your service. The next step is to advertise your service to potential users. All the technical information that is necessary to write a client and access the service is contained in the WSDL file. Consequently, you only have to advertise the location of this file, possibly as a URL, and everybody is able to use the service. But exactly here some major problems occur. Until now you only have specified the syntax of the service and its parameters. No information about the semantics, the orchestration, about you and your organization, about nonfunctional properties like availability, performance, security, charges, etc. is available. Moreover, do you really want to allow everybody to use your service without verifying his identity and authorization?

For the first group of these issues, Web services offer a solution called "universal description, discovery, and integration of Web services" UDDI [4]. The UDDI contains three kinds of information. The so-called *white pages* contain business information like name, address, phone number, or contact of a given organization. This is the right place for service providers to register themselves. The *yellow pages* contain service information that categorizes business domains and services. It should be based on standardized ontologies. This is the right place to advertise the "digital assets" in a standardized way, for example, to store some promotion about our Calculator service.

Although our Calculator is a typical exemplar of an arithmetic processor, some other calculators may provide slightly different ports or operations. This is the reason why the *green pages* contain technical information about the service and its implementation. Here, binding information as well as detailed information about the service specification, the so-called *technical model — tModel*, can be found. The easiest way is to store a reference to the WSDL file; but this excludes the provision of semantic information about the

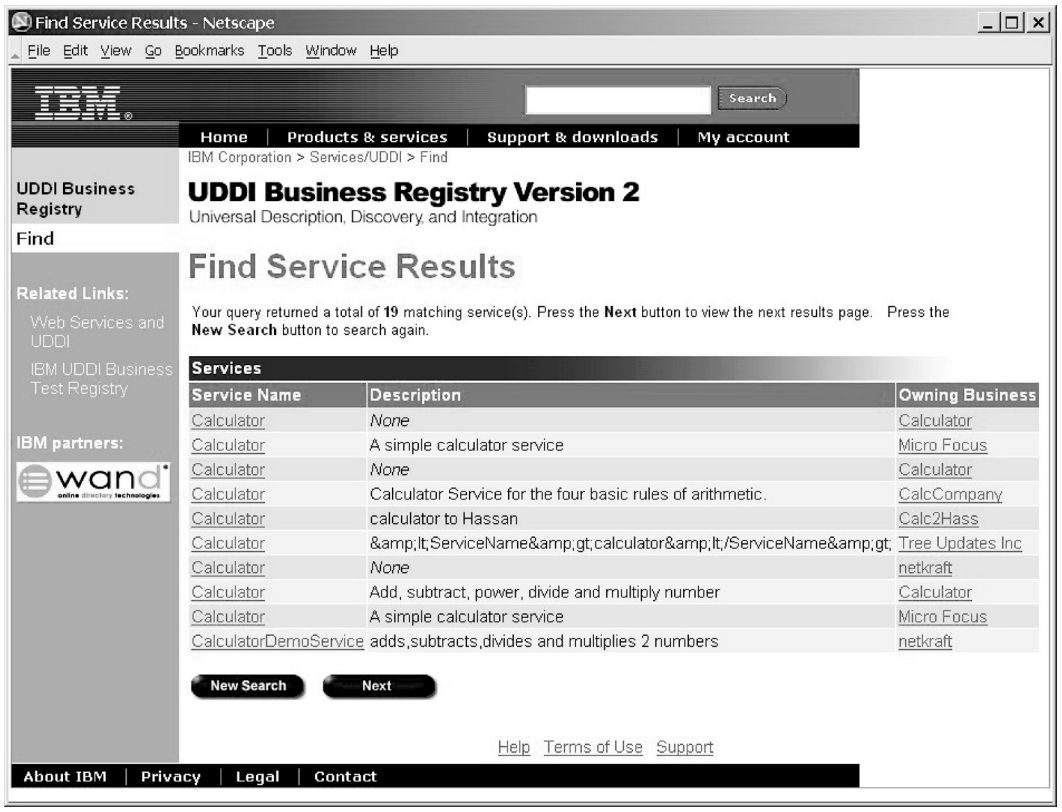

FIGURE 10.5 Searching for a calculator service in a public UDDI.

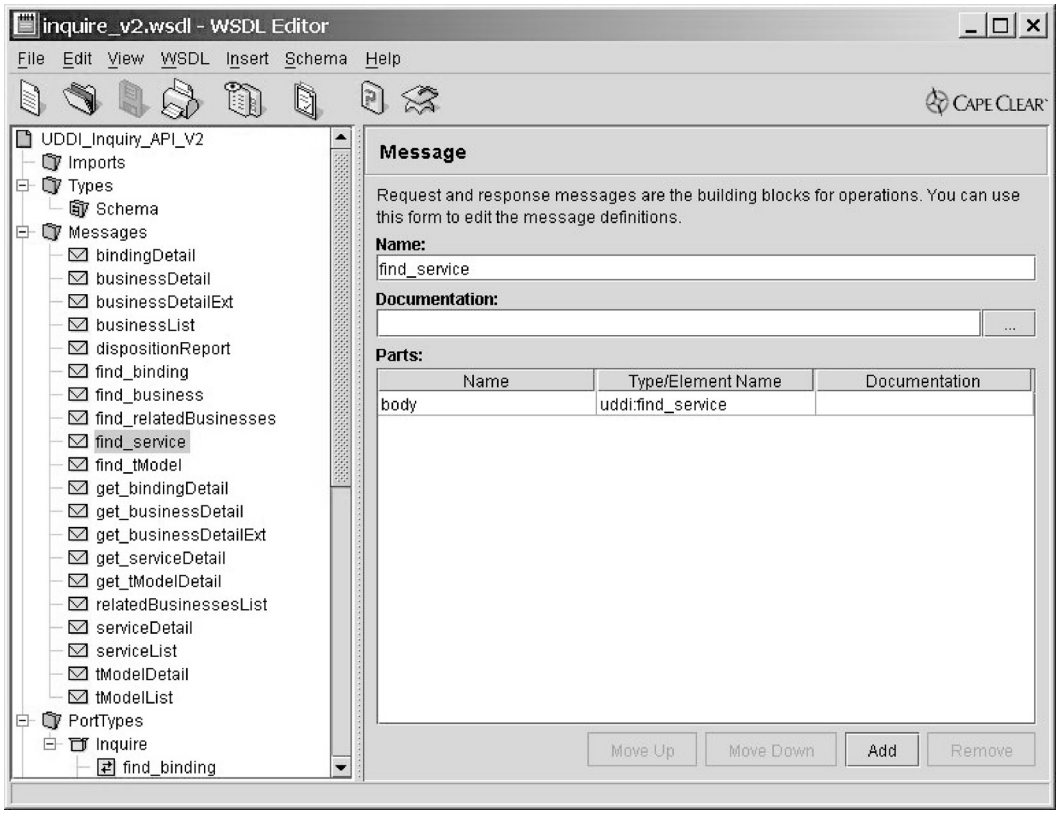

FIGURE 10.6 Access messages of the UDDI Web service.

service, its implementation, and usage. Like everywhere in the Web service's world, UDDI is specified in the form of an XML schema [5] and can itself be accessed via Web service operations. A subset of the appropriate definition is shown in Figure 10.6.

10.3 Introduction to SOAP

Assume that two processes running on different network nodes want to communicate. In such a situation, there exist two fundamental programming models. In a *remote procedure call* (RPC) like style, the client process sends a request to the server process and waits. The server process executes the request and sends a response back to the waiting client, who can continue his execution afterwards. In a *messaging*-like style, the client process sends a document to the server process and continues execution. The server process handles the document and could deliver a response message, containing the response document, later. The SOAP supports both programming models. Before going into more details about SOAP, let us have a look at what happens in an RPC-like communication.

During the implementation of the client, some knowledge about the operations provided by the server is necessary. In general, the client binds to the server and calls one or more of the provided operations. From the client's viewpoint, a local proxy called *client stub* of the server is invoked. The proxy delegates the request to the server, receives the response, and forwards it to its invoker. The request itself consists of the name of the operation and the parameters. The proxy has to encode the request to some "on-the-wire" transferable and convertible representation, to submit the request to the selected communication protocol, to wait for the response, and to decode the response after receiving it via the communication protocol. A similar *server stub* waits for incoming requests. The stub decodes the request, selects an executor for the

© 2005 by CRC Press LLC

required operation, forwards the request to this executor, waits for the response, encodes the response including possible exceptions, and submits the response to the communication protocol. Every RPC-like system has to perform these steps. In a pure messaging system, the *transmitter stub* must be able to encode the document and submit it to the communication protocol; a *receiver stub* must be able to decode the document and to forward it to the executor.

Let us now look at SOAP. SOAP Version 1.1 [2] is a lightweight protocol that defines a uniform way for the exchange of data in a decentralized, distributed environment. SOAP is an XML-based protocol that consists of three main parts (See Figure 10.7):

- An envelope that defines a framework for describing the content of a message and how to process it.
- A set of encoding rules for expressing instances of application defined data types.
- A convention for representing remote procedure calls and responses.

SOAP can potentially be used in a combination with other low-level communication protocols like HTTP or SMTP. The current draft specification of SOAP 1.2 [2] provides some more insight into the SOAP paradigm and its role in distributed system protocols:

> "SOAP is fundamentally a stateless, one-way message exchange paradigm, but applications can create more complex interaction patterns (e.g., request/response, request/multiple responses, etc.) by combining such one-way exchanges with features provided by an underlying protocol and/or application-specific information. SOAP is silent on the semantics of any application-specific data it conveys, as it is on issues such as the routing of SOAP messages, reliable data transfer, firewall traversal, etc. However, SOAP provides the framework by which application-specific information may be conveyed in an extensible manner. Also, SOAP provides a full description of the required actions taken by a SOAP node on receiving a SOAP message."

Elements of SOAP Messages

As shown in Figure 10.7, a SOAP message consists of an envelope including some optional headers and one mandatory body element. A SOAP header is an extension mechanism that provides a way to include application-independent information in a SOAP message. Headers may contain information about the user, the client process, and their contexts. The SOAP body is the mandatory element within the envelope that carries the end-to-end application-specific information included by the sender and read by the receiver of the message.

Let us look at these elements in some detail. The SOAP *envelope* is the top element of a SOAP message. It contains XML namespace declarations and some additional attributes like the encoding style. The *enve-*

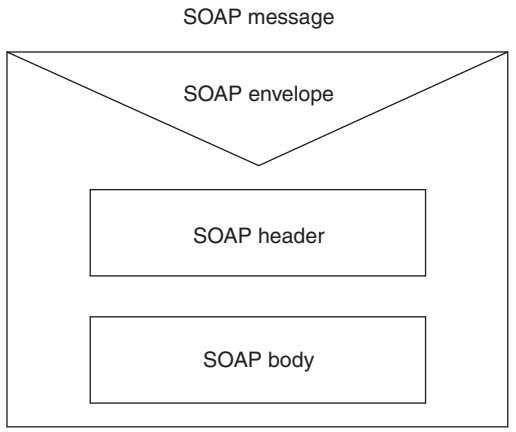

FIGURE 10.7 Elements of a SOAP message.

© 2005 by CRC Press LLC

lope element itself is associated with the namespace http://schemas.xmlsoap.org/soap/envelope. Additional namespaces may refer to XML schema definitions.

The *header* element is the first immediate child element of the *envelope* element. It contains additional information about the message like authentication, payment, context, or transaction-related data. The header contains attributes and application-specific header entries. As a SOAP message may travel from the sender to the receiver by passing several intermediary SOAP nodes, it is necessary to define as to which intermediary is allowed or committed to execute a SOAP header. The *actor* attribute may be used to address the header element to a particular endpoint. The *mustUnderstand* attribute is used to indicate whether a *header entry* is mandatory or optional for the recipient to process. If a *header entry* is tagged with a *mustUnderstand=1* attribute and the receiver is unable to process the entry, a SOAP *fault* element has to be returned.

The mandatory *body* element is used to exchange application-specific information between the initiator and the ultimate recipient of the message. RPC-like request, response, and error messages are typical examples of SOAP bodies. All child elements of the *body* element are called *body entries*. Each *body entry* is encoded as an independent element within the SOAP *body*.

A large part of the SOAP specification deals with SOAP encoding. Because this encoding style is the source of several interoperability problems [10], it is discouraged from using SOAP encoding. Thus, no more information related to SOAP encoding will be given here.

One of the main goals of SOAP is to encapsulate and exchange RPC requests and responses. To represent an RPC request, the following information is needed. First, the URI of the recipient is required. In case of an HTTP-mapping, the URI indicates the target of the invocation.

The RPC request itself is modeled as a *struct*. A *struct* is a compound value in which the unique accessor names are the only distinction among members.

```
<ns:structId>
      <acc_1>val_1</acc_1>
      ...
      <acc_n>val_n</acc_n>
</ns:structId>
```

The struct contains one accessor for each *in* or *in/out* parameter. It is named and typed identical to the method name (see Section 10.2). The accessors are named and typed corresponding to the types of the parameters. They appear in the same order as in the method signature (compare the definition of the WSDL <portType>). An RPC response and a PRC fault are modeled as a *struct* too. The response *struct* contains one accessor for each *out* or *in/out* parameter. It is named and typed identical to the method response. The accessors are named and typed corresponding to the types of the parameters. They appear in the same order as in the method signature. The name of the return value accessor is not significant. A convention is to name it after the method name with the string *Response* appended.

A method fault is encoded using the SOAP *fault* element. The *fault* element defines four different subelements. The *faultcode* subelement is intended for use by software, the *faultstring* subelement is intended to be used by humans, the *faultactor* provides information regarding who caused the fault, and the *detail* subelement is intended for carrying application-specific information related to the body element.

```
<soap:Body>
      <soap:fault xmlns=...>
            <faultcode>soap:VersionMismatch</faultcode>
            <faultstring>Mismatch in used version of WSDL</faultstring>
      </soap:fault>
</soap:Body>
```

© 2005 by CRC Press LLC

Thus, SOAP defines a natural way to map WSDL definitions to RPC-like method invocations and replies. Section "SOAP Binding in WSDL," introduces the relevant parts of this mapping.

Sample SOAP Messages

This is a sample SOAP 1.1 message and the associated HTTP-header for the *Add* request message,

```
<HTTPHeaders>
...
<content-type>text/xml; charset=utf-8</content-type>
<soapaction> HTTP://myHost:8080/serviceDir/Calculator#Add </soapaction>
<content-length>mmm</content-length>
...
</HTTPHeaders>

<?xml version="1.0" encoding="utf-8" ?>
<soap:Envelope
      xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/"
      xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
      xmlns:xsd="http://www.w3.org/2001/XMLSchema">
      <soap:Body>
            <Add xmlns="http://www.myorg.org/Calculator">
                  <x>100</x>
                  <y>200</y>
            </Add>
      </soap:Body>
</soap:Envelope>
```

and here follows the same for the *AddResponse* response message. In both examples, the SOAP body contains a reference to the namespace that is associated with the Web service's WSDL definition.

```
<HTTPHeaders>
...
<content-type>text/xml; charset=utf-8</content-type>
<content-length>nnn</content-length>
...
</HTTPHeaders>

<?xml version="1.0" encoding="utf-8" ?>
<soap:Envelope
      xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/"
      xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
      xmlns:xsd="http://www.w3.org/2001/XMLSchema">
      <soap:Body>
            <AddResponse xmlns="http://www.myorg.org/Calculator">
                  <AddReturn>300</AddReturn>
            </AddResponse>
      </soap:Body>
</soap:Envelope>
```

© 2005 by CRC Press LLC

The <soapaction> header field in the HTTP header is used to identify the intent of the SOAP request. It is omitted in the SOAP 1.2 specification. The value of the <content-type> header field will change from *text/xml to application/soap+xml*.

SOAP Binding in WSDL

WSDL includes a binding for SOAP 1.1 endpoints (refer to [9], the associated namespace is denoted <soapbind:xxx>) using WSDL extensibility elements. The binding specifies protocol-specific information, such as:

- an indication that a binding refers to the SOAP protocol,
- a way of specifying an address for a SOAP endpoint,
- the URI for the SOAPAction HTTP-header for the HTTP-binding of SOAP, and
- the list of definitions for headers that are transmitted as a part of the SOAP envelope.

The <soapbind:binding> element signifies that the binding is bound to the SOAP protocol format (envelope, header, and body). It makes no claims that the message follows a specific version like SOAP 1.1. The *style* attribute is either set to *rpc* or *document* for each contained operation. The *transport* attribute, which is required, indicates which SOAP transport this binding corresponds to. The value http://schemas.xmlsoap.org/soap/http corresponds to the HTTP binding in the SOAP specification.

The <soapbind:operation> element provides information for the operation as a whole. The *style* attribute indicates whether the operation is RPC-oriented, where messages contain parameters and return values, or document-oriented, and where messages contain one or more documents. The *soapAction* attribute specifies the value of the SOAPAction header for this operation. For the HTTP protocol binding of SOAP 1.1, one must specify a value. For other SOAP protocol bindings, it must not be specified, and the <soapbind:operation> element can be omitted.

The <soapbind:body> element specifies how to assemble the different message parts that appear inside the body element of the SOAP message. Parts of a message can be either abstract-type definitions or physical schema definitions. The optional *parts* attribute indicates which parts appear within the SOAP body portion of the message. If this attribute is omitted, all parts defined by the message are assumed to be included. The *use* attribute, which is required, indicates whether the message parts are encoded using some encoding rules, or if the parts define the physical schema of the message. If *use* is set to *encoded*, each message part references an abstract type using the *type* attribute. If *use* is set to *literal*, each part references a physical schema definition using either the *element* or *type* attribute. The *encodingStyle* attribute is set to a list of URIs, each separated by a single space. These URIs represent encodings used with the message, in order from the most restrictive to the least restrictive. The *namespace* attribute applies to content not explicitly defined by the abstract types.

State of Web Services

As mentioned above, SOAP is a stateless protocol and as a consequence, Web services are inherently stateless too. To implement state full services with Web service technology, an additional state preserving "façade" has to be introduced between the client and the Web service interface implementation.

A pointer identifying the state, for example, a session identification, can be passed at several levels of abstraction. The Apache Axis SOAP engine allows to pass *sessionIds* using cookies or SOAP headers. Both mechanisms are technology (http) or product (Axis) specific. Another possibility is to pass the *sessionId*, or even the whole state description, as an extra parameter. In this case, an appropriate extension of the <portType> definition is required.

10.4 Web Service Interoperability

Web services are an advancing technology. Even though there are only a few basic building blocks used in the Web service specifications, they can be combined in diverse modes, and each specification has its own

© 2005 by CRC Press LLC

design cycle. Thus, it is not surprising that some additional rules have to be introduced to define a consistent subset of the specifications. Additionally, guidelines for the usage of these specifications have to be defined to ensure interoperability between the code developed by different programmers or generated by different Web service tools. The Web Service Interoperability organization WS-I [10] addresses this need through the concept of *profiles*.

> "The Web Services Interoperability Organization is an open industry effort chartered to promote Web Services interoperability across platforms, applications, and programming languages. The organization brings together a diverse community of Web services leaders to respond to customer needs by providing guidance, recommended practices, and supporting resources for developing interoperable Web services."

A WS-I *profile* is a group of specific versions of Web service specifications, along with conventions about how they work together. The WS-I basic *profile specification* [1] defines the conformance of a Web service instance. The profile consists of the following set of nonproprietary Web services specifications:

- SOAP 1.1,
- WSDL 1.1,
- UDDI 2.0,
- XML 1.0 (Second Edition),
- XML Schema Part 1: Structures,
- XML Schema Part 2: Data types, and
- Diverse transport-oriented RFCs.

The *basic profile* [10] provides constraints and clarifications to those base specifications with the intent to promote interoperability. Where the profile is silent, the base specifications are normative. If the profile prescribes a requirement or constraint, it supersedes the underlying base specification. Some of the constraints imposed by the profile are intended to restrict, or require, optional behavior and functionality, so as to reduce the potential of interoperability problems. Some of the constraints or requirements are provided to clarify language in the base specification that may be the source of frequent misinterpretation. The following key constraints are imposed by the *basic profile*:

- preclude the use of SOAP encoding,
- require the use of HTTP binding for SOAP,
- require the use of HTTP 500 status response for SOAP *fault* messages,
- require the use of HTTP POST method,
- require the use of WSDL1.1 to describe the interface of a Web service,
- require the use of rpc/literal or document/literal forms of the WSDL SOAP binding,
- preclude the use of solicit–response and notification style operations,
- require the use of WSDL SOAP binding extension with HTTP as the required transport, and
- require the use of WSDL1.1 descriptions for UDDI tModel elements representing a Web service.

11.1 Introduction

Most of today's development tools support the generation of Web services. It does not matter if you use Microsoft's Visual Studio.net, the possibly embedded Apache Axis [1] SOAP engine for Java services, or design tools like ArcStyler [2] for the generation of Web service from UML models. Every tool has its own strategy to generate the necessary code fragments for Web service servers and their clients. Every tool uses its own mapping from language-specific signatures to WSDL and *vice versa*.

To explain the necessary steps for the implementation, deployment and usage of a Web service three different models will be explained.

Figure 11.1 shows what happens if the development process starts with the *implementation* of the server code. This can either be a Web service-aware code like in our .net example or a Web service-unaware code like in our Java example. The Web service tool considers the program code as input. It generates the WSDL file and the necessary server and client stubs. In most cases, the server code together with the server stubs will be automatically deployed in the local environment. The user-written client code together with the generated client stubs will be assembled into a client archive that can be deployed in the user's environment. Some exemplary client templates may be generated; but in many cases the developer of the Web service client has to study the tool's manuals for details.

Figure 11.2 shows a similar scenario. Here, the generation process starts with a *specification* of the signature of the Web service. This may be a syntactically correct Java class with empty implementation bodies like the Apache Axis implementation requests. Again, the Web service tool generates the WSDL and stubs and additionally a service template. The service developer has to refine this template and insert the service logic. In case of Apache Axis, the template contains an interface specification that corresponds to the given Java class. Both approaches have the disadvantage that they solely allow the implementation of different clients to a given Web service. They do not support the usage of different implementations of a

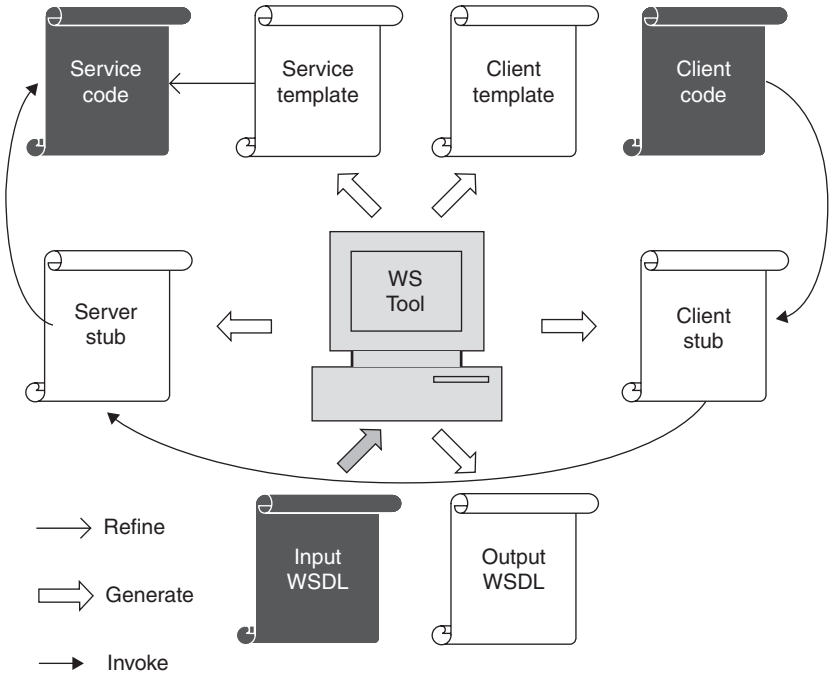

FIGURE 11.3 Starting with the WSDL.

Web service by one client. The latter scenario is important in the case of competing service providers or selective workflows. A solution for this scenario is shown in Figure 11.3.

Here, the Web service tool receives a WSDL file as input. The tool can generate client templates and client stubs that use the entire WSDL information. These clients will bind to the Web service server implementation that is referenced in the *binding* section. More important is the fact that the tool will generate service templates from the *message* and *port type* sections, together with new server stubs and a new WSDL file that contains the binding information to the service that will result from the new implemented and deployed service code. This example shows a problem in the usage of WSDL files. It is not guaranteed that the *message* and *port type* sections of the two WSDL files will remain unchanged in the future. There is neither a logical nor a physical link between both the input and output specifications, and the compliance of the two specifications is the responsibility of the service providers.

To exemplify these abstract models in technical details, let us start with the implementation of a .net Web service, according to the first model.

11.2 Programming a Web Service in the .net Framework

Sometimes, Microsoft Web services and .net are used as synonymous. This is understandable because Web services are one of the core technologies in .net [6]. As a result, the integration of Web services in .net and especially in Visual Studio .net is very high. You only have to say that you want to implement a Web service, and Visual Studio accordingly generates a template and creates several files in the background. The template contains some specific attributes or directives like [WebMethod] or [WebService] that can be used by the compiler to generate the necessary WSDL, stubs, and the other internally used information and files. In the following server implementation, the business code is displayed in *bold*, and the rest of the code is part of the generated template.

```
using System;
using System.Collections;
using System.ComponentModel;
using System.Data;
using System.Diagnostics;
using System.Web;
using System.Web.Services;
namespace CalcWebService
{
      [WebService(
            Namespace="http://www.myorg.org/webservices",
            Description = "The simple calculator Web service" )]
      public class CalcWebService : System.Web.Services.WebService
      {
            public CalcWebService()
            {
                  InitializeComponent();
            }
            #region Component Designer generated code
            ...
            #endregion
            [WebMethod(Description = "Add two integers")]
            public int Add(int x, int y){ return x + y; }
            [WebMethod(Description = "Divide two integers")]
            public int Div(int x, int y)
            {
                  if(y == 0)
                  {
                        throw new DivideByZeroException("Division by
zero!");
                  }
                  return x / y;
            }
      }
}
```

In the implementation of the C# client, the creation of a new *calculator* proxy is required. This can be done in a very natural way. Remember that the binding information is part of the WSDL and that the **ws** proxy is bound to the server that is specified in the WSDL. The client stubs and the client side SOAP engine are totally hidden to the programmer. The invocation of the Web service's operations on the proxy is done in a very natural way too.

{
      public class CalculatorClient : System.Windows.Forms.Form
      {
            private    server.CalcWebService    ws    =    new    server.
CalcWebService ();
            public CalculatorClient()
            {
                  InitializeComponent();
            }
            #region Windows Form Designer generated code
            ....
            #endregion
            private void buttonAdd_Click(object sender, System.EventArgs e)
            {
                  this.Cursor = Cursors.WaitCursor;
                  int ret = ws.Add(
                        Convert.ToInt16(textBoxParam1.Text),
                        Convert.ToInt16(textBoxParam2.Text));
                  textBoxOut.Text = Convert.ToString(ret);
                  this.Cursor = Cursors.Default;
            }
      }
}
```

The Global XML Web Services Architecture

The implementation and provision of real Web services, which can be used in a hard business context, involve much more than simply writing C# server and client code. To understand what pieces are missing in the whole puzzle, let us go back to the basics [8]. Every Web service implementation consists of the four layers shown in Figure 11.4.

Web service clients and servers communicate using some application-specific protocols. The used Web service infrastructure is more or less transparent to both the clients and the servers. This basic infrastructure is built on top of the three baseline XML Web service specifications WSDL, SOAP, and UDDI. These specifications provide the foundations for the integration and aggregation of Web applications. Complex Web applications are constructed combining multiple Web services from different vendors running in different technical and organizational domains. But these fundamental specifications leave a gap with respect to the provision of higher-level functionality such as security, reliability, routing, or transactions.

This functionality is often provided in proprietary, vendor-specific, and noninteroperable ways. This is the reason why Microsoft and other companies work on the specification and implementation of the *global XML Web services specifications* as part of the so-called *global XML Web services architecture* GXA [5]. GXA defines a framework for the development of .net Web services that supports additional SOAP modules, a high-level infrastructure, and enhanced description and discovery mechanisms for Web services.

© 2005 by CRC Press LLC

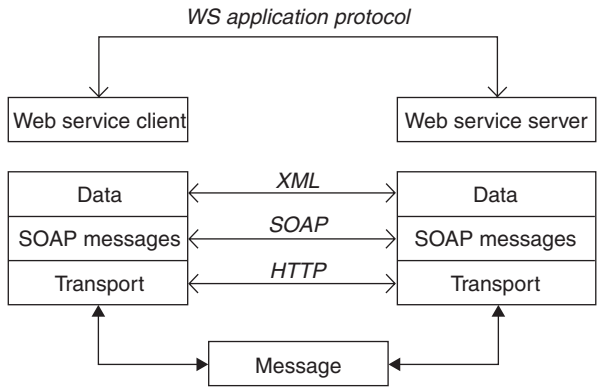

FIGURE 11.4 The Web services protocol stack.

The Web service infrastructure provides two services that support the interworking of Web services. The *WS-Coordination* specification describes an extensible framework for providing protocols that coordinate the actions of distributed Web applications. Such coordination protocols are used to support Web applications that need to reach a consistent agreement on the outcome of distributed transactions. The framework enables a Web service to create a context needed to propagate an activity to other Web services and to register for coordination protocols. It enables existing transaction processing, workflow, and other systems for coordination to conceal their proprietary protocols and to cooperate in a heterogeneous environment.

The *WS-Transaction* specification describes the two coordination types that are used with the extensible coordination framework introduced by the WS-Coordination specification: atomic transaction (AT) and business activity (BA). Developers can use either or both of these coordination types when building Web applications that require consistent agreement on the outcome of distributed activities. WS-Transaction is a building block used with other specifications of Web services like WS-Coordination or WS-Security and application-specific protocols that are able to accommodate a wide variety of coordination protocols related to the coordination actions of distributed Web applications.

UDDI allows to advertise and locate WSDL-based interface and protocol descriptions of Web services in global repositories. The Web service inspection language *WS-Inspection* relies on a distributed model for providing service-related information. It defines both a packaging model described by a schema and a querying model to retrieve a list of service offerings. Requests to retrieve the information are generally made directly to the entities that offer the services. The WS-Inspection specification does not stipulate any particular format for the service information. It relies upon other standards, including WSDL and UDDI, to define the description formats. By providing the ability to disseminate service-related information through existing protocols directly from the point at which the service is being offered, the WS-Inspection mechanism enables focused discovery to be performed on a single target. Due to its decentralized nature, however, the WS-Inspection specification does not provide a good mechanism if the communication partner is unknown. In cases such as this, UDDI would be a better alternative.

The Web services policy framework *WS-Policy* provides a model and a corresponding syntax to describe and communicate the policies of a Web service. At an abstract level, a policy is an expression of a set of conditions on an action that may result in a behavior that reflects these conditions. For Web services, the service provider generally has conditions under which he allows the usage of the service. A requester might use this information to decide whether or not to use the service. *WS-Policy* defines a base set of constructs to describe service requirements, preferences, and capabilities. It consists of two parts. *WS-PolicyAssertions* specify a set of common message policy assertions that can be specified within a policy. *WS-PolicyAttachment* specifies attachment mechanisms for using policy expressions. It defines how to associate policy expressions with WSDL <types> definitions and UDDI entities and how to associate implementation-specific policies with the WSDL <portType>.

© 2005 by CRC Press LLC

The following three specifications define SOAP extensions that define standardized SOAP headers to enable a higher level of security during the usage of Web services. The Web services routing protocol *WS-Routing* defines mechanisms for routing SOAP messages. SOAP does not actually define a mechanism for sending a message from one party to another. WS-Routing defines a new SOAP header and an associated processing model. It is a stateless protocol that extends SOAP by defining a means to specify an ordered route from the originator of the message, through intermediaries, to the ultimate message receiver. The Web services referral protocol *WS-Referral* is a simple SOAP-based protocol for configuring instructions about message routes in intermediary SOAP nodes called *routers*. WS-Referral is orthogonal to *WS-Routing* in that WS-Referral provides a way to configure *how* SOAP routers will build a message route, whereas WS-Routing provides a mechanism for describing an actual path of a message. SOAP routers are used to add nonfunctional properties like load-balancing, mirroring, caching, or client authentication services to a Web service in a manner that is transparent to users of the service.

The *WS-Security* specification defines a set of enhancements to SOAP messaging. Its goal is to provide quality of protection through message integrity, message confidentiality, and single message authentication. The associated mechanisms can be used to accommodate a wide variety of security models and encryption technologies. WS-Security provides an extensible, general-purpose mechanism for associating security tokens with messages. It describes how to encode binary security tokens like X.509 certificates and Kerberos tickets, as well as how to include opaque encrypted keys. It includes extensibility mechanisms that can be used to further describe the characteristics of the credentials that are included within a message. The *Web services security profile for XML-based tokens* describes how to use XML-based tokens such as the Security Assertion Markup Language (SAML) or the eXtensible rights Markup Language (XrML) with the WS-Security specification. *WS-Trust* defines extensions to request and issue security tokens and to manage trust relationships. Finally, *WS-SecureConversation* defines mechanisms for establishing and sharing security contexts, and for deriving session keys from these contexts.

The global XML Web services architecture GXA, as shown in Figure 11.5, consists of these upcoming specifications. It defines a framework for the development of future .net Web services. Some of these specifications result in APIs that will be directly used by the service developers. Others will result in specific deployment or configuration descriptors that have to be mapped by the run time environment to the appropriate specifications.

11.3 Programming a Java Web Service

For the implementation of a Java Web service, let us go into some more technical details. The following description applies to the usage of Apache Axis [1].

As in the C# example, the implementation of the Java server is quite forward. The tool generates the WSDL and server stubs from the implementation and deploys them in the Axis environment, transparent to the developer. The environment consists of an Apache Tomcat Web server and the Axis server-side SOAP engine.

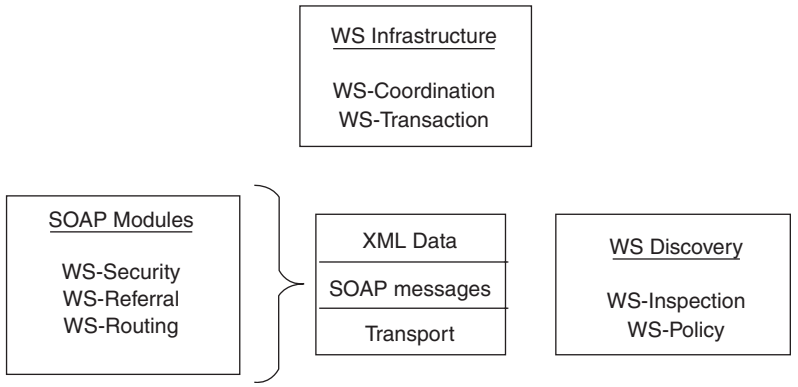

FIGURE 11.5 The global XML Web services architecure GXA.

© 2005 by CRC Press LLC

```
package calculator;
public class Calculator {
  public int add(int x, int y)
  {
    System.out.println("Add" + x + "+" + y);
    return x + y;
  }
  public int divide(int x, int y) throws DivideByZeroException
  {
    System.out.println("Divide " + x + "/" + y);
    if(y == 0)
    {
      throw new DivideByZeroException("Division by zero!");
    }
    return x / y;
  }
}
```

For the client-side binding and the calculator client stub, two Java interfaces and two Java classes are generated. As shown in Figure 11.6, the class *CalculatorServiceLocator* implements the interface *CalculatorService* and provides an operation *getCalculator* that returns an instance of the client-side proxy called *CalculatorSoapBindingStub*.

```
/**
 * CalculatorService.java
 *
 * This file was auto-generated from WSDL
 * by the Apache Axis WSDL2Java emitter.
 */
package calculator.generated;
public interface CalculatorService extends javax.xml.rpc.Service {
...
    public calculator.generated.CalculatorPortType
           getCalculator()
                      throws javax.xml.rpc.ServiceException;
}
```

This excerpt from the generated code shows the default implementation of the *getCalculator* operation. It uses the default binding information, stored in the Web service's deployment descriptor. There exist more operations that allow the user to explicitly bind to other implementations.

```
/**
 * CalculatorServiceLocator.java
 *
 * This file was auto-generated from WSDL
 * by the Apache Axis WSDL2Java emitter.
 */
package calculator.generated;
public class CalculatorServiceLocator
      extends org.apache.axis.client.Service
      implements calculator.generated.CalculatorService {
...
    public calculator.generated.CalculatorPortType
           getCalculator()
                 throws javax.xml.rpc.ServiceException {
        java.net.URL endpoint;
         try {
              endpoint = new java.net.URL(Calc_address);
         }
         catch (java.net.MalformedURLException e) {
             return null; // unlikely as URL was validated in WSDL2Java
         }
         return getCalculator(endpoint);
    }
    public calculator.generated.CalculatorPortType
           getCalculator(java.net.URL portAddress)
                 throws javax.xml.rpc.ServiceException {
         try {
              calculator.generated.CalculatorSoapBindingStub _stub =
                 new calculator.generated.CalculatorSoapBindingStub
                       (portAddress, this);
              _stub.setPortName(getCalcWSDDServiceName());
              return _stub;
         }
         catch (org.apache.axis.AxisFault e) {
              return null;
         }
    }
...
}
```

© 2005 by CRC Press LLC

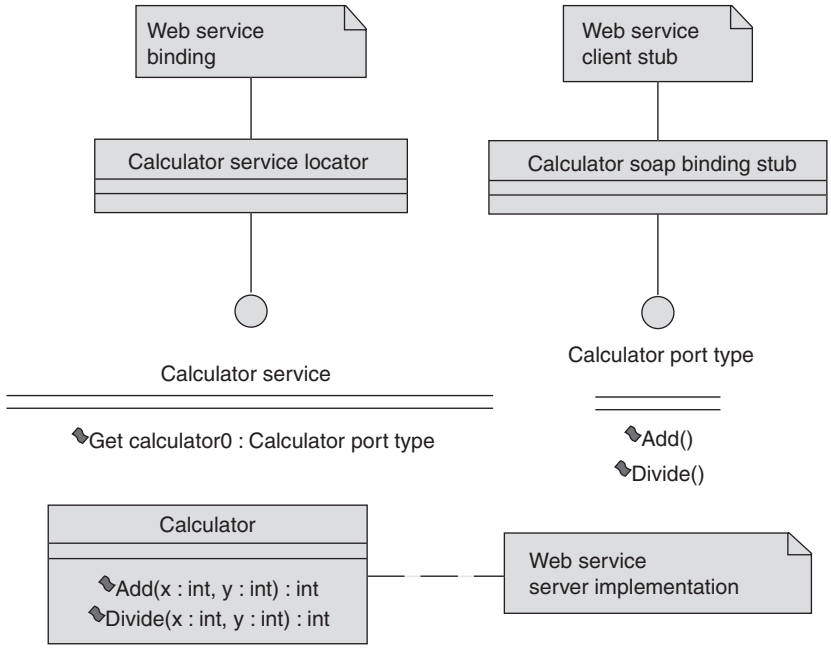

FIGURE 11.6 UML model of the generated Java classes and interfaces.

The generated <portType> proxy interface provides the same operations as the Web service implementation itself.

```
/**
 * CalculatorPortType.java
 *
 * This file was auto-generated from WSDL
 * by the Apache Axis WSDL2Java emitter.
 */
package calculator.generated;
public interface CalculatorPortType extends java.rmi.Remote {
    public int add(int x, int y) throws java.rmi.RemoteException;
    public int divide(int x, int y)
           throws java.rmi.RemoteException, DivideByZeroException;
}
```

The associated class *CalculatorSoapBindingStub* implements these operations. It creates and initializes a dynamic *Call* object and calls its *invoke* operation. This operation passes the object to the SOAP client-side engine that performs all the necessary housekeeping activities: encode the request, submit the request to the selected communication protocol, wait for the response, and decode the response.

© 2005 by CRC Press LLC

```
/**
 * CalculatorSoapBindingStub.java
 *
 * This file was auto-generated from WSDL
 * by the Apache Axis WSDL2Java emitter.
 */
package calculator.generated;
public class CalculatorSoapBindingStub
      extends org.apache.axis.client.Stub
      implements calculator.generated.CalculatorPortType {
...
    public CalculatorSoapBindingStub(
           java.net.URL endpointURL,
           javax.xml.rpc.Service service)
                 throws org.apache.axis.AxisFault {
           this(service);
           super.cachedEndpoint = endpointURL;
    }
...
    public int add(int x, int y) throws java.rmi.RemoteException {
         if (super.cachedEndpoint == null) {
              throw new org.apache.axis.NoEndPointException();
         }
         org.apache.axis.client.Call _call = createCall();
         _call.addParameter(new javax.xml.namespace.QName("", "x"),...
         _call.addParameter(new javax.xml.namespace.QName("", "y"),...
           _call.setReturnType(new javax.xml.namespace.QName(..., int.
class);
         _call.setUseSOAPAction(true);
         _call.setSOAPActionURI("");
         _call.setOperationStyle("rpc");
         _call.setOperationName(
                 new    javax.xml.namespace.QName("http://calculator",
"Add"));
         java.lang.Object _resp = _call.invoke(new java.lang.Object[]
           {new java.lang.Integer(x), new java.lang.Integer(y)});
...
}
```

The implementation of the Java test client is quite forward. It creates a *CalculatorServiceLocator* object and calls the *getCalculator* operation to bind itself to the default Web service implementation and to obtain a *CalculatorPortType* interface as a local proxy. This proxy provides the same operations as the Web service itself and can be used in a similar way.

© 2005 by CRC Press LLC

```
package calculator.generated;
public class CalculatorClient {
  public static void main(String [] args) throws Exception {
    calculator.generated.CalculatorServiceLocator locator =
          new calculator.CalculatorServiceLocator();
    calculator.CalculatorPortType obj = locator.getCalculator();
    System.out.println("Test add: " + obj.add (100 , 200));
  }
}
```

As in the .net example, the implementation of a Web service client is quite simple as long as the client binds to the server that is referred in the WSDL file and as long as the Web service tool generates all the necessary client-side classes. It is worth mentioning that the client-side interfaces to the SOAP engine as well as the server side interfaces are totally hidden in this example. If you want to write a Web service client by hand, you have to satisfy these interfaces and you probably have to parse and interpret the WSDL file yourself. More information about the appropriate Java APIs is given in Section 11.4 "The Java community process."

Exception Handling

In distributed environments in many cases, the treatment of exceptions is much more difficult than the treatment of the positive cases. In both the .net and the Java examples, the server implementations throw exceptions on the level of the appropriate programming language. This section shows how WSDL supports the definition of exceptions. It is up to the client-side stub to remap these exceptions to the programming language used by the client stub.

The following example shows an excerpt from the WSDL specification, generated from the source file of the Java implementation of the calculator service. In addition to the previous examples, a new <types> element is included that defines the exception that is thrown by the *Divide* operation in case of an attempt to divide by zero. It has to be mentioned that the generated WSDL differs from tool to tool. Thus, this example has to be considered as one of several possible syntactical representations of the specification of the same calculator Web service too. Different tools may generate different names.

```
<definitions ...
     xmlns:soapbind=http://schemas.xmlsoap.org/wsdl/soap/ ...>
<types>
     <schema ...
          <complexType name="Calculator.DivideByZeroException">
               <sequence/>
          </complexType>
     </schema>
</types>
```

The exception is expressed as a special return message <part name="fault">.

© 2005 by CRC Press LLC

```
<message name="Div">
      <part name="x" type="xsd:int"/>
      <part name="y" type="xsd:int"/>
</message>
<message name="DivResponse">
      <part name="DivReturn" type="xsd:int"/>
</message>
<message name="Calc$DivideByZeroException">
      <part name="fault"
            type="xsd1:Calculator.DivideByZeroException"/>
</message>
```

The definition of the associated <portType> contains the new message.

```
<portType name="Calculator"> ...
      <operation name="Div" parameterOrder="x y">
            <input name ="Div" message="tns:Div"/>
            <output name ="DivResponse" message="tns:DivResponse"/>
            <fault name="Calc$DivideByZeroException"
                  message="tns:Calc$DivideByZeroException"/>
      </operation>
</portType>
```

In the <binding> section, the new *fault* element is included.

```
<binding name="CalculatorBinding" type="tns:Calculator">
...
      <fault name="Calc$DivideByZeroException">
            <soapbind:fault
                  use="encoded"
                  encodingStyle="http://schemas.xmlsoap.org/soap/encoding/"
                  namespace="Calculator"/>
      </fault>
</binding>
```

11.4 Web Services and Java standardization

In contrast to .net, the integration of Web service technology into the Java world is still under development. The following two upcoming approaches are of major importance.

Web Services and J2EE

In many cases, the implementation of a Web service is not given by one or more Java classes but by an Enterprise Java Bean. Because Web services are inherently stateless, the only EJB type that is a natural

© 2005 by CRC Press LLC

candidate for a Web service is a stateless session bean. Some of today's Web service tools use an EJB archive as input and generate a WSDL file out of a selected remote interface. Additionally, these tools generate a servlet as a Web service proxy that maps the incoming SOAP requests to RMI requests and forwards them to the EJB implementation.

The upcoming EJB specification 2.1 [7] includes an extension for stateless session beans that allows a Web client to access the bean via a *Web service endpoint interface*. The *service–endpoint–interface* element in the Web service client's deployment descriptor defines a fully qualified Java class that represents the service endpoint interface of a WSDL *port*. The Web service itself is directly implemented by the bean and runs in the associated Web container.

The developer is responsible for defining a *service-ref* element for each Web service that the client wants to reference. This includes a logical name for the reference that is used in the client's code, the fully qualified name of the service interface class returned by the JNDI lookup and references to WSDL ports. More technical details can be found in [3].

The Java Community Process

The Java community process JCP [4] is an open organization of international Java developers and licensees, whose charter is to develop and revise Java technology specifications, reference implementations, and technology compatibility kits. JCP publishes a set of so-called Java specification requests JSR that define Java APIs for domain-specific problems. The following JSRs deal with Web service technology and have to be applied by application developers to implement Java Web services by hand or by tool developers to ensure standard conformity and interoperability.

- The XML Parsing JAXP (JSR63) defines a set of implementation-independent portable APIs supporting XML Processing.
- The Java API for WSDL (JSR 110) provides a standard set of APIs for representing and manipulating services described by WSDL documents.
- The Java API for XML-registries JAXR (JSR 93) supports a set of distributed registry services that enables business-to-business integration between business enterprises, using the protocols being defined by ebXML.org, Oasis, ISO 11179.
- The Java API for XML-based PRCs (JSR 101) supports emerging industry XML-based RPC standards.
- The Java API for XML messaging JAXM (JSR 67) supports packaging and transporting business transactions using on-the-wire protocols being defined by ebXML.org, Oasis, W3C and IETF including SOAP with attachment APIs for Java (SAAJ).
- The J2ME Web Service Specification (JSR 172) defines an optional package that provides standard access from mobile J2ME clients to Web services.

12.1 Introduction

The relational data model, which was introduced by Codd in 1970 and earned him the Turing Award a decade later, was the foundation of today's multi-billion-dollar database industry. During the 1990s, a new type of data model, the *multidimensional data model*, has emerged, which has taken over from the relational model where the objective is to *analyze* data, rather than to perform on-line transactions.

Multidimensional data models are designed expressly to support data analyses. A number of such models have been proposed by researchers from academia and industry. In academia, formal mathematical models have been proposed, while the industrial proposals have typically been specified more or less *implicitly* by the concrete software tools that implement them.

Briefly, multidimensional models categorize data as being either *facts* with associated numerical *measures*, or as being *dimensions* that characterize the facts and are mostly textual. For example, in a retail business, *products* are sold to *customers* at certain *times* in certain *amounts* and at certain *prices*. A typical fact would be a *purchase*. Typical measures would be the amount and price of the purchase. Typical dimensions would be the location of the purchase, the type of product being purchased, and the time of

[1]Based on "Multidimensional Database Technology" by Torben Bach Pedersen and Christian S. Jensen which appeared in IEEE Computer 34(12):40–46. ©2001 IEEE.

© 2005 by CRC Press LLC

the purchase. Queries then aggregate measure values over ranges of dimension values to produce results such as the total sales per month and product type.

Multidimensional data models have three important application areas within data analysis. First, multidimensional models are used in *data warehousing*. A data warehouse is a large repository of integrated data obtained from several sources in an enterprise for the specific purpose of data analysis. Typically, these data are modeled as being multidimensional, as this best supports data analyses.

Second, multidimensional models lie at the core of *On-Line Analytical Processing* (OLAP) systems. Such systems provide fast answers to queries that aggregate large amounts of so-called detail data to find overall trends, and they present the results in a multidimensional manner. Consequently, a multidimensional data organization is ideal for OLAP.

Third, multidimensional data are increasingly becoming the basis for *data mining*, where the aim is the (semi) automatic discovery of unknown knowledge in large databases, as it turns out that multidimensionally organized databases are particularly well suited for queries posed by data mining tools.

This chapter describes fundamental concepts in multidimensional data models. It aims to communicate the essence of the multitude of proposed models in a clear and easily understood form. In doing so, we hope that the chapter will serve as an introduction of the concepts and benefits of multidimensional databases, which are well known in the database community by now, to the broader community of computer science. In-depth coverage of the features of individual models may be found elsewhere [18, 23]. The chapter also addresses implementation technologies and gives an overview of commercial systems.

12.2 Background

Related Terminology

It is useful to be familiar with a few special terms when studying the literature on issues related to multidimensional databases.

OLAP: OLAP abbreviates *On-Line Analytical Processing*. As opposed to the well-known On-Line *Transaction* Processing (OLTP), the focus is on data analyses rather than transactions. Furthermore, the analyses occur "On-Line," that is, a fast query response is required. OLAP systems always adopt a multidimensional view of data.

Data warehouse: A data warehouse (DW) is a repository of integrated enterprise data that are used specifically for decision support, that is, there is (typically) only one data warehouse in an enterprise. The data in a DW are typically collected from a large number of sources within (and sometimes also outside) the enterprise.

Data mart: A data mart (DM) is a subset of a data warehouse that is specialized to the needs of a special user group, for example, the marketing department.

ETL: Extract-Transform-Load (ETL) is the three-step process that puts data into the DW. First, data are *extracted* from the operational source systems, for example, ERP systems. Second, data are *transformed* from the source system formats into the DW format. This includes combining data from several sources and performing *cleansing* to correct errors such as missing or wrong data. Third, data are *loaded* into the DW. At times, ETL is also referred to as Extract-Transform-Transport (ETT).

Multidimensional History

Multidimensional databases do not have their origin in database technology, but stem from multidimensional matrix algebra, which has been used for (manual) data analyses since the late 19th century.

During the late 1960s, two companies, IRI and Comshare, independently began the development of systems that later evolved into multidimensional database systems. The IRI Express tool became very popular in the marketing analysis area in the late 1970s and early 1980s; it later evolved into a market-leading OLAP tool and was acquired by Oracle. Concurrently, the Comshare system evolved into System W, which was used considerably for financial planning, analysis, and reporting during the 1980s.

© 2005 by CRC Press LLC

In 1991, Arbor was formed with the specific purpose of creating "a multiuser, multidimensional database server," which resulted in the Essbase system. Arbor, now Hyperion, later licensed a basic version of Essbase to IBM for integration into DB2. It was Arbor and Codd who in 1993 coined the term OLAP [2].

Another significant development in the early 1990s was the advent of large *data warehouses* [10], which are typically based on relational *star* or *snowflake* schemas, an approach to implementing multidimensional databases using relational database technology.

In 1998, Microsoft shipped its MS OLAP Server, the first multidimensional system aimed at the mass market. This has led to the current situation, where multidimensional systems are increasingly becoming commodity products that are shipped at no extra cost together with leading relational database management systems.

A more in-depth coverage of the history of multidimensional databases is available in the literature [21].

12.3 Spreadsheets and Relations

Assume that we want to analyze data about sales of products, for which we capture the sales price, the product sold, and the city in which it was sold. A simple example with two dimensions is shown in Table 12.1.

When considering how to analyze such data, *spreadsheets* immediately come to mind as a possibility — Table 12.1 is just a (two-dimensional) spreadsheet.

Our first analysis requirement is that we do not just want to see sales by product and city, but also the two kinds of subtotals, sales by product and sales by city, and the grand total of sales. This means that formulas for producing the (sub)totals must be added to the spreadsheet, each requiring some consideration. It is possible, if rather cumbersome, to add new data to the spreadsheet, for example, if new products are sold. Thus, for two dimensions, we can perhaps somehow manage with spreadsheets.

However, if we go to three dimensions, for example, to include time, we have to consider carefully what to do. The obvious solution is to use separate worksheets to handle the extra dimension, with one worksheet for each dimension value. This will work only when the third dimension has few dimension values and only to some extent. Analyses involving several values of the third dimension are cumbersome, and with many thousands of, say, time dimension values, the solution becomes infeasible. The situation becomes even worse if we need to support four or more dimensions, which in any case will require a very complex setup.

Another problem arises if we want to group, for example, the product into higher-level product types like "food" and "non-food." Then, we must duplicate the grouping information across all worksheets, which results in a system that uses considerable extra space and is very difficult to maintain. The essence of the problem is that spreadsheets tie the storage of data too tightly to the presentation — the *structure* and the *desired views* of the information are not separated. However, spreadsheets are good for *viewing and querying* multidimensional data, for example, using *pivot tables*. A pivot table is a two-dimensional table of data with associated subtotals and totals. For example, if we add subtotals by City and Product and a City/Product grand total to Table 12.1, we obtain an example of a pivot table. To support viewing of more complex data, several dimensions may be nested on the x- or y-axis, and data may be displayed on multiple pages, for example, one for each product. Pivot tables generally also offer support for interactively selecting subsets of the data and changing the displayed level of detail.

With spreadsheets falling short in meeting our requirements for the management of multidimensional data, we may then consider using an SQL-based, relational system for data management, as the relational

TABLE 12.1 Sales Data

	City			
Product	Aalborg	Copenhagen	Berkeley	New York
Milk	123	555	145	5001
Bread	102	250	54	2010
Jeans	20	89	32	345
Lighbulps	22	213	32	9450

© 2005 by CRC Press LLC

model offers considerable flexibility in the modeling and querying of data. The problem here is that many desirable computations, including cumulative aggregates (sales in year to date), totals and subtotals together, and rankings (top 10 selling products), are difficult or impossible to formulate in standard SQL.

The main underlying issue is that *interrow* computations are difficult to express in SQL — only *intercolumn* computations are easy to specify. Additionally, transpositions of rows and columns are not easily possible, but rather require the manual specification and combination of multiple views. Although extensions of SQL, such as the *data cube operator* [7] and *query windows* [5], advanced by the standards bodies, will remedy some of the problems, the concept of hierarchical dimensions remains to be handled satisfactorily.

To summarize, we have seen that neither spreadsheets nor relational databases fully support the requirements posed by advanced data analyses. To be fair, these technologies may be adequate in more restricted circumstances. For example, if we have only a few dimensions, do not need hierarchical dimensions, and the data volume is small, spreadsheets may provide adequate support. However, the only robust solution to the above problems is to provide data models and database technology that offer inherent support for the full range of multidimensional concepts.

12.4 Cubes

Data cubes provide true multidimensionality. They generalize spreadsheets to any number of dimensions. In addition, hierarchies in dimensions and formulas are first-class, built-in concepts, meaning that these are supported without duplicating their definitions. A collection of related cubes is commonly referred to as a *multidimensional database* or a *multidimensional data warehouse*.

Figure 12.1 shows a cube capturing the product sales from Table 12.1 for the two Danish cities, with the additional dimension Time. The combinations of dimension values define the *cells* of the cube. The actual sales prices are stored within the corresponding cells.

In a cube, dimensions are first-class concepts with associated domains, meaning that the addition of new dimension values is easily handled. Although the term "cube" implies three dimensions, a cube can have any number of dimensions. It turns out that most real-world cubes have 4–12 dimensions [10, 21]. Although there is no theoretical limit to the number of dimensions, current tools often experience performance problems when the number of dimensions is more than 10–15. To better illustrate the high number of dimensions, the term "hypercube" is often used instead of "cube."

FIGURE 12.1 Sales cube.

© 2005 by CRC Press LLC

Depending on the specific application, a highly varying percentage of the cells in a cube are nonempty, meaning that cubes range from *sparse* to *dense*. Cubes tend to become increasingly sparse with increasing dimensionality and with increasingly finer granularities of the dimension values.

A nonempty cell is called a *fact*. The example has a fact for each combination of time, product, and city where at least one sale was made. A fact has a number of *measures* associated with it. These are numerical values that "live" within the cells. In our case, we have one measure, the sales price.

Generally, only two or three dimensions may be viewed at the same time, although for low-cardinality dimensions, up to four dimensions can be shown by nesting one dimension within another on the axes. Thus, the dimensionality of a cube is reduced at query time by *projecting* it down to two or three dimensions via *aggregation* of the measure values across the projected-out dimensions. For example, if we want to view just sales by City and Time, we aggregate over the entire Product dimension for each combination of City and Time. In our example, we obtain the total sales for Copenhagen in 2001 by adding 127 and 211.

An important goal of multidimensional modeling is to "provide as much context as possible for the facts" [10]. The concept of *dimension* is the central means of providing this context. One consequence of this is a different view on *data redundancy* than in relational databases. In multidimensional databases, controlled redundancy is generally considered appropriate, as long as it considerably increases the information value of the data. One reason to allow redundancy is that multidimensional data are often *derived* from other data sources, for example, data from a transactional relational system, rather than being "born" as multidimensional data, meaning that updates can be handled more easily [10]. However, there is usually no redundancy in the facts, only in the dimensions.

Having introduced the cube, we describe its principal elements, dimensions, facts, and measures, in more detail.

12.5 Dimensions

The notion of a dimension is an essential and distinguishing concept in multidimensional databases. Dimensions are used for two purposes: *selection* of data and *grouping* of data at the desired level of detail.

A dimension is organized into a containment-like hierarchy, composed of a number of *levels* that each represent a level of detail that is of interest to the analyses to be performed. The instances of the dimension are typically called *dimension values*. Each such value belongs to a particular level. In some cases, it is advantageous for a dimension to have *multiple hierarchies* defined on it, for example, a Time dimension that has hierarchies for both *Fiscal Year* and *Calendar Year*. Multiple hierarchies share one or more common lowest level(s), for example, Day and Month, and then group these into multiple levels higher up, for example, Fiscal Quarter and Calendar Quarter to allow for easy reference to several ways of grouping. Most multidimensional models allow multiple hierarchies. A dimension hierarchy is defined in the metadata of the cube, or the metadata of the multidimensional database, if dimensions can be shared. This means that the problem of duplicate hierarchy definitions as discussed in Section 12.3 is avoided.

In Figure 12.2, the schema and instances of a sample *Location* dimension for the data in Table 12.1 are shown.

The Location dimension has three levels, the City level being the lowest. City-level values are grouped into *Country*-level values, that is, countries. For example, Aalborg is in Denmark. The $\top$ ("top") level represents *all* of the dimension, that is, every dimension value is part of the $\top$ ("top") value.

In some multidimensional models, a level may have associated with it a number of *level properties* that are used to hold simple, nonhierarchical, information. For example, the package size for a given product can be a level property in the Product level of the Product dimension. This information could also be captured using an extra Package Size dimension. Using the level property has the effect of not increasing the dimensionality of the cube.

Unlike the linear spaces used in matrix algebra, there is typically no ordering and/or distance metric on the dimension values in multidimensional models. Rather, the only ordering is the containment of lower-level values in higher-level values. However, for some dimensions, for example, the Time

© 2005 by CRC Press LLC

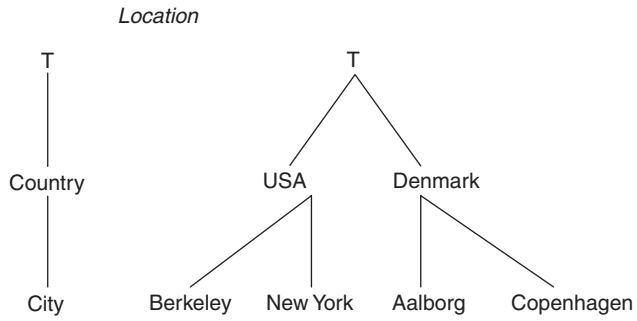

FIGURE 12.2 Schema and instances for the Location dimension.

dimension, an ordering of the dimension values is available and is used for calculating cumulative information such as "total sales in year to date."

Most models require dimension hierarchies to form *balanced trees*. This means that the dimension hierarchy must have a uniform height everywhere, for example, all departments, even small ones, must be subdivided into project groups. Additionally, direct links between dimension values can only go between immediate parent–child levels, and not jump two or more levels. For example, all cities are first grouped into states and then into countries; cities cannot be grouped directly under countries (as is the case in Denmark, which has no states). Finally, each nontop value has precisely one parent, for example, a product must belong to exactly one product group. In Section 12.10, we discuss the relaxation of these constraints.

12.6 Facts

Facts are the objects that represent the *subject* of the desired analyses, that is, the interesting "thing," or event or process, in the enterprise that is to be analyzed to better understand its behavior.

In most multidimensional data models, the facts are *implicitly* defined by their combination of dimension values. If a nonempty cell exists for a particular combination, a fact exists; otherwise, no fact exists. (Some other models treat facts as first-class objects with a separate identity [18].) Next, most multidimensional models require that each fact be mapped to precisely one dimension value at the lowest level in each dimension. Other models relax this requirement [18].

A fact has a certain *granularity*, determined by the levels from which its combination of dimension values are drawn. For example, the fact granularity in our example cube is "Year by Product by City." Granularities consisting of higher- or lower-level dimension levels than a given granularity, for example, "Year by product Type by City" or "Day by Product by City" for our example, are said to be *coarser* or *finer* than the given granularity, respectively.

It is commonplace to distinguish among three kinds of facts: *event* facts, *snapshot* facts, and *cumulative snapshot* facts [10]. Event facts (at least at the finest granularity) typically model *events in the real world*, meaning that a unique instance, for example, a particular sale of a given product in a given store at a given time, of the overall real-world process that is captured, for example, sales for a supermarket chain, is represented by one fact. Examples of event facts include sales, clicks on web pages, and movements of goods in and out of (real) warehouses (flow).

A snapshot fact models the *state* of a given process at a given point in time. Typical examples of snapshot facts include the inventory levels in stores and warehouses, and the number of users using a web site. For snapshot facts, the same object, for example, a specific can of beans on a shelf, with which the captured real-world process, for example, inventory management, is concerned may occur in several facts at different time points.

Cumulative snapshot facts are used to handle information about *a process up to a certain point in time*. For example, we may consider the total sales in year to date as a fact. Then the total sales up to and including the current month this year can be easily compared to the figure for the corresponding month last year.

© 2005 by CRC Press LLC

Often, all three types of facts can be found in a given data warehouse, as they support complementary classes of analyses. Indeed, the same base data, for example, the movement of goods in a (real) warehouse, may often find its way into three cubes of different types, for example, warehouse flow, warehouse inventory, and warehouse flow in year-to-date.

12.7 Measures

A *measure* has two components: a *numerical property* of a fact, for example, the sales price or profit, and a *formula* (most often, a simple aggregation function such as SUM) that can be used to combine several measure values into one. In a multidimensional database, measures generally represent the properties of the chosen facts that the users want to study, for example, with the purpose of optimizing them.

Measures then take on different values for different combinations of dimension values. The property and formula are chosen such that the value of a measure is meaningful for all combinations of aggregation levels. The formula is defined in the metadata and thus not replicated as in the spreadsheet example. Although most multidimensional data models have measures, some do not. In these, dimension values are also used for computations, thus obviating the need for measures, but at the expense of some user-friendliness [18].

It is important to distinguish among three classes of measures, namely *additive*, *semiadditive*, and *nonadditive* measures, as these behave quite differently in computations.

Additive measure values can be combined meaningfully along any dimension. For example, it makes sense to add the total sales over Product, Location, and Time, as this causes no overlap among the real-world phenomena that caused the individual values. Additive measures occur for any kind of fact.

Semiadditive measure values cannot be combined along one or more of the dimensions, most often the Time dimension. Semiadditive measures generally occur when the fact is of type snapshot or cumulative snapshot. For example, it does not make sense to sum inventory levels across time, as the same inventory item, for example, a specific can of beans, may be counted several times, but it is meaningful to sum inventory levels across products and warehouses.

Nonadditive measure values cannot be combined along any dimension, usually because of the chosen formula. For example, this occurs when averages for lower-level values cannot be combined into averages for higher-level values. Nonadditive measures can occur for any kind of fact.

12.8 Querying

A multidimensional database naturally lends itself toward certain types of queries.

The queries known as *slice and dice* perform selections on a cube, thus reducing the cube. Their effect is similar to that of preparing an onion for cooking. For example, we may slice the cube in Figure 12.1 by considering only those cells that concern "Bread," and we may further slice this resulting slice, for example, by considering only the cells for year "2000." When we select a single value in a dimension, we, in a sense, reduce the dimensionality of the cube (strictly speaking, a degenerate dimension remains), but more general selections are also possible.

The operations known as *drill-down* and *roll-up* are inverses of each other and make use of dimension hierarchies and measures to perform aggregations. Consider the location dimension in Figure 12.2 together with the cube, where the (additive) measure is the count of sales together with the function SUM. We may roll-up from City level to Country level. This results in the measure values for all cities in the same country being combined into one by the associated formula. In our cube, values for "Aalborg" and "Copenhagen" are added to obtain a single "Denmark" value. For the "Bread" slice, this yields two cells, with values 180 (for year 2000) and 172 (for year 2001).

Slicing and dicing may be combined with drill-down and roll-up. Rolling up to the top value in a dimension corresponds in a sense (slightly different from the one above) to omitting the dimension.

© 2005 by CRC Press LLC

When a multidimensional database consists of several cubes that share one or more dimensions, it is possible to combine the cubes via the shared dimensions, via a so-called *drill-across* operation. In terms of relational algebra, this operation performs a join.

Next, operations are also available that enable the user to manipulate the visualization of a cube, for example, by *rotating* it to make a different set of dimensions "face the user," that is, to see the data grouped by other dimensions.

Queries involving order are very important in data analyses and are thus supported by all multidimensional data analysis tools. These may order cells in results, and they may return only those cells that appear at the top or bottom of the specified order. For example, one may wish to retrieve the ten best-selling products in "Copenhagen" in the year 2000. Such queries are often referred to as *ranking* or *TOP N/BOTTOM N* queries [21].

12.9 Implementation Technologies

One may distinguish between two major approaches to implementing multidimensional databases, termed multidimensional vs. relational on-line analytical processing. We first contrast the two and then consider the latter in additional detail.

Multidimensional vs. Relational OLAP

Multidimensional OLAP (MOLAP) systems [21] store data on disk in specialized multidimensional structures. These typically include provisions for handling sparse arrays, and they apply advanced indexing and hashing to locate the data when performing queries [21]. In contrast, *Relational OLAP* (ROLAP) systems [10] use relational database technology for storing the data. In order to achieve good query performance, ROLAP systems employ specialized index structures such as bit-mapped indices [6], as well as materialized views [24]. We offer more information regarding DW performance at the end of this section.

Generally, MOLAP systems provide faster query response and more space-efficient storage, while ROLAP systems scale better in the number of facts, are more flexible with respect to cube redefinitions, and provide better support for frequent updates.

The virtues of the two approached are combined in the *Hybrid OLAP* (HOLAP) approach, which generally stores higher-level summary data using MOLAP technology, while using ROLAP technology to store the detailed data. Some HOLAP systems allow even more flexibility, giving users a choice between MOLAP and ROLAP at the level of individual cubes and/or materialized aggregates.

Relational OLAP Schemas

ROLAP is the most commonly used technology for the detailed data in the DW; hence, we go on to describe the typical schemas found in ROLAP DWs.

ROLAP implementations typically use *star* or *snowflake* schemas [10], both of which store the data in *fact tables* and *dimension tables*. A fact table holds one row for each fact in the cube. It has a column for each measure. In a row, this column then contains the measure value for the fact that the row represents. A fact table also has one column for each dimension. In a row, these columns contain foreign keys that reference dimension tables.

The difference between star and snowflake schemas lies in their handling of dimensions. A star schema has one dimension table for each dimension. The dimension table contains a key column. It also has one column for each level in the dimension. In a row, such a column contains a textual description of a dimension value at its level. Finally, the dimension table contains one column for each level property in the dimension. An example star schema for the Sales cube can be found in Figure 12.3.

The fact table of the star schema holds the sales price for one particular sale. The fact table also has a foreign key column for each of the three dimensions, Product, Location, and Time. The dimension tables have

© 2005 by CRC Press LLC

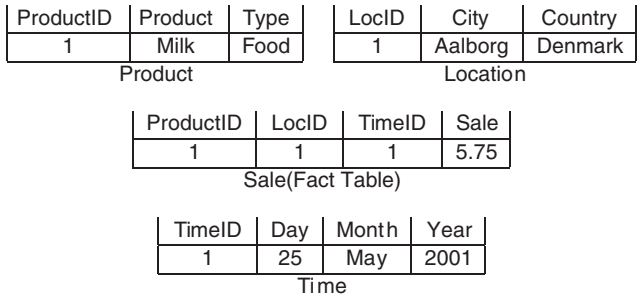

FIGURE 12.3 Star schema for sales cube.

corresponding key columns and one column for each of their levels, for example, LocID, City, and Country for Location. No column is needed for the T level, as that column would always hold the same value. The key column in a dimension table is typically a "dummy" integer key without any semantics. This has several advantages over the option of using information-bearing keys from the source systems, including better storage use, prevention of problems associated with key reuse, and better support for dimension updates [10].

It can be seen that there will be a redundancy in higher-level data. For example, with 31 day values in May 2001, the year value "2001" will be repeated 30 times for this month alone. However, as dimensions typically take up only 1–5% of the total storage required for a cube, redundancy is not a problem space-wise; and since the updates of dimensions are handled centrally, it is also possible to ensure consistency. Thus, it is often a good idea to use redundant dimension tables because this supports a simpler formulation of (better-performing) queries.

Snowflake schemas contain several dimension tables for each dimension, namely one table for each level. This means that redundancy is avoided, which may be advantageous in some situations. The dimension tables contain a key, a column having textual descriptions of the level values, and possibly columns for level properties. Tables for lower levels also contain a foreign key to the containing level.

Figure 12.4 shows a snowflake schema for the Sales cube. For example, the Day table in Figure 12.3 contains an integer key, a date, and a foreign key to the Month table. Note that no year values are replicated.

The choice of star vs. snowflake schemas depends highly on the desired properties of the system being developed. Due to space constraints, we do not provide a full discussion here.

Achieving Fast Query Response Time

The most essential performance-enhancing technique in multidimensional databases is *precomputation* and its more specialized cousin, *preaggregation*. In ROLAP systems, this is referred to as *materialized views*. This technique enables the delivery of response times to queries involving potentially large amounts of data that are fast enough to allow interactive data analysis.

As an example application of preaggregation, we may compute and store (materialize) the total sales of a product by country and month. This enables fast answers to queries that ask for the total sales, for example, by month alone, by country alone, or by quarter and country in combination. These answers may be derived from the precomputed results alone; access to the bulks of detail data in the data warehouse is unnecessary.

Preaggregation has attracted substantial attention in the research community [17], and recent versions of commercial relational database products, as well as the dedicated multidimensional systems, offer query optimization based on precomputed aggregates, as well as automatic maintenance of the stored aggregates when the detailed data on which the aggregates are based are updated [24].

Full preaggregation, where all combinations of aggregates are materialized, is infeasible as it takes too much storage and initial computation time. Instead, modern OLAP systems adopt the *practical*, or partial, preaggregation approach of materializing only select combinations of aggregates and then reuse these

© 2005 by CRC Press LLC

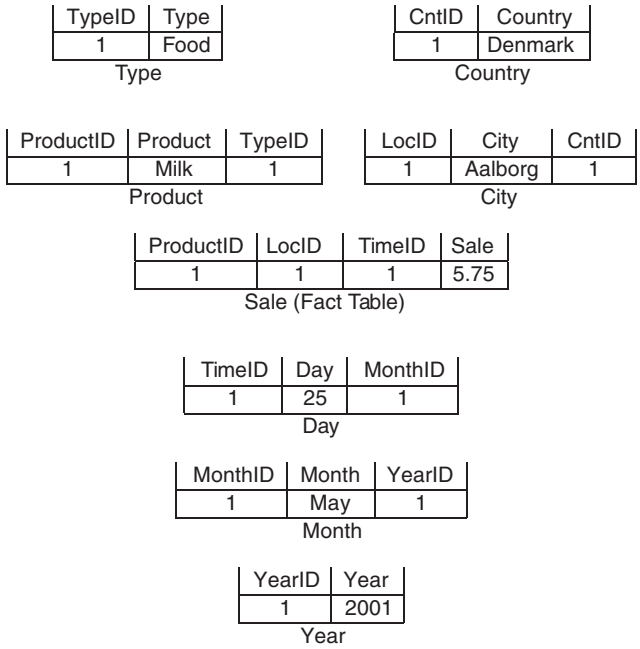

FIGURE 12.4 Snowflake schema for sales cube.

to efficiently compute other aggregates [21, 22]. This reuse of aggregates requires a well-behaved structure of the multidimensional data.

12.10 Complex Multidimensional Data

The traditional multidimensional data models and implementation techniques assume that the data being modeled conform to a quite rigid regime. Specifically, it is typically assumed that all facts map (directly) to dimension values at the lowest levels of the dimensions and only to one value in each dimension. Further, it is assumed that the dimension hierarchies are simply balanced trees. In many cases, this is adequate to support the desired applications satisfactorily. However, situations occur where these assumptions are too rigid for comfort.

In such situations, the support offered by "standard" multidimensional models and systems is inadequate, and more advanced concepts and techniques are called for. A more comprehensive treatment of complex multidimensional data is available in the literature [4]. We proceed to review the impact of irregular hierarchies on practical precomputation.

Complex multidimensional data are problematic as they are not summarizable. Intuitively, data are *summarizable* if the results of higher-level aggregates can be derived from the results of lower-level aggregates. Without summarizability, users will either obtain wrong query results, if they base them on lower-level results, or computation may be prohibitively time consuming because we cannot use precomputed lower-level results to compute higher-level results. When it is no longer possible to precompute, store, and subsequently reuse lower-level results for the computation of higher-level results, aggregates must instead be calculated directly from base data, which is what leads to the increased computational costs.

It has been shown that summarizability requires that aggregate functions be distributive and that the ordering of dimension values be *strict*, *onto*, and *covering* [11, 18]. Informally, a dimension hierarchy is *strict* if no dimension value has more than one (direct) parent, *onto* if the hierarchy is balanced, and *covering* if no containment path skips a level. Intuitively, this means that dimension hierarchies must be balanced trees. If this is not the case, some lower-level values will be either double-counted or not counted when reusing intermediate query results.

© 2005 by CRC Press LLC

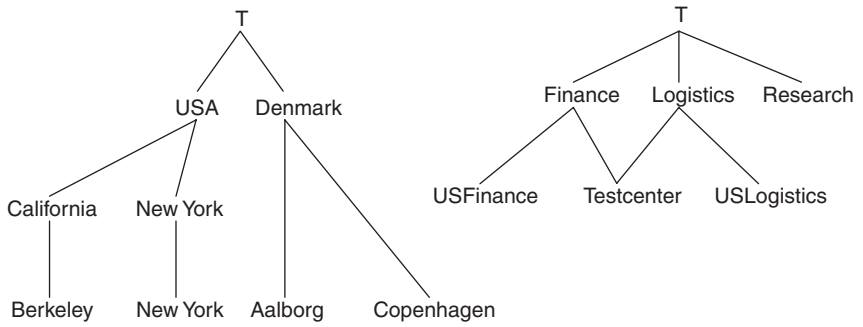

FIGURE 12.5 Irregular dimensions.

Figure 12.5 contains two dimension hierarchies: a Location dimension hierarchy including a State level, and an Organization dimension hierarchy that describes the organization in some company. The hierarchy to the left is *noncovering* because Denmark has no states. If we precompute aggregates at the State level, we will have no values for Aalborg and Copenhagen, meaning that facts mapped to these cities will not be taken into account when computing country aggregates from precomputed State-level aggregates.

The hierarchy to the right in the figure is *nononto* because the Research department has no further subdivision. If we materialize aggregates at the lowest level, facts mapping directly to the Research department will not be counted. The hierarchy is also *nonstrict* because the TestCenter is shared between Finance and Logistics. If we materialize aggregates at the middle level, data for TestCenter will be used twice, for both Finance and Logistics, which is what we want at this level. However, this means that the data will also be used twice if we combine these aggregates into the grand total.

Irregular dimension hierarchies occur in many contexts, including organization hierarchies [26], medical diagnosis hierarchies [14], and concept hierarchies for web portals [25]. A solution to the problems with irregular hierarchies is to *normalize* the hierarchies, a process that pads nononto and noncovering hierarchies with "dummy" dimension values to make them onto and covering, and fuses sets of parents in order to remedy the problems with nonstrict hierarchies. This transformation may be accomplished transparently to the user, rendering preaggregation applicable also to the more generalized types of dimension hierarchies discussed here [17].

12.11 Commercial Systems

As noted in Section 12.2, the development of multidimensional database systems began more than 35 years ago. However, it is only in the last 5–6 years that multidimensional technology has begun to enter the mainstream. Below, we introduce some of the most common commercial systems in the area. We have focused on the offerings from the "big-3" software vendors (IBM, Microsoft, Oracle) as well as the systems having a market share of at least 5% in the 2002 OLAP market, as measured by the acknowledged, independent OLAP market research report "The OLAP Report" [15].

Generally, commercial multidimensional systems fall into two groups: tools that are primarily multidimensional database servers and client-oriented analysis and reporting tools.

The multidimensional database server market is dominated by three products, each of which is backed by one of the "big-3" vendors. The number one server is Microsoft's Analysis Services [12, 22], which comes bundled with the MS SQL Server RDBMS. The number two server is Hyperion Essbase [8], long the market leader. A version of Essbase is sold along with IBM DB2 as DB2 OLAP Services [9]. The number three server is Oracle 9i OLAP R2 [16], which is based on the Oracle RDBMS and the late Express MOLAP server. All three servers offer flexible HOLAP technology, with flexible storage of data using ROLAP and/or MOLAP technology. All three servers generally provide a good query and load performance, as well as advanced query functionality.

© 2005 by CRC Press LLC

The three largest vendors of client-oriented tools are Cognos [3], Business Objects [1], and Microstrategy [13]. They all provide tools for both "real" interactive OLAP analyses as well as more traditional static reporting, including paper-based reports. Another common functionality is support for building web portals that integrate analysis results with other data from the enterprise. They also include embedded server components that are primarily intended as back-ends for the client tools rather than as stand-alone OLAP servers.

The OLAP server vendors also have some client-side offerings for data analysis. Microsoft ships the Data Analyzer OLAP client and an Excel OLAP plug-in for OLAP analysis, and Reporting Services for traditional reports. Hyperion (IBM) has a large suite of client tools and a large market share in customized OLAP applications. Oracle offers both a range of general analysis tools and more specialized systems allowing easy analysis of data from the Oracle Applications ERP system. SAP offers the similar mySAP Business Intelligence and SAP Business Information Warehouse (BIW) products [20], which allow easy DW integration and subsequent analysis of data from the SAP ERP system, as well as from other source systems.

In summary, the most popular server and client tools generally offer sufficient functionality and performance to meet the needs of most customers. The choice of tools should thus be based on criteria such as existing system portfolio, the overall IT strategy, vendor support, and any specialized requirements, to name but a few criteria.

12.12 Summary

The continued advances in key information technology areas as well as the increasing electronic capture of business data have enabled the collection of very large volumes of business data. Advances in software technologies have contributed significantly to the provision of systems with response times that enable interactive analyses of such data.

At the core of these software technologies lies a type of data model that espouses a multidimensional view of data. While this type of model originally evolved from multidimensional matrix algebra, it has in recent years been influenced and enriched by the insights gained in the areas of semantic as well as scientific and statistical data models.

Multidimensional models view data as consisting of business facts, with associated measures, that are characterized by descriptive data values organized in multiple dimensions. Dimension values are organized in containment-type hierarchical structures that enable the computation of aggregate queries at different levels of granularity. This data organization lends itself toward graphical formulation of aggregate queries and graphical display of their results, and it is also conducive to the efficient evaluation of aggregate queries.

A wide variety of commercial systems exist that support multidimensional databases, both on the client and the server side. In recent years, multidimensional database functionality has become available as an integrated part of the leading relational database management systems.

13.1 ISO/OSI Reference Model

The ISO/OSI reference model [ISO7498] was developed by ISO, the International Standard Organization, and completed in 1982. The Open Systems Interconnection (OSI) reference model allows the connection of open systems. This objective is reached by applying a layered approach. The communication system is divided into seven layers (see Figure 13.1) [PET2000]. The lowest three layers are network dependent. They provide support for data communication between and linking of two systems. The upper three layers are application oriented. They allow the end-user application processes

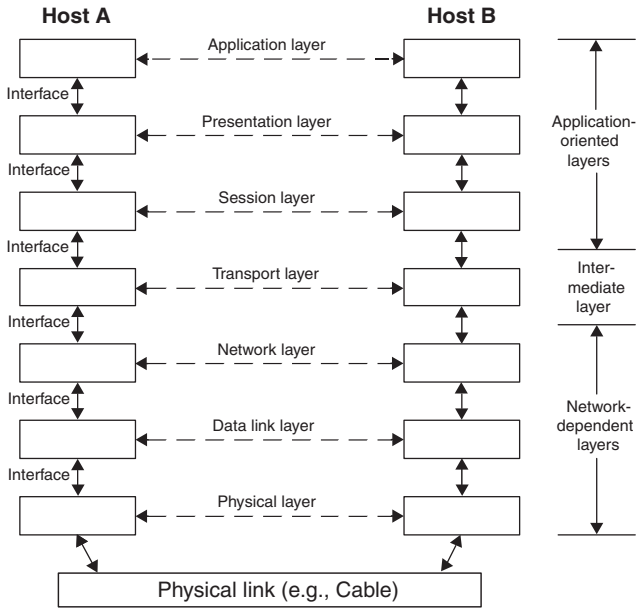

FIGURE 13.1 ISO/OSI reference model.

to interact with each other. The intermediate layer (transport layer) isolates the application-oriented layers from the communication details at the lower layers [HAL1996].

Each layer performs a well-defined function. This allows reducing the level of complexity at each layer and is defined by a protocol. The information flow between the layers is directed through interfaces and should be minimized [TAN1996]. Each layer exchanges messages using services of the layer below. It communicates with the related peer at the same level in a remote system and provides services to the layer above [COL2000]. At each layer, the source host adds a header to the packet, which is read and removed again by the receiver. It is important to note that the implementation of one layer is therefore independent from the implementation of the other layers. In the next section, each of the layers is discussed separately starting from the lowest one.

The Physical Layer

The lowest layer is concerned with the transmission of raw bits from the electrical interface of the user equipment to the communication channel. This can either be an electrical, optical, or wireless medium and transfers a serial stream of data. It has to be assured that a sent 1 bit is seen by the receiver as a 1 bit, and not as a 0 bit. Design issues at this layer are, for example, how long one bit lasts and by which wavelength of light or by which voltage level a 1 and a 0 bit is represented. Additionally, the handling of the initial connection and the closure of the connection are carried out at the physical layer.

Also, mechanical properties of the network equipment such as size and shape of connectors and cables have to be specified. Furthermore, electrical (or optical) parameters must be determined. These are the voltage levels, electrical resistance of the cable, duration of signaling elements, and voltage changes and the coding method. The next issue handled by the physical layer is the functional specification. It concerns the meaning of switched connections distinguishing between data and control wires and specifying the clock rate and ground.

The Data Link Layer

As the physical layer is only concerned with the transmission of raw data, the main function of the data link layer is to recognize and correct transmission errors. For this reason, the sender divides the data stream into frames that are transmitted sequentially. When the frame is received, an acknowledgement

© 2005 by CRC Press LLC

may be sent back to the sender. If a frame is destroyed by a burst in the line and is therefore not acknowledged, it is retransmitted by the sender. As the acknowledgement frame could also be lost, care has to be taken that no duplicate frames are inserted into the data stream. The data link layer therefore solves problems arising from lost, damaged, or duplicate frames.

This layer may also offer different service classes, for example, for protected or unprotected services. If the receiver is slower than the sender, frames can be lost because of different processing speeds. To prevent this scenario, a mechanism is implemented to regulate network traffic. Therefore, the sender should know how much buffer space is left at the receiver.

Another task of the data link layer is media access control within broadcasting networks. In these networks, all connected computers perceive all data transferred; they share a common link. Therefore, it has to be ensured that there is only one sender at a time to avoid data collision. If a collision occurs, it has to be detected and retransmission of all affected data has to be initiated. When data can be transmitted in both directions simultaneously, the acknowledgement frame for the sender *A* sending to receiver *B* competes with data frames that *B* is sending to *A*. A solution for this problem is piggybacking, where the acknowledgement information is added to data packages sent instead of sending additional frames.

The Network Layer

The network layer is responsible for the setup, the handling, and the termination of networkwide connections; it controls the operation of the subnet. There are two possible types of network connections: virtual connections and datagram connections. Virtual connections are set up at the start of a transmission to fix the route for the following data packets; packets are always sent using the same route. Using datagram connection, the route is chosen separately for each package. Sometimes, it has to be assured that packets arrive in the same order that they were sent in. A packet *B* sent after a packet *A* may arrive ahead of *A* using a different route in datagram communication.

Additionally, the network layer is concerned with package routing from source to destination. Routing information can either be stored in a static table or be determined dynamically at the start of each transmission. The chosen route can also depend on the current network load. If too many packets are sent in one subnet, a capacity bottleneck forms. To avoid this situation, the network layer may implement congestion control. To be able to analyze network traffic, an accounting mechanism is incorporated at this layer. This mechanism counts how many packets are sent, also storing information about packet source and destination. The information gathered can be used to produce billing information. Also, there may be problems when a packet is traveling through heterogeneous networks. The network layer handles the issues of different packet sizes, varying addressing schemas or different protocols.

The Transport Layer

This layer is the interface between the higher application-oriented layers and the underlying network-dependent layers. Thus, the session layer can transfer messages independent of the network structure. Seen from layers above, messages can be transferred transparently without having knowledge of the underlying network structure. The transport layer basically cuts messages into smaller packets if needed and passes them to the network layer. At the sender, the messages are assembled again and passed to the session layer.

An important task of the transport layer is the handling of transport connections. Normally, one network connection is created for each transport connection required by the session layer. If the session layer requires an output higher than can be handled by one connection, the network layer might create additional connections. On the other hand, if one wants to save costs, a number of transport connections can be multiplexed onto one network connection. As there is the possibility of setting up multiple connections, a transport header is added to distinguish between them.

The transport layer provides different classes of quality of service (QoS). The lowest service class provides only basic functionality for connection establishment; the highest class allows full error control and flow control. To avoid the situation of a fast sender overrunning a slower receiver with messages, an algorithm

© 2005 by CRC Press LLC

for flow control is provided. The most popular type of connection is an error-free point-to-point connection where messages are delivered in the same order that they were sent in. Additionally, messages with no guaranteed order can be sent. It is also possible to send messages not only to one but also to multiple destinations or to send broadcast messages.

The transport layer establishes and terminates connections across the network. Therefore, the need for a naming mechanism arises, allowing processes to choose with whom they converse.

The Session Layer

Layer 6 organizes and synchronizes the data exchange for two application layer processes. It sets up and clears the communication channel for the whole duration of the network transaction between them, and therefore sets up sessions between users on different machines. A session might be used to log into another machine in a remote timesharing environment or to transfer a file. The session layer provides interaction management (also called dialog control). Data can be exchanged using duplex or half-duplex connections. A duplex connection transfers data both ways simultaneously. A half-duplex connection can transfer either one or the other way, where the session layer decides which party is allowed to use the link.

Another task of the session layer is token management. It is useful when both sides are not allowed to perform the same operation at the same time. To schedule these operations, a token is issued only to one process at each given time, allowing only the process that holds the token to perform the critical task. For large data transmissions, synchronization points can be set periodically. If the network connection fails, the transmission is restarted at the last synchronization point set. Thus, retransmission of the whole data can be avoided. Nonrecoverable exceptions during transmissions are reported to the application layer.

The Presentation Layer

The main task of the presentation layer is the representation of data, for example, integers, floating point numbers, or character strings. Therefore, the syntax for these data containers is defined. As different computer may use varying internal data representations, for example, for characters or numbers, a conversion has to be done. The data sent are converted into an appropriate transfer syntax and are transformed back to the receivers internal data format upon receipt. Those converters for the syntax of data do not necessarily have to understand the semantics. This layer may also provide services for data encryption and data compression.

The Application Layer

It provides services not to other layers but directly to application programs. Thus, there is no specific service in this layer but there is a distinct combination of services offered to each application process. As the connected hosts may use different file systems, the application layer handles the differences and avoids incompatibilities. Therefore, this layer provides the means for networkwide distributed information services. This allows the application processes to transfer files, send emails, or perform directory lookups.

Furthermore, the application layer provides services for the identification of intended communication partners to verify the availability of an intended communication partner, verify communication authority, provide privacy services, authenticate communication partners, select the dialog discipline, reach an agreement on the responsibility for error recovery, and identify the constraints in data syntax [HAL1996].

13.2 The TPC/IP Reference Model

TCP/IP was first used when the ARPANET was emerging. This network was developed for use by the US armed forces. Therefore, it was required that even when some parts of the network are destroyed during a battle, it should still provide communication services. As long as two hosts were still functioning and there was a path available between them, communication must be possible. Another important issue was the ability to connect multiple different networks together irrespective of the underlying protocols, physical transport medium, or provided bandwidth. The TCP/IP reference model is structured in a manner similar to the ISO/OSI model introduced in the last chapter; but it consists of only four layers. A comparison of both

© 2005 by CRC Press LLC

models is done in the next chapter. The lowest layer is the host-to-network layer, where the internet layer is attached. Above the transport layer, the highest layer is the application layer (Figure 13.2) [SCO1991].

The next section gives an overview of the services provided by the TCP/IP model layers, starting with the lowest one.

The Host-to-Network Layer

The TCP/IP protocol does not specify services or operations at the host-to-network layer. It is only required that the host can somehow connect to the network to enable the internet layer to send packets. As this layer is not defined, the implementation can vary in each system. The network service may be provided by an Ethernet, Token Ring, ATM, WAN technologies, wireless technologies, or any other means of transferring network packets.

The Internet Layer

The main features of the internet layer are addressing, packet routing, and error reporting. Additionally, services for fragmentation and reassembly of packets are provided [HAL1996]. The core protocols at the internet layer are the internet protocol (IP) [RFC791], the address resolution protocol (ARP) [RFC826], the internet control message protocol (ICMP) [RFC792], and the internet group management protocol (IGMP) [RFC2376].

The IP is concerned with packet routing, IP addressing, and the fragmentation and reassembly of packets. It is a packet-switching protocol based on a best-effort connectionless architecture. Packets travel independent of each other from source-to-destination host. Each packet may be routed differently through the network, thus packets may be delivered in a different order they were sent. Packets may also be lost, because delivery is not guaranteed. To be able to route packets across the network, each host has to know the location of a gateway or a router. The gateway decides which path a packet has to travel. For this reason, a routing table is maintained at the internet layer. To send packets across networks that only support small packet sizes, the packets are broken down in size at the source host and are assembled again at the destination host.

ARP [RFC826], the address resolution protocol, translates network-layer addresses to link-layer (hardware) addresses. Thus, an IP-address is translated to, for example, an Ethernet address. The Internet Control Message Protocol (ICMP) [RFC792] is concerned with datagram error reporting and is able to provide certain information about the internet layer. The Internet Group Management Protocol (IGMP) [RFC2376] is used to manage IP multicast groups [RFC1122].

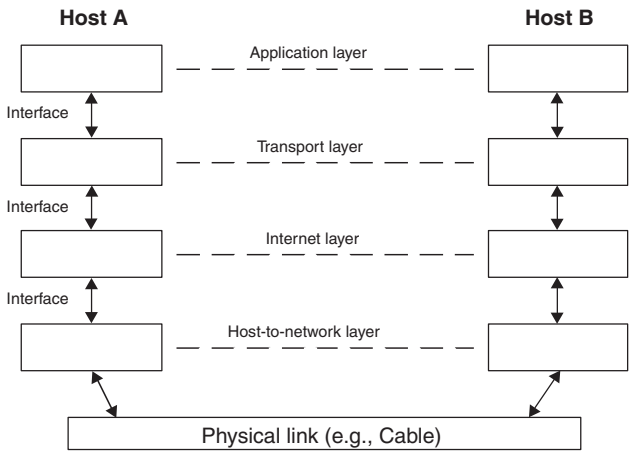

FIGURE 13.2 TCP/IP reference model.

© 2005 by CRC Press LLC

The Transport Layer

The transport layer provides stream and datagram communication services. Protocols specified at this layer are the transmission control protocol (TCP) [RFC793] and the user datagram protocol (UDP) [RFC768]. Both protocols deliver end-to-end communication services (i.e., message transfer).

The transmission control protocol is a connection-oriented and reliable point-to-point communication service [RFC793]. A data stream is sent to any other host in the Internet without errors. This data stream is broken down into messages and handed down to the internet layer. TCP sets up and terminates the connection, and it sequences and acknowledges the packets it sends. It is also responsible for retransmitting packets lost during transmission. Also, a service for flow control is implemented, thus preventing a receiver from being flooded by a faster sender.

The user datagram protocol is a connectionless, unreliable communication protocol [RFC768]. Thus, sequencing or flow control is not provided. It is used when prompt delivery of packets is more important than error-free transmission, as demanded for the transmission of video or audio content. Compared to TCP, there is no connection establishment, no connection state, a smaller packet overhead, and an unregulated send rate [KUR2001].

The Application Layer

This layer provides services to application processes. It accesses services of the transport layer and allows processes at different hosts to communicate with each other using a variety of protocols.

These include the Hypertext Transfer Protocol (HTTP) [RFC2616] to send and receive files that make up Web pages. Also, protocols for sending electronic mail, the Simple Mail Transfer Protocol (SMTP) [RFC821], and interactive file transfer, the File Transfer Protocol (FTP) [RFC959] are implemented at this layer. Another provided and often used service is Telnet, which is a terminal emulation protocol [RFC854]. It enables the user to log on to remote hosts. To access news articles at virtual blackboards, the Network News Transfer Protocol (NNTP) [RFC977] is provided.

Additionally, protocols for the management of TCP/IP networks are available at this layer. The Domain Name Service (DNS) [RFC1034, RFC1035] resolves a host name to an IP address. Network management, including the collection and exchange of management information, is facilitated by the Simple Network Management Protocol (SNMP) [RFC1157].

Besides these basic protocols, a wide variety of other protocols are implemented for use at the TCP/IP application layer. An overview of the assignment of the protocols mentioned in this section to the respective layer is given in Figure 13.3:

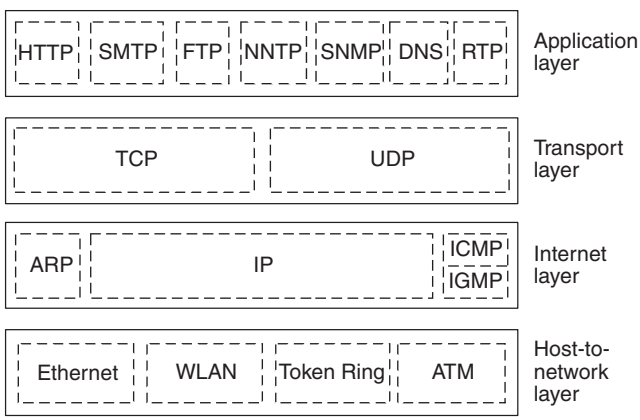

FIGURE 13.3 TCP/IP Protocol Architecture.

© 2005 by CRC Press LLC

13.3 Reference Model Comparison

Both reference models described above are based on a layered approach. Also, the layers provide quite similar services. The application layer of the TCP/IP model corresponds to the application layer of the ISO/OSI reference model. Presentation and session layers are not present in the TCP/IP reference model. Thus, in the TCP/IP model, services provided by these two layers have to be performed by the application process itself. The two transport layers perform similar services. The next layer in the TCP/IP model, the Internet layer, is equivalent to the network layer in ISO/OSI. The data link layer and the physical layer of the OSI reference model are represented by the host-to-network layer in the TCP/IP model (Figure 13.4). In both models, layers above the transport layer are application dependent [TAN1996].

The ISO/OSI model is mainly a conceptual model; it is an example of a universally applicable structured network model. It introduced three main concepts, which were also followed when the TCP/IP reference model was developed. Each layer provides exactly defined *services* to the layer above and uses services of the layer below. These services are accessed using *interfaces* specifying, whose parameters are expected and the results returned. *Protocols* defined in each layer communicate with their peers at the remote host, independent of the underlying network structure. These ideas in both protocols are similar to object-oriented software development [TAN1996].

In the beginning, the TCP/IP model did not strictly separate between services, interfaces, and protocols; these concepts have been introduced later. Thus, protocols in the ISO/OSI model are better encapsulated than in the TCP/IP model. Therefore, it is easier to alter services in the ISO/OSI reference model [TAN1996]. As the ISO/OSI model was developed before the respective protocols and their implementation, it was possible to easily distinguish between services, interfaces, and protocols for each layer. The developers were able to choose the appropriate number of layers, such that each one could perform only a distinct set of matching services. For TCP/IP, the protocols were developed first, and afterwards the abstract model was created. The problem with this approach was that the model did not fit with any existing protocol stacks [TAN1996].

Finally, there are differences in the area of connectionless vs. connection-oriented communication. The ISO/OSI reference model provides services for both kinds of communication at the network layer, but only connection-oriented services at the transport layer. The TCP/IP reference model supports both

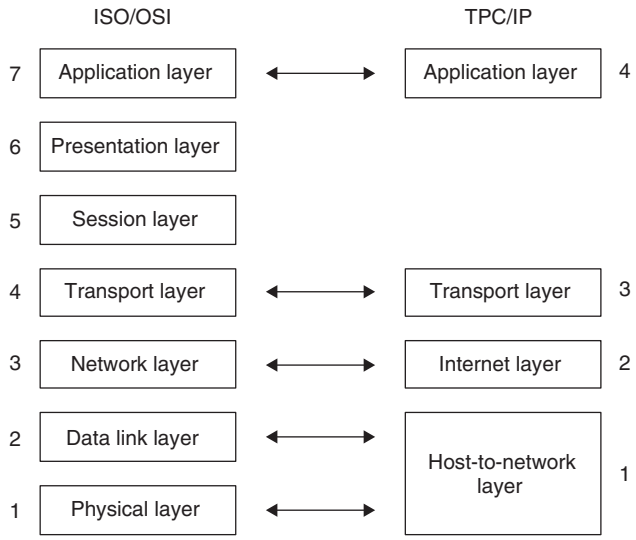

FIGURE 13.4 ISO/OSI vs. TCP/IP.

© 2005 by CRC Press LLC

connectionless and connection-oriented communication at the transport layer, but only connectionless services at the network layer [TAN1996].

In the following, the most important TCP/IP protocols and services, their functionality, and their position in the OSI stack will be described.

13.4 Data Link Layer Protocols and Services

In the OSI model, the *data link layer* is situated at layer 2, and at the host-to-network layer in the TCP/IP reference model. Its purpose is to offer services to OSI layer 3 in such a way that protocols at layer 3 may send data to neighboring computers (i.e., computers directly connected via a network link or via layer 1 or 2 repeaters, bridges, hubs, or switches) in a reliable way. The data link layer may offer one of the following services to layer 3.

- Using an *unacknowledged connectionless* service, no measures are taken to detect lost packets by the sender or the receiver.
- In *acknowledged connectionless* services, the receiver must acknowledge the data it received by sending back an acknowledgment to the sender. If the sender does not receive the acknowledgment after a certain amount of time, it assumes that the data were lost and retransmits them again.
- In *connection-oriented* services, the data link layer must first create a (possibly virtual) path between the sender and receiver before data can be sent. Furthermore, the data link layer adds sequence numbers to the sent data units in order to detect lost or erroneous data units.

The bit-error rate of modern wire-line (electrical or optical) LAN interconnections is too low to justify the additional effort for virtual path creation at this level. In LANs, therefore, usually acknowledged (e.g., Token Ring) or unacknowledged (e.g. Ethernet) connectionless services are used at layer 2. Lost packets or packets delivered out of order can then be often detected at layer 4 or even higher. Wireless networks, however, may severely suffer from lost packets or high bit-error rates. Under these conditions, sophisticated data link layer protocols like IBM's *Synchronous Data Link Control* (SDLC), or the closely related ISO norms *High-Level Data Link Control* (HDLC) and the CCITT recommendation *Link Access Procedure* (LAP), or the IEEE 802.2 norm *Logical Link Control* (LLC) are often used.

Frame Creation

One major task of layer 2 is to pack the data it receives from a higher layer for transfer into so-called *frames*, that is, data packets, which are then modulated onto the physical network medium. This is done in such a way that the desired receivers are able to (i) detect that a frame has been sent, (ii) to decode the frame reliably and retrieve the sender and receiver addresses, and to (iii) identify those frames that are meant for themselves.

Frames are nothing more than a sequence of bits modulated onto a carrier. In order to be able to decode information stored in a frame, a receiver first has to be able to identify the first bit of a frame. This *start bit* is then usually followed by a specific sequence of bits containing frame information like the frame length, the content type, checksums, etc. A simple method for finding the frame start is given by *bit-stuffing*. In protocols like for instance X.25, the start of a frame is signaled by six following 1's. If the data transported in the frame also contain six 1's in a row, then after the fifth 1, a 0 has to be inserted by the data link layer. The receiving data link layer then knows that if it receives five consecutive 1s followed by a 0, the sender must have inserted the 0 and therefore removes it.

Another method for synchronizing senders and receivers at the bit-level is given by sending *sync-bytes*, as, for instance, is done in *Digital Video Broadcast* (DVB) [REI2001]. Here, data frames are 204 bytes long and contain a certain value (0×47) always at the same position (*sync-byte*). The task of a *sync-byte detector* is to detect the regular occurrence of this value every 204 bytes. If this value is detected five times, then the sender and receiver are synchronized and the receiver may easily compute the frame start from it. Other methods include, for instance, *octet counting* or *octet stuffing* and will be described in the context of application protocols.

© 2005 by CRC Press LLC

Error Detection and Correction

Sending data over certain media types is often unreliable and may be severely disturbed by external disruptions causing data to be lost or wrongly received. Thus, another important task of the data link layer is to either correct corrupted frames, or at least to detect the occurrence of bit errors. In order to detect or correct bit errors, the sender must add checksum information additional to the transported headers and user data. The more information is added, the more wrong bits may be detected or even corrected.

A popular method for error detection and correction is given by *Hamming codes*. Here, certain code words are sent, which are different at a specific number of bits, the so-called *Hamming distance*. For instance, a code containing the words 000111, 111000, 000000, and 111111 has the Hamming distance 3, that is, code words differ at at least 3 bits from each other. In order to identify that d bits have been changed during transmission, a Hamming distance of $d+1$ is required. If the receiver has to be able to correct d bits, then a Hamming distance of $2d+1$ must be retained. The code above is thus able to detect 2 wrong bits and correct 1 wrong bit. A simpler way for detecting wrong bits is given by the so-called *parity bit*. Here, only one bit is added to each code word counting the number of 1's in the word. If this number is even, the parity bit is set to 0; otherwise it is set to 1 (or vice versa). Codes with parity bits may detect 1 wrong bit per code word only.

A more sophisticated error detection code is given by the *Cyclic Redundancy Check* (CRC) code. Here, each sequence of bits is treated as a polynomial over the field of binary numbers (modulo 2). The number 101, for instance, is treated as the polynomial x^2+1. Modulo 2 means that each addition of single bits is treated as an exclusive-or (XOR) operation, that is, $0+0=0$, $0+1=1+0=1$, and $1+1=0$. For CRC codes, a fixed polynomial is chosen, called *generator polynomial* $G(x)$. If a code word $W(x)$ is to be sent, it is replaced by another polynomial $R(x)$, which can be divided by $G(x)$ with rest 0, and from which the original code word $W(x)$ can be reconstructed. The polynomial $R(x)$ is then transmitted and received. If the received $R(x)$ can be divided by $G(x)$ without rest, then the transmission has been error-free with high probability. Otherwise, bit errors are detected and the transmitted code word is dropped.

Other error correction techniques include *Reed-Solomon codes* and *Convolutional codes*, but will not be treated here.

Media Access Control

An important part of the data link layer is given by the *media access control* (MAC) sublayer. At this sublayer, access to the physical medium is controlled, which may be shared by several senders concurrently. Depending on the media type, one or several senders may transmit data at the same time. In case of conflicts, several techniques exist in order to grant the right to use the medium.

ALOHA: The *ALOHA* technique, developed at the University of Hawaii, allows all senders to send their data to a commonly shared *broadcast medium* whenever they wish to. In a broadcast medium, the data sent by one host are received by all others listening to the same medium. In case of collisions due to the concurrent sending of two or more senders, the colliding frames are discarded and must be sent anew.

CSMA/CD: For *Carrier Sense Multiple Access/Collision Detection* (CSMA/CD), as, for example, implemented in Ethernet, several network cards share the same broadcast medium, for example, an electrical wire. Each network card listens to the medium (carrier sense); if no signal is detected, then a new sender may use the medium immediately. Due to the limited speed of signals, two or more senders may send simultaneously without noticing each other in time, resulting in collisions. At such an instance, all colliding frames are discarded and each sender waits for a random amount of time until it tries to send again.

TDMA: In *Time Division Multiple Access* (TDMA), time is divided into *time slices*, and each sender is granted one slice where it may send its data into the medium. Here, bandwidth may be wasted, as senders own their time slice whether they have something to send or not.

FDMA: In *Frequency Division Multiple Access* (FDMA), several sending frequencies exist and for each frequency one sender may transmit without fearing interference from other frequencies. For example, GSM uses a mixture of TDMA and FDMA for its calls. Additionally, GSM terminals change their frequency according to a fixed scheme (*frequency hopping*).

© 2005 by CRC Press LLC

CDMA: The concept of *Code Division Multiple Access* (CDMA) is fundamentally different from the previous concepts. Here, each sender is assigned a unique bit sequence of length N bits called *chip*. Each sent bit is then added (modulo 2) to the chip bits, yielding the chip if a 0 is to be sent, or the inverse chip, if a 1 is to be sent. If a terminal wants to transmit R bits per second (bps), then R chips have to be transferred per second, making necessary a much higher bandwidth of $R \times N$ bps in total. Thus, the necessary frequency band is broadened significantly. In essence, the signal is spread over a broad spectrum; thus, the chip is also often called *spreading sequence*. In CDMA, senders with different chips can send concurrently and do not disturb the reception of other signals. This works because different chips are mathematically *orthogonal* to each other with respect to the inner product of chips (which can also be interpreted as bit vectors) and their inverse. Also, due to the use of a broader spectrum, the reconstruction of the signal is more robust with respect to other noise sources.

13.5 Network-Layer Protocols and Services

IPv4

The term *Internet Protocol* (IP) usually denotes IP version 4 (IPv4), which has been specified in [RFC791, RFC1122] and is the established standard protocol for the Internet at layer 3 of the ISO/OSI reference model, in the TCP/IP reference model at the Internet layer. The task of IP is to transport a packet from one source computer to a destination computer, where both computers are interconnected by an Internet. Here, *internet* denotes any (possibly privately managed) heterogeneous network that is interconnected using IP and IP-based routers. In contrast, *the Internet* denotes the well-known worldwide IP-based network interconnecting millions of computers and being managed by *network information centers* (NICs) and *Internet service providers* (ISPs). When traveling through an internet, a packet may pass by several intermediary networks with different network technologies, for instance, Ethernet, Token Ring, ATM, etc., used at layers 1 and 2. At the border between two different networks, the packet's destination network address is examined by a *router*, that is, a computer that is connected to both networks, and that is able to select other routers in the path between sender and receiver, or to find the receiver in its own network. Routing decisions are usually done using predefined and regularly updated *routing tables*. However, the next chosen router is by no means fixed and may depend on runtime situations like congestion or link failures, or it may simply be chosen at random. As a consequence, packets may travel through different paths from the sender to the receiver, and neither the delivery itself nor the delivery in the original order can be guaranteed.

IP packets are called *datagrams*, which may have a total length of 65,535 bytes. Datagrams may be cut into a sequence of smaller datagrams, if the datagram size is larger than the network's *maximum transfer unit* (MTU), that is, the largest OSI layer 2 frame that may be transmitted by the network. For Ethernet, for instance, the MTU is 1500 bytes. This process is called *fragmentation*, and the IP header reflects several fields for reassembling such fragments into the original datagram again.

Each datagram or fragment is led by a 20 bytes header containing the following information:

- The *Version* number of the IP protocol (4).
- The *IP Header Length* (*IHL*), which may be larger than 20.
- The *Total Length* of the datagram including header.
- An *Identification* number for reassembling fragmented datagrams. All fragments with the same ID belong to the same datagram.
- Flags, including the *Don't Fragment* (DF) flag, flagging that the datagram should not be fragmented, and the *More Fragments* (MF) flag, signaling that more fragments are still to come.
- A *Fragment Offset* identifying the offset of the received fragment in the whole datagram.
- The *Time to Live* (TTL) counter, which is decreased by one by each router. A datagram with TTL equal zero is discarded. This prevents faulty datagrams from circling through the Internet forever.
- A number identifying the used transport *Protocol* (6 for TCP, 17 for UDP, …).

© 2005 by CRC Press LLC

- A header *Checksum*.
- The IP *Source* and *Destination Addresses.*

An important aspect of IPv4 is given by the 32-bit-long IP addresses. The written form follows the *dotted decimal notation* scheme $X_1.X_2.X_3.X_4$, where the X_i are decimals between 0 and 255.

Each address starts with an address class identifier, and is then followed by the network address, and finally by the host address. There are different network classes as shown in Table 13.1.

Each network card attached to the Internet must have a unique IP address. The address assignment scheme is a two-step strategy. First, each site managing a network connected to the Internet is assigned a unique network address by a central authority called *Network Information Center* (NIC). Then, each site may assign the unique host addresses belonging to this network address, which may include $2-2=16{,}177{,}214$ addresses (class A), $2^{16}-2=65{,}534$ (class B), or $2^8-2=254$ (class C) unique host addresses.

IP defines a set of *private addresses* that may be used freely, but whose traffic should not be routed over the Internet without modification [RFC1918]. The three address blocks are:

- 10.0.0.0 − 10.255.255.255 (one class A network).
- 172.16.0.0 − 172.31.255.255 (16 contiguous class B networks).
- 192.168.0.0 − 192.168.255.255 (256 contiguous class C networks).

Multicast addresses are special addresses reserved for groups of hosts receiving the same multimedia program via multicast from a single source [RFC1112]. Multicast addresses may range from 224.0.0.0 to 239.255.255.255.

Two host addresses are reserved in each (sub)network. The host address 0 denotes the network itself; the highest possible host address denotes a broadcast address that is received by all hosts of a given network.

IPv6

The *Internet Protocol version 6* (IPv6) has been designed for replacing the old IPv4 in the next-generation Internet [RFC1883, RFC1887]. It represents a totally new approach and is incompatible with version 4. As most Internet hosts and routers still only support IPv4, IP packets following IPv6 often cannot be transported from the sender to the receiver without further modification. Usually, when leaving the IPv6 subnetwork of the sender, IPv6 packets are tunneled over IPv4, that is, are transported in IPv4 packets, where the whole IPv6 packet is treated as pure IPv4 data.

The header has been simplified and contains only seven fixed fields (the IPv4 header includes 13):

- A *Version* field containing the value 6.
- A *Priority* field distinguishing between data and real-time traffic.
- A *Flow Label* for supporting pseudo end-to-end connections with guaranteed QoS.
- The *Payload Length* specifies the size of the data contained in the packet.
- The *Next Header* points at the next optional header or an ID for the used transport protocol (TCP or UDP).
- The *Hop Limit* is decreased by each passed by router; a packet with zero Hop Limit is discarded. This prevents faulty packets from circling through the network forever.
- Finally, the 16 byte *Source* and *Destination Addresses* are contained.

TABLE 13.1 IP Network Classes

Class	Most significant bits	Network address	Host address
A	0	7 bits	24 bits
B	10	14 bits	16 bits
C	110	21 bits	8 bits
D	1110	28 bits	0 bits
E	11110	Reserved	Reserved

© 2005 by CRC Press LLC

IPv6 offers the following enhancements with respect to IPv4:

- Addresses are 16 bytes long, written in groups of four hexadecimal digits separated by colons (e.g., 8000:0000:1111:2222:3333:4444:ABCD:EFFF). This solves the shortage of IPv4 addresses caused by the exponential growth of the Internet. Even when wasting a lot of such addresses due to the inefficient use of network addresses, thousands of IP addresses could be assigned to each square meter of the earth's surface.
- New address classes exist, including addresses for Internet service providers and geographical regions.
- Due to the simpler header, routing is made more efficient. Additionally, IPv6 supports an arbitrary list of options that may be skipped by routers that do not support them.
- IPv6 supports authentication and encryption.
- IPv6 supports QoS for real-time applications.

Even though IPv6 offers substantial advantages, its implementation is costly and requires to buy new routers and to reconfigure existing hosts. For these reasons, IPv4 still is the Internet protocol today, and IPv6 will not dominate the Internet until the year 2010 or even later.

Address Resolution Protocol

The ARP defined in [RFC826] and its complement, the *Reverse Address Resolution Protocol* (RARP) defined in [RFC903], are a means for connecting OSI layer 2 addresses (MAC addresses) to their corresponding layer 3 IP addresses.

Basically, computers communicate with each other by sending messages on the data link layer (and subsequently the physical layer), for instance, by sending an Ethernet frame over an Ethernet variant. On this level, all network cards are identified by a globally unique 48-bit identifier. In order to successfully send an Ethernet frame, each sending network card must put both its own Ethernet address and the Ethernet address of the receiving card into the Ethernet frame. If too many computers are connected by a single layer 2 network (possibly via hubs, bridges, or switches), senders often know only the IP address of a receiver. However, for Ethernet cards, IP addresses are meaningless. In such situations, ARP can be used to find out the Ethernet address of a network card, which is bound to a given IP address at a higher layer.

If a computer *A* wants to find out the Ethernet address of a network card on computer *B*, which according to its IP address belongs to the same layer 2 subnet, then on computer *A*, ARP is automatically activated. At first, computer *A* looks into a small ARP cache to find out if the desired binding is already stored there. If not, computer *A* generates an ARP request message (*who is B.B.B.B tell A.A.A.A*, where B.B.B.B is the IP address of computer *B* and A.A.A.A the IP address of computer *A*), which is no more than a special Ethernet frame containing the following information:

- Ethernet protocol type is set to 0x806.
- Sender Ethernet address.
- Sender IP address.
- Receiver Ethernet address is set to the Ethernet broadcast address FF:FF:FF:FF:FF:FF.
- Receiver IP address.

As the receiver in this Ethernet frame is the broadcast address, all network cards connected to the same subnet will receive this request, including computer *B*. Upon receiving the ARP request message, computer *B* will then activate its own ARP protocol, which will immediately send an ARP response message (*B.B.B.B is HH:HH:HH:HH:HH:HH*, where B.B.B.B is the IP address and HH:HH:HH:HH:HH:HH is the Ethernet address of the network card of computer *B*).

Once the ARP response message has been received by computer *A*, computer *A* will store this IP-Ethernet address binding for computer *B* in its ARP cache and may start sending Ethernet frames to computer *B*. In order to avoid outdated ARP caches, these caches are periodically emptied.

The purpose of RARP is to let computers find out their IP addresses upon startup, in case they only know their Ethernet address. This can be the case, for example, for diskless workstations, which

© 2005 by CRC Press LLC

automatically attach to a server, or for workstations with identical disk images (which do not require a manual setup). RARP works similar to ARP, except that the protocol type value is set to 0x8035. Also, a router is required, which contains a table with the Ethernet-IP bindings. Alternatives to RARP are given by the Bootstrap Protocol (BOOTP) or the Dynamic Host Configuration Protocol (DHCP), which allow to resolve IP addresses in a more flexible way.

Internet Control Message Protocol

The *Internet Control Message Protocol* (ICMP), defined in [RFC792, RFC1122], is used for automatically sending control signals and commands between computers attached to an IP network. Also, ICMP messages can be used for testing connections and measuring interconnection performance. ICMP messages are sent as special IP packets and thus can be handled by routers. As a consequence, ICMP messages can be sent to or received from arbitrary computer connected with each other over an IP network. An ICMP message contains the following data:

- The *Type* defines the purpose of the ICMP packet. There are over thirty different ICMP types.
- The *Code* further defines the packet's purpose.
- A header *Checksum*.
- The rest of the packet may then contain further data depending on the ICMP type.

The most important ICMP packet types are as follows:

- *Echo Request*: When receiving such an ICMP packet, the receiver should answer with an ICMP Echo Reply packet.
- *Echo Reply*: Answer to an ICMP Echo Request packet.
- *Timestamp Request*: The same as Echo Request, except that the receiver answers with a Timestamp Reply packet, which holds additional timestamps.
- *Timestamp Reply*: The answer to an ICMP Timestamp Request, which holds the time points at which the Timestamp Request was received and the Timestamp Reply was sent back.
- *Destination Unreachable*: This message is returned by a router to the source host to inform that the destination of a previously sent packet cannot be reached.
- *Time Exceeded*: Sent from a router to a source host to inform that the lifetime of a previously sent packet has reached zero.
- *Parameter Problem*: Sent to a source host to inform that a previously sent packet contains invalid header data.
- *Source Quench*: Sent to a source host to inform it that due to insufficient bandwidth it should lower its sending bitrate.

13.6 Transport-Layer Protocols and Services

Transmission Control Protocol

The *Transmission Control Protocol* (TCP) operates at OSI layer 4 (in the TCP/IP reference model at the transport layer) on top of IP and is assigned the IP protocol number 6. It constitutes the most important Internet protocol and is defined in [RFC793, RFC1122, RFC1323]. The purpose of TCP is twofold:

- To guarantee the correct delivery of packets sent over an intrinsically unreliable packet-oriented internet and
- To control the output bitrate of each sender in order to minimize packet losses due to congested routers or receivers.

TCP operates connection oriented in full duplex. Applications using TCP may assume that a TCP connection opened from a source host to a receiver host is like a reliable pipeline or byte stream. Data (arbitrary bytes) placed in this pipeline are guaranteed to reach the receiver without losses and in correct order (Figure 13.5).

© 2005 by CRC Press LLC

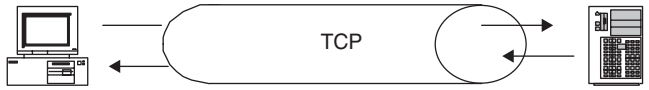

FIGURE 13.5 Full duplex TCP connection.

In order to guarantee this correctness, TCP divides the data to send into so-called segments, which are themselves sent in IP packets. In principle, IP packets may contain up to 65,535 bytes. However, in order to avoid fragmentation, the size of TCP segments is more importantly limited by the network's MTU. Each segment starts with a TCP header, which is at least 20 bytes long, but may hold additional options. The rest of the segment may hold user data, but may also be empty. The TCP header contains the following information:

- *Source Port* and *Destination Port.*
- A *Sequence Number* identifying each sent byte. This is wrapped back to zero, in case the highest number has been used.
- An *Acknowledgement Number* denoting the number of the next expected byte. This field only contains valid data if the ACK bit is set.
- The *Data Offset* holding the size of the TCP header.
- *Explicit congestion notification* (*ECN*) and control bits, including *URG*, *ACK*, *PSH*, *RST*, SYN, and *FIN*.
- Sender receives *Window* size.
- A header *Checksum*.
- An optional pointer to urgent data (URG flag set) and optional TCP headers.

In order to create a TCP connection between two applications X and Y running on computers A and B, both applications first must get a *port number*, an identifier between 0 and 65,535, which can be assigned only once on each computer. The application X initiating the connection must then provide its own port number, the IP address of computer B, and the port number of the partner application Y to TCP. TCP then sends a segment to the given IP address and port number, where the SYN flag is set to 1 and ACK is set to 0, and a random sequence number x is chosen. If application Y correctly waits at the given port, the TCP protocol on computer B answers with a segment, where the SYN and ACK bits are set, the sequence number of side B is set to a random number y, and the acknowledgement number is set to $x+1$. Upon receiving this second segment, the TCP on computer A again sends a segment, where the SYN and ACK flags are set, the sequence number is set to $x+1$, and the acknowledgement number is set to $y+1$. As three segments must be sent for establishing a TCP connection, this process is called *three-way handshake* (see Figure 13.6).

After the establishment of the connection, each side may send arbitrary bytes to the other side. If one side wants to terminate the connection, a segment with set FIN flag must be sent. Otherwise, if, for instance, application X sends data to Y, then the data are placed in one or more TCP segments, which are then sent via IP to computer B. Due to the sequence numbers of each segment, the TCP layer at B is able to realize missing segments or out-of-order delivery of segments. For each correctly received segment, B must send an acknowledgement segment back to A, where the acknowledgement number identifies the number of the next expected byte. The TCP on computer A, on the other hand, starts a so-called *retransmission timer* for each sent segment. If no acknowledgement is received within a certain amount of time, computer A assumes that the segment is lost and has to be sent again.

TCP also maintains two so-called *sliding windows* in order to control the transmission bitrate of each sender (*flow control*). One window simply tells each sender how many bytes the receiver may currently receive without risking a buffer overflow. This information is transmitted in each ACK segment in the receive window size field. The second window is called *congestion window* (CWND). Here, each sender additionally restricts the number of bytes it may send without acknowledgement to the congestion window size. Initially, the window size is set to 1 packet (i.e., the maximum allowed segment size), a strategy that is called *slow start*. For each acknowledged byte, TCP increases the size of its congestion window, at first with exponential speed, but after reaching a certain threshold h, only with linear speed. If a timeout of the retransmission timer

© 2005 by CRC Press LLC

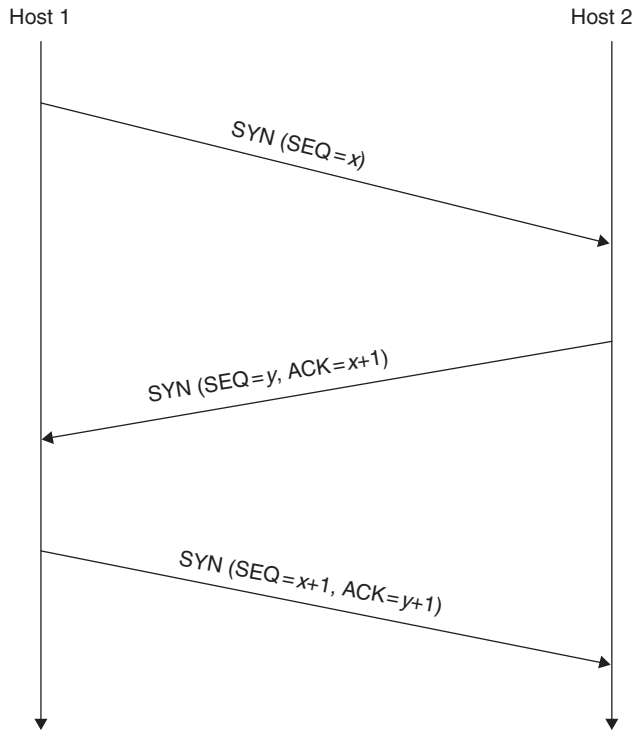

FIGURE 13.6 TCP three-way handshake.

occurs, *h* is set to *h/2* and the congestion window is reset to 1 packet. Instead of waiting for the retransmission timer to time out, a strategy called *fast retransmit* enables receivers to send duplicate ACKs to the sender, in case out-of-order segments are received. A sender receiving more than two or three of such duplicate ACKs may deduce that an intermediate segment has been lost rather than that the segments have been just remixed on the way, and may retransmit the missing segment earlier [RFC1122].

User Datagram Protocol

The UDP is the second important IP protocol at OSI layer 4 (in the TCP/IP reference model at the transport layer) [RFC768, RFC1122] and is assigned the IP protocol number 17. It is meant for transporting application data in a message-oriented, unreliable manner from one application to another. As most functionality is already provided by IP, the UDP header only contains the port numbers of the source and receiver applications, the length of the UDP packet, and a checksum.

As UDP does not provide any functionality for detecting lost packets or out-of-order delivery, it is mostly used either in local networks with large bandwidths and reliable layer 2 transport, or for transporting multimedia data like live broadcasts, where a few lost packets will not seriously decrease the perceived quality of the presentation.

In any case, detection of lost packets or out-of-order delivery must be carried out by the receiving applications, usually by including sequence numbers in the UDP application data. The interpretation of these numbers is left solely to the applications.

Resource Reservation Protocol

IPv4 does not contain mechanisms for guaranteeing a minimum quality of service for its traffic, for instance, a minimum sustainable end-to-end bitrate, or a maximum end-to-end delay or jitter (delay

© 2005 by CRC Press LLC

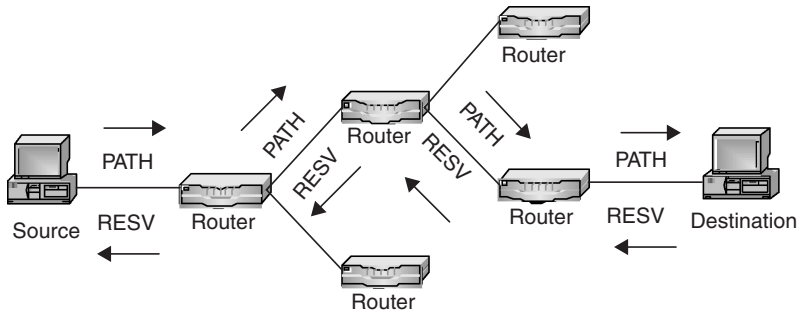

FIGURE 13.7 RESV and PATH messages in a multicast tree.

variation). This may severely affect the presentation quality of real-time transmissions, using, for example, RTP (see application-layer protocols). The *Resource Reservation Protocol* (RSVP) tries to fill this gap by providing means for guaranteeing certain quality of service parameters [RFC2205, RFC2750]. It is an optional add-on for Internet routers and clients using IP (IPv4 and IPv6), and is currently available on a small subset of Internet hosts only. Being at the same level as TCP or UDP, it has its own IP protocol number (47). RSVP is no routing protocol itself but rather a signaling protocol. It cooperates with other routing protocols for controlling efficient unicast and multicast over IP.

RSVP allows two different QoS modes. In the *controlled load service*, RSVP simulates a lightly loaded network for its clients, although the network itself may be overloaded [RFC2211]. Although no hard QoS parameters are met, a lightly loaded network is likely to be sufficient for many load tolerant and adaptive applications like A/V streaming. In contrast, the *guaranteed service* guarantees that the RSVP path will meet the agreed QoS service level at all times [RFC2212].

A client application wishing to receive a multicast multimedia stream passes this request to its local RSVP daemon. This daemon then sends a reservation (*RESV*) request to adjacent RSVP routers toward the multimedia source along the reverse multicast tree path. The RESV request contains a description of the desired quality of service in a so-called *flow descriptor*. Coming from the other side, the multicast source periodically sends *PATH* messages down the multicast tree. PATH messages create and acknowledge valid and active multicasting paths (FIGURE 13.7). Also, they carry information about the quality of service of the path from source to receiver. RSVP routers may merge different QoS requests into one single reservation, here choosing the maximum of each request as the pre-reserved QoS level.

During run time, reservations may be changed to other QoS levels. Also, RSVP paths must be acknowledged periodically by PATH and RESV messages; but RSVP is fault tolerant with respect to a few missing messages. Only if none have been received for a certain time, the whole path is cancelled.

On each RSVP router, an RSVP daemon manages and controls the IP routing process. It consists of the following modules: an incoming QoS reservation request is approved or denied by the *admission control*, depending on whether the QoS request can be satisfied or not. The rights for making reservations are checked in the *policy control* module. Incoming data packets are sorted by the *packet classifier*, which puts them into different queues. Finally, the *packet scheduler* is responsible for granting the agreed QoS to the packets in the routing queues, packets belonging to the same queue are treated identically.

13.7 Presentation-Layer Protocols and Services

Applications may send arbitrary data to others, often embedding complex data structures into their messages. In this process, the data structures have to be transformed (flattened, marshaled) into a sequence of bytes, containing the data itself as well as information about the used data representation. The receiver must be able to understand the structure of the byte sequence and how to interpret the single bytes in order to reconstruct the sent data structures. This is achieved by the *presentation layer* (layer 6 of the ISO/OSI model).

© 2005 by CRC Press LLC

The presentation layer assures that two computer systems may successfully communicate even if they use different data representations. Due to different data representation schemes, the presentation layer is often forced to translate sent or received messages. This, however, should be done in a manner being totally transparent to the OSI application layer above.

Problems may arise, for instance, because of the CPU byte order. In modern 32-bit architectures, CPUs store values and addresses using 32 bits, stored in four consecutive bytes. In Intel processors, for example, the least significant byte is stored first, the most significant byte last. This is called *little endian*. On the other hand, for example, Motorola processors store a 4-byte value in the reverse order, called *big endian*. If an Intel-based computer sends a 32-bit value to a Motorola based computer, without further corrective measures, the receiver totally misinterprets the received value. This may be prevented, for instance, by forcing the sender to convert the data to the receiver's format before sending, or alternatively forcing the receiver to convert the data from the sender's format after receiving. A third approach is to agree to a commonly used format, and to convert to this format before sending or from this format after receiving. TCP/IP, for instance, defines a common *network byte order*. Using, for example, the C programming language, 32-bit values may be converted to and from this format by the macros `hton()` and `ntoh()`. Another system using an external data format is given by the *External Data Representation* (XDR) [RFC1832].

Another problem arising in different computers is the code interpretation. For instance, characters may be stored using one of the following codes: ASCII (common in Intel compatibles, 8 bits/character), EBCDIC (used on IBM mainframes, 8 bits/character), or UNICODE (16 or 20 bits/character). Here, the presentation layer is responsible for automatically translating between the various code schemes.

At the next higher decoding level, received complex data structures should be reconstructed (unmarshalled) from their flattened byte sequence representation. For inhomogeneous data, the data structures must be described by metadata, for instance, defining the data types belonging to each structure, being followed by the data values themselves. This, for instance, can be achieved by using the standardized *Abstract Syntax Notation 1* (ASN.1) [X680].

Other tasks of the presentation layer include the encryption of messages and supporting authentication. Finally, the presentation layer may also be responsible for the compression of data.

13.8 Application-Layer Protocols and Services

In both the ISO/OSI scheme, and the TCP/IP reference model, the *application layer* defines protocols directly to be used by applications for exchanging data with each other. These include, for instance, authentication, distributed databases and files systems, file transport, data syntax restrictions, coordination and agreement procedures, quality-of-service issues, e-mail, or terminal emulation.

Many standard protocols are already specified by the IETF. They define standard data structures that are to be exchanged between applications. Applications following these protocols are guaranteed to be able to successfully interact with other applications over the Internet, even if these applications have been created by different sources. For instance, Web browsers following the HTTP protocol may download Web pages from any Web server connected to the Internet.

The IETF-specified protocols usually use TCP for reliable transport and UDP for the transport of real-time multimedia data (although real-time multimedia data may also be sent over TCP). Usually, both control commands and pure data can be transmitted over the same TCP connection. For signaling the end of a data transmission, one of three approaches is used. In *octet stuffing*, the end of a data transmission is signaled by a certain byte sequence (similar to the bit stuffing used at the data link layer). If the transported data also contain this very sequence, the sequence is changed (escaped) to another sequence. The receiver must detect such a change and undo it. An example for octet stuffing is SMTP. In *octet counting*, transported messages contain special headers that specify the number of data bytes to be transferred. This concept is used, for instance, in HTTP. Finally, in *connection blasting*, the end of a transmission is signaled by closing the TCP connection. This is used, for instance, in FTP.

© 2005 by CRC Press LLC

TELNET

The *TELNET* protocol is meant for providing a general 8-bit interface for the communication between users, hosts, and processes [RFC854]. Generally, a TELNET client running on computer *A* opens a TCP connection to port 23 of a TELNET server on computer *B*. Both sides then emulate a certain simple type of terminal called *network virtual terminal* (NVT), but may negotiate additional services after the connection has been established. An NVT is a bi-directional character device, consisting of a printer that shows the information received from the other side, and a keyboard where keystrokes are produced and sent to the other side.

TELNET defines a set of commands that may be sent in-band with the stream of data. The mechanism used here is the octet stuffing. The byte 255 is called *interpret as command* (IAC) and signals that the following byte specifies a TELNET command, for example, for sending an interrupt to the running process, or for erasing the last character. If a data byte with value 255 is to be sent, then two bytes with value 255 are sent. On receiving two consecutive bytes with value 255, the receiver side must remove one of them automatically.

File Transfer Protocol

The *File Transfer Protocol* (FTP) is used for transporting arbitrary binary data from one Internet host to another [RFC959]. On a computer *A*, an FTP client is started with the IP or DNS address of the Internet computer *B* with which communication is desired. The FTP client then opens a TCP connection to port 21 of computer *B*, representing the *control connection*. The control connection uses the TELNET protocol underneath, and users may send *control commands* to the FTP server on computer *B*, including the request for showing the contents of the current directory at computer *B* (LIST) as well as changing this current directory to another one (CWD), creating new directories (MKD), etc. Additionally, the user may start uploads (STOR) or downloads (RETR) of files to and from the current directory. Upon receiving a control command over the control connection, the server will answer with a reply, sending status or error information to the client. One has to distinguish between the FTP control command that is actually sent over the control channel and commands that are typed in by users into a command line application, which may be different.

Once data are to be sent, a TCP *data connection* is opened by the server on computer *B* from port 20 to the user client on computer *A* listening on port 21. Then, depending on the specified direction, the data are sent either from *A* to *B* or *vice versa*. After transmitting the last byte, the sender must close the data connection, indicating to the other side that the transmission has ended.

It is worth noting that FTP knows different transmission modes. In the *binary* mode, the data are sent without modification. In the *ascii* mode, the FTP protocol automatically changes different character representation codes, for instance, when sending a pure text file from an IBM mainframe (using EBCDIC) to a PC (using ASCII), or when exchanging data between different operating systems like Microsoft Windows and Unix or Unix-like operating systems (having different end-of-line representations in text files).

Hypertext Transfer Protocol

The HTTP is available as version 1.0 [RFC1945] and version 1.1 [RFC2616]. Its purpose is to manage the download of documents being part of the World Wide Web (WWW), usually following the *Hypertext Markup Language* (HTML) [RFC1866].

Most Web browsers and servers nowadays understand HTTP/1.0, although [RFC1945] is not a standard but rather an informational guideline. Newer Web clients and servers also support the standardized HTTP/1.1.

HTTP is a client/server-based protocol following the octet counting approach. A client wishing to download a specific document from a Web server opens a TCP connection to the server port 80 (sometimes 8080). The client then sends a request, containing a request line, various headers, an empty line, and an optional body. The request line specifies what the client wants the server to do. For example, a request line "GET /dir1/dir2/the_document.html HTTP/1.1" informs the server that the client wants to download the document the_document.html, which is situated in the directory /dir1/dir2 by using HTTP/1.1.

© 2005 by CRC Press LLC

Clients may also send data to the server, for example, a form that has been filled out by a user. This can be done, for instance, using the "PUT" command.

The server then answers by sending a status line containing a code for success or an error description, various headers describing the downloaded document, for instance, its size or the time stamp of its last change, followed by an empty line. Finally, in the message body, the HTML document itself is transported to the client.

HTTP/1.1 masters several limitations of HTTP/1.0. For example, an HTML document may contain several other subdocuments, like photos, wall papers, frames, etc. In HTTP/1.0, for each subdocument a new TCP connection has to be created. In HTTP/1.1, all subdocuments can be transported over the same *persistent* TCP connection.

Simple Mail Transfer Protocol

The SMTP defines the exchange and relay of text mails over TCP/IP [RFC821]. If a mail client running on computer *A* wants to send a mail to a receiver on computer *B*, it opens a TCP connection to port 25 of either computer *B* itself, or an intermediate mail server that is able to pass on the mail to the receiver on computer *B*. Then, the sender client sends SMTP commands to the receiver, who replies by sending SMTP responses. Once the sender wants to send an electronic mail, it sends the command MAIL with an identifier for the *sender*. If the receiver is willing to accept mails from the sender, it answers with an OK reply. Now, the sender client sends a sequence of RCPT commands, which identify the receivers of the mail. Each recipient is acknowledged individually by an OK reply. Once all receivers have been specified, the client sends a DATA command followed by the mail data itself. In order to indicate the end of the mail, the client sends a line containing only a period. If such a line is part of the message, the sender will introduce an additional period, which is removed by the receiver automatically (octet stuffing).

In SMTP, a (text) mail must be composed of 7-bit ASCII characters only (byte values 0 – 127), a limitation that was not severe in 1982 when SMTP was designed. Nowadays, electronic mail often contains multimedia attachments like audio or video files, where each byte may contain any value between 0 and 255. In order to be able to transport binary data over SMTP, these data are usually transformed into a sequence of 7-bit ASCII characters by using a byte-to-character mapping like *Base64* or *uuencode*. Upon receiving such a transformed character sequence, the receiver must apply the inverse of the transform in order to retrieve the original binary data.

Resource Location Protocol

Computers connected over an IP network may offer a variety of services to others, including services standardized by the IETF like DNS, SMTP, FTP, etc., as well as self-created services, for instance, for managing personal information. The *Resource Location Protocol* (RLP) has been designed to enable arbitrary computers to automatically find other computers that provide specific services [RFC887].

For this purpose, RLP defines a set of request messages that may be sent by the searching computer. RLP uses UDP as transport protocol. A request message is sent to the UDP port 39 of another host and contains a question and a description of one or more services that are looked for. Depending on the question, hosts that provide the service or know of others that do answer by sending a reply message. RLP defines the following request messages:

- *Who Provides*? is usually broadcast into a LAN. Hosts providing one of the described services may answer, hosts that do not provide any of the specified services may not.
- *Do You Provide?* is directly sent to some specific host. It may not be broadcast. A host receiving this message must answer, regardless of whether it provides any of the specified services or not.
- *Who Anywhere Provides?* also is usually broadcast into a LAN. Hosts either providing any service or knowing other hosts that do so may answer.
- *Does Anyone Provide?* again is sent to a specific host, which must send back an answer, regardless of whether it knows of any host providing any of the services or not.

© 2005 by CRC Press LLC

There are two possible answers. The *I Provide* reply contains a (possibly empty) list of services that are supported by the answering host. The *They Provide* reply contains a (possibly empty) list of supported services, qualified by a list of host-IP addresses supporting them. An RLP message contains the following fields:

- The *Type* field defines the question or reply type.
- The flag *Local Only* specifies, whether only hosts with the same IP network address should answer or be included into the answer list.
- A *Message ID* enables the mapping of received answers to previously sent requests.
- Finally, the *Resource List* contains a description of the looked for or provided services and supporting hosts.

Resources and services may be described by several fields. The first description byte specifies the IP protocol number of the IP transport protocol that the service uses, for instance, 6 for TCP or 17 for UDP. The next byte defines the port that is usually used by the service, for instance, 23 for TELNET or 25 for SMTP. Additional bytes may then define arbitrary self-created services.

Real-Time Protocol

The *Real-Time Protocol* (RTP) has been designed for carrying real-time multimedia data like audio or video information [RFC1889]. Multimedia data usually are produced as a continuous stream of bits. For carrying this stream over the network, it must be packetized and sent as a sequence of packets to one (unicast) or several (multicast) receivers. For real-time traffic, UDP is preferred to TCP, as the delivery of late or lost packets (which is mandatory for TCP) may cause the presentation to stall, which is undesirable, for example, for video conferences. Instead, in case of (a few) lost packets, small artifacts may be visible or audible, which are less annoying than a complete connection breakdown or stall. At the receiver, the original sequence of RTP packets and its content are restored, and lost packets are identified. Pure RTP does not know anything about the payload content. Instead, RTP headers may be altered to fit the needs of specific applications like audio and video conferences. Such changes are then defined in so-called *profile specifications*. Additionally, different RTP payload formats may be defined in payload format specifications, as, for instance, are given by [RFC2190] for H.263. The RTP specification defines the following header fields:

- The RTP *Version* (1 or 2).
- *Padding* and header *Extension* flags.
- Contributing sources (*CSRC*) *count*, that is, length of the CSRC List.
- A marker flag *M* to be used freely by profiles.
- Payload type (*PT*), must be interpreted by the application.
- *Sequence Number*, increased by one for each new RTP packet.
- *Timestamp* of the sampling of the first RTP payload byte.
- RTP *Synchronization Source Identifier*, which must be unique for concurrent RTP sessions.
- An optional contributing sources list (*CSRC List*).

As RTP is transported over the best-effort protocols TCP/UDP/IP, no guarantee can be made that a required bitrate is available for the real-time transport. Instead, RTP provides a means for measuring and controlling the output bitrate and perceived quality of service of a real-time stream. This procedure is provided by the *Real Time Control Protocol* (RTCP). RTCP can carry the following information:

- In a *sender report*, statistics for each active sender are sent to the receivers.
- In a *receiver report*, receivers (which are not senders) send reception statistics to the active senders.
- Sender attributes like e-mail addresses, etc. (*source description*).
- The request for leaving the presentation.
- *Application-specific* control information.

For each real-time session (transporting exactly one medium like audio or video), each participant needs two ports: one for RTP and one for RTCP. RTP is able to multiplex several sessions into one. This

© 2005 by CRC Press LLC

is done by a so-called *mixer*. For example, the audio data of several participants of an audio conference may be mixed into one single audio stream and sent over a connection with low bandwidth. Here, the mixer would act as a new synchronization source; the IDs of the original sources, however, may then be stored additionally after the RTP header in the list of *contributing sources*. Another RTP entity is a *translator*, which is able to change payload content or tunnel packets through a firewall.

13.9 Summary

The TCP/IP protocol suite consists of numerous protocols covering several layers of the ISO/OSI stack or alternatively the TCP/IP reference model. Starting at OSI layer 2, protocols are defined for link-level services for secure frame transport, over IP at OSI layer 3 for the unreliable delivery of datagrams from one host connected to the Internet to another. At OSI layer 4, transport protocols regulate the either reliable and controlled or the unreliable transport of data from process to process. Further services may alter the data due to different presentation schemes, or finally offer direct support to applications.

14.5 Protocols to Improve QoS
Integrated Services (IntServ) • Differentiated Services (DiffServ) Multi-Protocol Label Switching Combining QoS Solutions

Wolfgang Kampichler
Frequentis Nachrichtentechnik Gesellschaft m.b.H.

14.1 Introduction

The Internet offers only very simple Quality of Service (QoS): point-to-point best-effort data delivery. Before IP multicast and real-time applications can be broadly implemented, the Internet infrastructure must be modified to support different levels of services, and to receive secure, predictable, measurable, and guaranteed service.

QoS refers to the ability of a network element to have some level of assurance that its traffic and service requirements can be satisfied. Enabling QoS requires the cooperation of all network layers on every network element from end to end. Thus, such QoS assurances are only as good as the weakest link in the chain between the sender and the receiver.

14.2 What is Quality of Service?

It is difficult to find an adequate definition of what Quality of Service (QoS) actually is. There is a danger that because we wish to use quantitative methods, we might limit the definition of QoS to only those aspects of QoS that can be measured and compared. In fact, there are many subjective and perceptual elements to QoS, and there has been a lot of work done trying to map the perceptual to the quantifiable (particularly in the telephone industry). However, as yet there does not appear to be a standard definition of what QoS actually is in measurable terms.

When considering the definition of QoS, it might be helpful to look at the old story of the three blind men who happen to meet an elephant on their way. The first man touches the elephant's trunk and determines that he has stumbled upon a huge serpent. The second man touches one of the elephant's massive legs and determines that the object is a large tree. The third man touches one of the elephant's ears and

© 2005 by CRC Press LLC

determines that he has stumbled upon a huge bird. All three of the men envision different things, because each man examines only a small part of the elephant. In this case, think of the elephant as a concept of QoS. Different people see QoS as different concepts, because various and ambiguous QoS problems exist. Hence, there is more than one way to characterize QoS. Briefly described, QoS is the ability of a network element (e.g., an application, a host, or a router) to provide some level of assurance for consistent and timely network data delivery [3].

By nature, the basic IP service available in most of the network is best effort. For instance, from a router's point of view, this service could be described as follows:

Upon receiving a packet at the router:

- It determines first where to send the incoming packet (the next-hop of the packet). This is usually done by looking up the destination address in the forwarding table.
- Once it is aware of the next-hop, it will send the packet to the interface associated to this next-hop. If the interface is not able to immediately send the packet, it is stored on the interface in an output queue.
- If the queue is full, the arriving packet is dropped. If the queue already contains packets, the newcomer is subjected to extra delay due to the time needed to emit the older packets in the queue.

Best effort allows the complexity to stay in the end-hosts; so the network can remain relatively simple. This scales well, as evidenced by the ability of the Internet to support its growth. As more hosts are connected, network degrades gracefully. Nevertheless, the resulting variability in delivery delay and packet loss does not adversely affect typical Internet applications (e.g., email or file transfer). Considering applications with real-time requirements, delay, delay variation, and packet loss will cause problems. Generally, applications are of two main types:

- Applications that generate elastic traffic — that is, the application would rather wait for reception of traffic in the correct order, without loss, than display incoming information at a constant rate (such as an email) and
- Applications that generate inelastic traffic — that is, timeliness of information is more important to the application than zero loss, and traffic that arrives after a certain delay is essentially useless (such as voice communication).

In an IP-based network, applications run across User Datagram Protocol (UDP) or Transmission Control Protocol (TCP) connections. TCP guarantees delivery, doing so through some overhead and session-layer sequencing of traffic. It also throttles back transmission rates to behave gracefully in the face of network congestion.

By contrast, UDP is connectionless; thus, no guarantee of delivery is made, and sequencing of information is left to the application itself. Most elastic applications use TCP for transmission and, in contrast, many inelastic applications use UDP as a real-time transport. Inelastic applications are often those that demand a preferential class of service or some form of reservation to behave properly. However, many of the mechanisms that network devices use (such as traffic discard or TCP session control) are less effective on UDP-based traffic since it does not offer some of TCP's self-regulation.

Common for all packets is that they are treated equally. There are no guarantees, no differentiation, and no attempt enforcing fairness. However, the network should try to forward as much traffic as possible with reasonable quality. One way to provide a guarantee to some traffic is to treat packets differently from packets of other types of traffic.

Increasing bandwidth is seen as a necessary first step for accommodating real-time applications, but it is still not enough. Even on a relatively unloaded network, delivery delays can vary enough to continue to affect time-sensitive applications adversely. To provide an appropriate service, some level of quantitative or qualitative determinism must be supplemented to network services. This requires adding some "intelligence" to the net, to distinguish traffic with strict timing requirements from others.

Yet, there remains a further challenge: in the real world, the end-to-end communication path consists of different elements utilizing several network layers. Therefore, it is unlikely that QoS protocols will be used independently, and in fact they are designed for use with other QoS technologies to provide

© 2005 by CRC Press LLC

top-to-bottom and end-to-end QoS between senders and receivers. What does matter is that each element has to provide QoS control services and the ability to map other QoS technologies in the correct manner. The following gives a brief overview of end-to-end network behavior and some key QoS protocols and architectures. For a detailed description, please let me refer to other articles in this book.

14.3 Factors Affecting the Network Quality

A typical end-to-end communication path might appear as illustrated in Figure 14.1 and consists of two machines, each connected through a Local Area Network (LAN) to an enterprise network. Further, these networks might be connected through a Wide Area Network (WAN). The data exchange can be anything from a short email message to a large file transfer, an application download from a server, or communication data from a time-sensitive application. While networks, especially LANs, have been becoming faster, perceived throughput at the application has not always increased accordingly.

An application is generally running on a host CPU, and its performance is a function of the processing speed, memory availability, and the overall operating system load. In many situations, it is the processing that is the real limiting factor on throughput, rather than the infrastructure that is moving data [17].

Network interface hardware transfers incoming packets from the network to the computer's memory and informs the operating system that a packet has arrived. Usually, the network interface uses the interrupt mechanism to do so. The interrupt causes the CPU to suspend normal processing temporarily and to jump to a code called a device driver. The device driver informs the protocol software that a packet has arrived and must be processed.

Similar operations occur in each intermediate network node. Routing devices pass packets along a chain of hops until the final address is reached. These hops are routing machines of various kinds, which generally maintain a queue (or multiple queues) of outgoing packets on each outgoing physical port [2]. If these queues of outgoing data packets become full, it simply starts discarding packets randomly to ease the buildup of congestion. It is evident that such nodes are customized for forwarding operations, which are mostly processed in hardware.

In recent years, however, the Internet has seen increasing use of applications that rely on the timely, regular delivery of packets, and that cannot tolerate the loss of packets or the delay caused by waiting in queues. In general, the one-way delay is equivalent to the sum of single-hop delays suffered between each pair of consecutive pieces of equipment encountered on the path. Measurable factors [7, 8] that are used to describe network QoS are as follows.

Bandwidth

Bandwidth (better described as data rate in this context) is the transmission capacity of a communications line, which is usually stated in bit/sec. The figure given is a nominal figure. In reality, as data

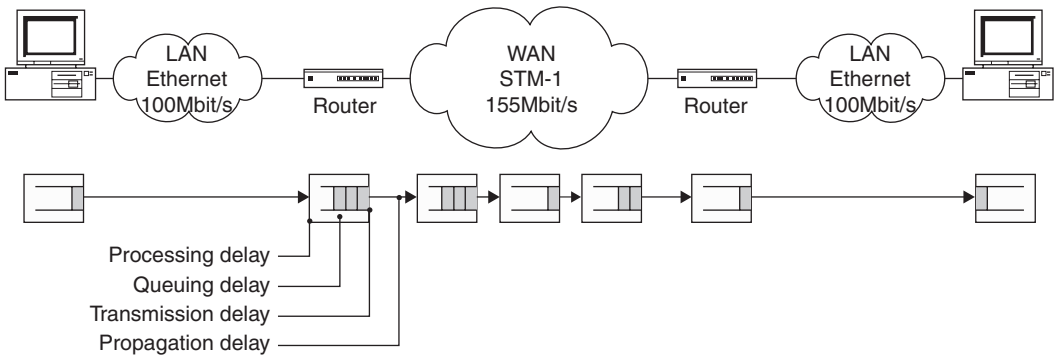

FIGURE 14.1 Network end-to-end communication path.

© 2005 by CRC Press LLC

exchange nears the maximum limit (in a shared environment), delays and collisions might mean a drop in quality. Basically, the bandwidths of all networks utilized in an end-to-end path need to be considered, as the narrowest section provides the maximum speed of data transfer for the entire path. A routing device needs to be capable of transmitting data at a rate commensurate with the potential bandwidth of the network segments that it is servicing. The cost of bandwidth has fallen in recent years; but demand has obviously gone up.

Throughput

Throughput is the average of actual traffic transferred over a given link, in a given time span expressed in bit/sec. It can be seen, for congestion aware transport protocols such as TCP, as t*ransport capacity* = (*data sent*)/(*elapsed time*) where "*data sent*" represents the unique "data" bits transferred (i.e., not including header bits or emulated header bits). It should also be noted that the amount of data sent should only include the unique number of bits transmitted (i.e., if a particular packet is retransmitted, the data it contains should be counted only once). Hence in such a case, the throughput is also limited by the value of the round-trip time.

Latency

In general, latency is the time taken to transmit a packet from a sending to a receiving node. This encompasses a delay in a transmission path or in a device within the transmission path. The nodes might be end-stations or intermediate routes. Within a single router, latency is the amount of time between the receipt of a data packet and its transmission, which includes processing and queuing delay as described next among other sources of delay.

Queuing Delay

The major random component of delay (i.e., the only source of jitter) for a given end-to-end path consists of queuing delay in the network. Queuing delay depends on the number of hops in the path and the queuing mechanisms used, and it also increases with the offered load, leading to packet loss if the queues are filled up. The last packet in the queue has to wait (*N*8*) / *X* seconds before being emitted by the interface, where *N* is the number of bytes that have to be sent before the last queued packet and *X* is the sending rate (bit/sec). Typical queuing delay values of state of the art routers are summarized in Table 14.1.

Values are about 0.5 to 1 msec; thus, it can be said that queuing delay in a well-dimensioned backbone network (using priority scheduling mechanisms, as described later) would not dramatically increase latency, even if there are 5 to 8 hops within the path. At this point, it should be mentioned that queuing delay may be impaired by edge-routers connecting high and low bandwidth links and could easily reach tens of milliseconds, thus increasing latency more distinctly.

Transmission Delay

Transmission or serialization delay is the time taken to transmit all the bits of the frame containing the packet, that is, the time between emission of the first bit of the frame and emission of the last bit; see also [4]. It is inversely proportional to the line speed, or in other words, the ratio between packet size (bit) and transmission rate (bit/sec). For example, a transmission of a 1500 byte packet over a 10 Mbit/sec link

TABLE 14.1 Queuing Delays

Number of queued 1000 bit packets	STM-1 (155 Mbit/*s*)	STM-4 (622 Mbit/s)	Gigabit Ethernet (1 Gbit/s)
40 (80% load)	256 µs	64 µs	40 µs
80 (85% load)	512 µs	128 µs	80 µs
200 (93% load)	1280 µs	320 µs	200 µs
500 (97% load)	3200 µs	800 µs	500 µs

© 2005 by CRC Press LLC

takes 1.2 ms and compared to a 64 kbit/sec link, it takes 187.5 msec (the protocol overhead is not considered in either case). In general, a small packet size and a high transmission rate lower the transmission time.

Propagation Delay

Propagation delay is the time between emission (by the emitting equipment) of the first bit (or the last bit) and the reception of this bit by the receiving equipment. It is mainly a function of the speed of the light and the distance traveled. For local area networks, the propagation delay is almost negligible. For wide area connections, it typically adds 2 msec per 250 mil to the total end-to-end delay. One can assume that a well-designed homogeneous high-speed backbone network (e.g., STM-4) would have a network delay (only propagation and queuing taken into account) of 10 msec when considering 10 hops using priority queuing mechanisms and a network extension of about 625 mil.

Processing Delay

Most networks use a protocol suite that provides connectionless data transfer end-to-end, in our case IP. Link-layer communication is usually implemented in hardware; but IP will usually be implemented in software, executing on the CPU in a communicating end station. Normally, IP performs very few functions. Upon inputting of a packet, it checks the header for correct form, extracts the protocol number, and calls the upper-layer protocol function. The executed path is almost always the same.

Upon outputting, the operation is very similar, as shown in the following IP instruction counts:

- Packet receipt: 57 instructions.
- Packet sending: 61 instructions.

Since input occurs at interrupt time, arbitrary procedures cannot be called to process each packet. Instead, the system uses a queue along with message passing primitives to synchronize communication. When an IP datagram arrives, the interrupt software must en-queue the packet, and invokes a send primitive to notify the IP process that a datagram has arrived. When the IP process has no packets to handle, it calls the receiving primitive to wait for the arrival of another datagram. Once the IP process accepts an incoming datagram, it must decide where to send it for further processing.

If the datagram carries a TCP segment, it must go to the TCP module; if it carries a UDP datagram, it is forwarded to the UDP module. Being complex, most TCP designs use a separate process to handle incoming segments. A consequence of having separate IP and TCP processes is that they must use an inter-process communication mechanism when they interact. Once TCP receives a segment, it uses the protocol port numbers to find the connection to which the segment belongs. If the segment contains data, TCP will add the data to a buffer associated with the connection and return an acknowledgement to the sender. If the incoming segment carries an acknowledgement for outbound data, the input process must also communicate with the TCP timer process to cancel the pending retransmission.

The process structure used to handle an incoming UDP datagram is quite different from that used for TCP. As UDP is much simpler than TCP, the UDP software module does not execute as a separate process. Instead, it consists of conventional procedures that the IP process executes for handling of an incoming UDP datagram. These procedures examine the destination UDP protocol port number, and use it to select an operating system queue for the incoming datagram. The IP process deposits the UDP datagram on the appropriate port, where an application program can extract it [18].

Jitter

Jitter is best described as the variation in end-to-end delay, and has its main source in the random component of the queuing delay. Jitter can be expressed as the distortion of inter-packet arrival times when compared to the inter-packet departure times from the original sending station. For instance, if packets are sent out at regular intervals, they may arrive at varying irregular intervals. Jitter is the variation in interval times. When packets are taking multiple paths to reach their destination, extreme jitter can lead

© 2005 by CRC Press LLC

to packets arriving out of order. Jitter is generally measured in milliseconds, or as a percentage of variation from the average latency of particular connection.

Packet Loss

Packets that fail to arrive, or arrive so late that they are useless contribute to packet loss. Lost (or dropped) packets are a product of insufficient bandwidth on at least one routing device on the network path. Some packets may arrive, but have been corrupted in transit and are therefore unusable. Note that loss is relative to the volume of data that is sent, and is usually expressed as a percentage of data being sent. In some contexts, a high loss percentage can mean that the application is trying to send too much information and is overwhelming the available bandwidth. Packet loss becomes a real problem when the percentage of loss exceeds a specific threshold, or when loss occurs in bursts. Thus, it is important to know both the percentages of lost packets and their distribution [5].

14.4 QoS Delivery

As packet-switched networks are operated in a store-and-forward paradigm, a solution for service differentiation in the forwarding process is to give priority to packets requiring, for instance, an upper-bounded delay over other packets. Considering that queuing is the central component in the internal architecture of a forwarding device, it is not difficult to imagine that managing such queuing mechanisms appropriately is crucial for providing the underlying QoS, thus being one of the fundamental parts for differentiating service levels.

The queuing delay can be minimized and kept below a certain value, even in the case of interface congestion. To achieve this, the forwarding device has to support classification, queuing, and scheduling (CQS) techniques to classify packets according to a traffic type and its requirements, to place packets on different queues according to this type. Finally, to schedule outgoing packets by selecting them from the queues in an appropriate manner, see Figure 14.2.

The following descriptions of queuing disciplines focus on output queuing strategies, being the predominant strategic location for store-and-forward traffic management and QoS-related queuing [3], common for all QoS policies.

FIFO Queuing

First-in, first-out (FIFO) queuing is considered to be the standard method for store-and-forward handling of traffic from an incoming interface to an outgoing interface. Many router vendors have highly

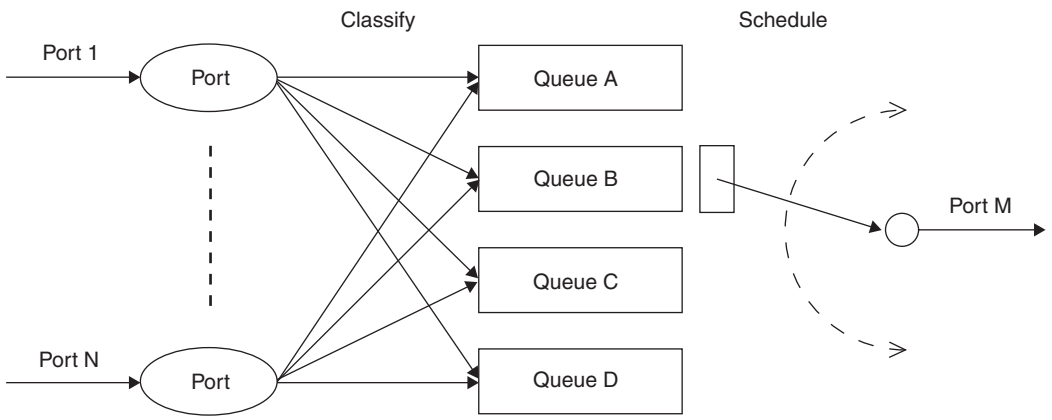

FIGURE 14.2 Classification, queuing, and scheduling.

© 2005 by CRC Press LLC

optimized forwarding performances that make this standard behavior as fast as possible. When a network operates in a mode with a sufficient level of transmission capacity and adequate levels of switching capability, FIFO queuing is highly efficient. This is because, as long as the queue depth remains sufficiently short, the average packet-queuing delay is an insignificant fraction of the end-to-end packet transmission time. Otherwise, when the load on the network increases, the transient bursts raise significant queuing delay, and when the queue is full, all subsequent packets are discarded.

Priority Queuing

One of the first queuing variations to be widely implemented was priority queuing. This is based on the concept that certain types of traffic can be identified and shuffled to the front of the output queue so that some traffic is always transmitted ahead of other types of traffic. Priority queuing may have an adverse effect on forwarding performance because of packet reordering (non-FIFO queuing) in the output queue.

This method offers several levels of priority, and the granularity in identifying traffic to be classified into each queue is very flexible. Although the level of granularity is fairly robust, the more differentiation attempted, the more the impact on computational overhead and packet-forwarding performance. Another possible vulnerability in this queuing approach is that if the volume of high-priority traffic is unusually high, normal traffic to be queued may be dropped because of *buffer starvation*. This usually occurs because of overflow caused by too many packets waiting to be queued and there is not enough room in the queue to accommodate them.

Class-Based Queuing (CBQ)

Another queuing mechanism introduced several years ago is called class-based queuing or custom queuing. Again, this is a well-known mechanism used within operating system design intended to prevent complete resource denial to any particular class of service. CBQ is a variation of priority queuing, where several output queues can be defined. CBQ provides a mechanism to configure how much traffic can be drained off each queue in a servicing rotation. This servicing algorithm is an attempt to provide some semblance of fairness by prioritizing queuing services for certain types of traffic, while not allowing any one class of traffic to monopolize system resources.

CBQ can be considered a primitive method of differentiating traffic into various classes of service, and for several years, it has been considered an efficient method for queue-resource management. However, CBQ simply does not scale to provide the desired performance in some circumstances, primarily because of the computational overhead concerning packet reordering and intensive queue management in networks with very high-speed links.

Weighted Fair Queuing (WFQ)

WFQ is another popular method of queuing that algorithmically attempts to deliver predictable behavior and to ensure that traffic flows do not encounter buffer starvation. It gives low-volume traffic flows preferential treatment and allows higher-volume traffic flows to obtain equity in the remaining amount of queuing capacity. WFQ uses a servicing algorithm that attempts to provide predictable response times and negate inconsistent packet-transmission timing, which is done by sorting and interleaving individual packets by flow, and queuing each flow based on the volume of traffic in each flow [6]. The weighted aspect of WFQ is dependent on the way in which the servicing algorithm is affected by other extraneous criteria. This aspect is usually vendor-specific, and at least one implementation uses the IP precedence bits in the Type of Service (TOS) field to weigh the method of handling individual traffic flows.

WFQ possesses some of the same characteristics as priority and class-based queuing — it simply does not scale to provide the desired performance in some circumstances, primarily because of computational overhead. However, if these methods of queuing (priority, CBQ, and WFQ) could be moved completely into hardware instead of being done in software, the impact on forwarding performance could be reduced greatly.

14.5 Protocols to Improve QoS

Delivering network QoS for a particular application implies minimizing the effects of sharing network resources (bandwidth, routers, etc.) with other applications. This means effective QoS aims to minimize delay, optimize throughput, and minimize jitter and loss. The reality is that network resources are shared with other, competing applications. Some of the competing applications could also be time-dependent services (inelastic traffic); others might be the source of traditional, best-effort traffic. For this reason, QoS has the further goal of minimizing the parameters mentioned for a particular set of applications or users, but without adversely affecting other network users.

In order to regulate network capacity, the network must classify traffic and then handle it in some way. The classification and handling may occur on a single device consisting of both classifiers and queues or routes. In a larger network, however, it is likely that classification will occur at the periphery where devices can recognize application needs, while handling is performed at the core where congestion occurs. The signaling between classifying devices and handling devices can occur in a number of ways, like the ToS of an IP header, or other protocol extensions.

Classification can occur based on a variety of information sources such as protocol content, media identifier, the application that generated the traffic, or extrinsic factors such as time of the day or congestion levels.

Similarly, handling can be performed in a number of ways:

- Through traffic shaping (traffic arrives and is placed in a queue; where its forwarding is regulated, access traffic will be discarded).
- Through various queuing mechanisms (FIFO, priority weighting, and CBQ).
- Through throttling using various flow-control algorithms such as used in TCP.
- Through the selective discard of traffic to notify transmitters of congestion.
- Through packet marking for sending instructions to downstream devices that will shape the traffic.

QoS protocols are designed to act that way, but they never create additional bandwidth; rather, they manage it to be used more effectively. Briefly summarized, QoS is the ability of a network element (e.g., an application, a host, or a router) to provide some level of assurance for consistent and timely network data delivery. The following sections provide a brief overview of some of the key QoS protocols and architectures.

Integrated Services (IntServ)

The IntServ architecture provides a framework for applications to choose between multiple controlled levels of delivery of services for their traffic flows. Two basic requirements exist to support this framework. The first requirement is for the nodes in the traffic path to support the QoS control mechanisms and guaranteed services. The second requirement is for a mechanism by which the applications can communicate their QoS requirements to the nodes along the transit path, as well as for the network nodes to communicate between each other about the requirements that must be provided for the particular traffic flow. All this is provided by a Resource Reservation Set-up Protocol called RSVP [9] that is best described as a QoS signaling protocol. The information presented here is intended to be a qualitative description of the protocol as in [3].

There is a logical separation between the Integrated Services QoS control services and RSVP. RSVP is designed to be used with a variety of QoS control services, and the QoS control services are designed to be used with a variety of setup mechanisms [11]. RSVP does not define the internal format of the protocol objects related to characterizing QoS control services; rather it can be seen as a signaling mechanism transporting the QoS control information. RSVP is analogous to other IP control protocols, such as ICMP, or one of the many IP routing protocols. RSVP itself is not a routing protocol; but it uses the local routing table in routers to determine routes to the appropriate destinations.

In general terms, RSVP is used to provide QoS requests to all router nodes along the transit path of the traffic flows and to maintain the state necessary in the routers required to actually provide the requested

© 2005 by CRC Press LLC

services. RSVP requests generally result in resources being reserved in each router in the transit path for each flow.

RSVP requires the receiver to be responsible for requesting specific QoS services instead of the sender. This is an intentional design in the RSVP protocol that attempts to provide for efficient accommodation of large groups (e.g., multicast traffic), dynamic group membership (also for multicast), and diverse receiver requirements.

There are two fundamental RSVP message types, the *Resv message* and the *Path message*, which provide for the basic RSVP operation, illustrated in Figure 14.3.

An RSVP sender transmits Path messages downstream along the traffic path provided by a discrete routing protocol (i.e., Open Shortest Path First, OSPF). The *Resv message* is generated by the receiver and is transported back upstream toward the sender, creating and maintaining a reservation state in each node along the traffic path.

RSVP still can function across intermediate nodes that are not RSVP capable. However, end-to-end resource reservations cannot be made, because non-RSVP capable devices in the traffic path cannot maintain reservation or *Path state* in response to appropriate RSVP messages. Although intermediate nodes that do not run RSVP cannot provide these functions, they may have sufficient capacity to be useful in accommodating tolerant real-time applications.

Since RSVP relies on a discrete routing infrastructure to forward RSVP messages between nodes, the forwarding of *Path messages* by non-RSVP-capable intermediate nodes is unaffected, since the *Path message* is carrying the IP address of the previous RSVP-capable node as it travels toward the receiver.

Summing up, Integrated Services are capable of enhancing the IP network model to support real-time transmissions and guaranteed bandwidth for specific flows. In this case, a flow is defined as a distinguishable stream of related datagrams from a unique sender to a unique receiver that results from a single-user activity and requires the same QoS. The Integrated Services architecture promises precise per-flow service provisioning but never really made it as a commercial end-user product, which was mainly accredited to its lack of scalability [19].

Differentiated Services (DiffServ)

Differentiated Services mechanisms do not use per-flow signaling, and as a result, do not consume per-flow state within the routing infrastructure. Different service levels can be allocated to different groups of users, which means that all traffic is distributed into groups or classes with different QoS parameters. This reduces the maintenance overhead in comparison to Integrated Services. Network traffic is classified and apportioned to network resources according to bandwidth management criteria. To enable QoS, network elements give preferential treatment to classifications identified as having more demanding requirements.

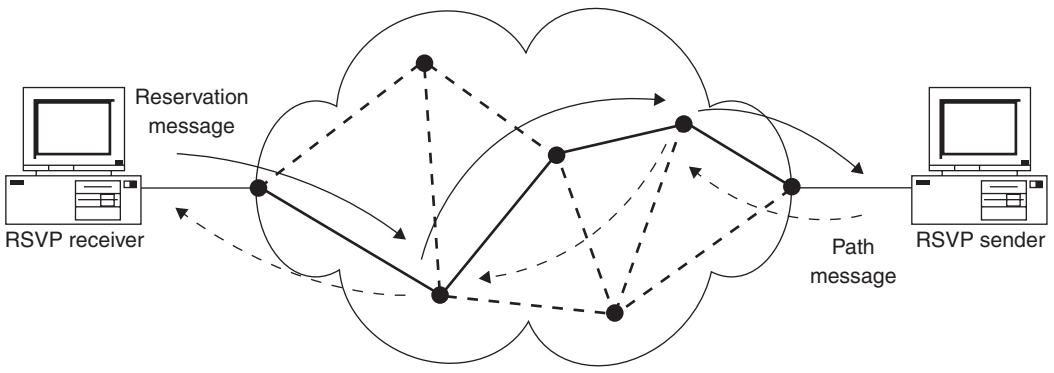

FIGURE 14.3 Traffic flow of the RSVP Path and Resv message.

© 2005 by CRC Press LLC

DiffServ provides a simple and coarse method of classifying services of applications. The main goal of DiffServ is more scalable and manageable architecture for service differentiation in IP networks [16]. The initial premise was that this goal could be achieved by focusing not on individual packet flows, but on traffic aggregates, large sets of flows with similar service requirements.

By carefully aggregating a multitude of QoS-enabled flows into a small number of aggregates, giving a small number of differentiated treatments within the network, DiffServ eliminates the need to recognize and store information about each individual flow in core routers. This basic trick to scalability succeeds by combining a small number of simple packet treatments with a larger number of per-flow policies to provide a broad and flexible range of services.

Each DiffServ flow is policed and marked at the first QoS enabled downstream router according to a contracted service profile, or Service Level Agreement (SLA). Downstream from this router, a DiffServ flow is mingled with similar DiffServ traffic into an aggregate. Then, all further forwarding and policing activities are performed on these aggregates. Current proposals [15] are using a few bits of the IPv4 ToS byte or the IPv6 Traffic Class byte, now called the DiffServ Code Point (DSCP), for marking packets.

There are currently two standard per-hop behaviors defined that effectively represent two service levels (traffic classes):

- *Expedited Forwarding* (EF): It has a single code point (DiffServ value). EF minimizes delay and jitter and provides the highest level of aggregate QoS. This is like a virtual leased line. The EF treatment polices on network ingress and shapes on egress to maintain the service contract to the next provider. Any traffic that exceeds the traffic profile, which is defined by local policy, is discarded.
- *Assured Forwarding* (AF): It defines four priorities (classes) of traffic receiving different bandwidth levels (the "Olympic services" Gold, Silver, Bronze, and best effort). There are three-drop preferences each resulting in 12 different code points. The worse the drop preference, the more chance of getting dropped during congestion. Excess traffic is not delivered with as high a probability as the traffic within profile, which means it may be demoted but not necessarily dropped.

The PHBs are expected to be simple and define forwarding behaviors that may suggest, but do not require a particular implementation or queuing discipline. In general, a classifier selects packets based on one or more predefined sets of header fields. The mapping of the network traffic to the specific behaviors is indicated by the DSCP. The traffic conditioners enforce the rules of each service at the network ingress point. Finally, PHBs are applied to the traffic by the conditioner at a network ingress point according to pre-determined policy criteria. The traffic may be marked at this point, and routed according to the marking, and then unmarked at the network egress.

Each DiffServ-enabled edge router implements traffic conditioning functions, which perform metering, shaping, policing, and marking of packets to ensure that the traffic entering a DiffServ network conforms to the SLA, as illustrated in Figure 14.4.

The simplicity of DiffServ to prioritize traffic belies its extensibility and power. Using RSVP parameters (as described in the next section) or specific application types to identify and classify constant-bit-rate (CBR) traffic might help to establish well-defined aggregate flows that may be directed to fixed bandwidth pipes. DiffServ is more scalable at the cost of coarser service granularity, which may be the reason why it is not yet commercially available to end users either; see also [19].

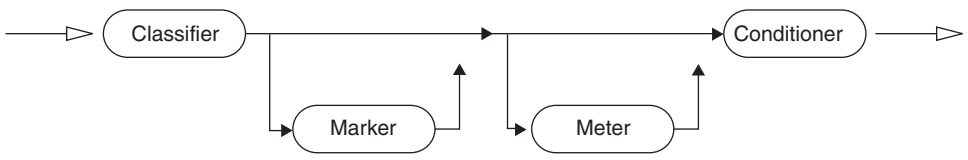

FIGURE 14.4 Edge router: DiffServ classification and conditioning.

Multi-Protocol Label Switching

As stated, we can see that IntServ and DiffServ adopt different approaches to solve the QoS challenge. Meanwhile, another approach exists that is slightly different but already in use: Multi Protocol Label Switching (MPLS). In contrast, it is not primarily a QoS solution, although it can be used to support QoS requirements. MPLS is best viewed as a new switching architecture and is basically a forwarding protocol that simplifies routing in IP-based networks. It specifies a simple and scalable forwarding mechanism, since it uses labels instead of a destination address to make the routing decision. The label value that is placed in an incoming packet header is used as an index to the forwarding table in the router. This lookup requires only one access to the table, in contrast to the traditional routing table access that might require uncountable lookups [1].

One of the most important uses of MPLS is in the area of traffic engineering, which can be summarized as the modeling, characterization, and control of traffic to meet specified performance objectives. Such performance objectives might be traffic oriented or resource oriented. The former deals with QoS and includes aspects such as minimizing delay, jitter, and packet loss. The latter deals with optimum usage of network resources, particularly network bandwidth.

The current situation with IP routing and resource allocation is that the routing protocols are not well equipped to deal with traffic-engineering issues. For example, a protocol such as OSPF can actually promote congestion because it tends to force traffic down the shortest route, although other acceptable routes might be less loaded. With MPLS, a set of flows that share specific attributes can be routed over a given path. This capability has the immediate advantage to steer certain traffic away from the shortest path, which is likely to become congested before other paths.

In conclusion, we may say that label-switching offers scalability to networks by allowing a large number of IP addresses to be associated with one or a few labels. This approach further reduces the size of address (actually label) tables, and allows a router to support more users or to set up fixed paths for different types of traffic. Since the main attributes of label switching are fast relay of the traffic, scalability, simplicity, and route control, label switching can be a valuable tool to reduce latency and jitter for data transmission on packet-switched networks.

Combining QoS Solutions

The QoS solutions described previously adopt different approaches, and each has its advantage and disadvantage. The Integrated Service approach is based on a sophisticated background of research in QoS mechanisms and protocols for packet networks. However, the acceptance of IntServ from network providers and router providers has been quite limited, at least so far, mainly due to scalability and manageability problems [10].

The scalability problems arise because IntServ requires routers to maintain control and forwarding state for all flows passing through them. Maintaining and processing per-flow state for gigabit or terabit links, with several simultaneously active flows, is significantly difficult from an implementation point of view. Hence, the IntServ architecture makes the management and accounting of IP networks significantly more complicated. Additionally, it requires new application–network interfaces and can only provide service guarantees when all elements in the flow's path support IntServ.

MPLS may be used as an alternative intra-domain implementation technology. These architectures in combination can enable end-to-end QoS. End hosts may use RSVP requests with high granularity (e.g., bandwidth, jitter, threshold, etc.). Border routers at backbone ingress points can then map those RSVP "reservations" to a class of service indicated by a DS byte or to a dedicated MPLS path. At the backbone egress point, the RSVP provisioning may be honored again, to the final destination; see Figure 14.5.

Such combinations clearly represent a trade-off between service granularity and scalability: as soon as flows are aggregated, they are not as isolated from each other as they possibly were in the IntServ part of the network. This means that, for instance, unresponsive flows can degrade the quality of responsive

© 2005 by CRC Press LLC

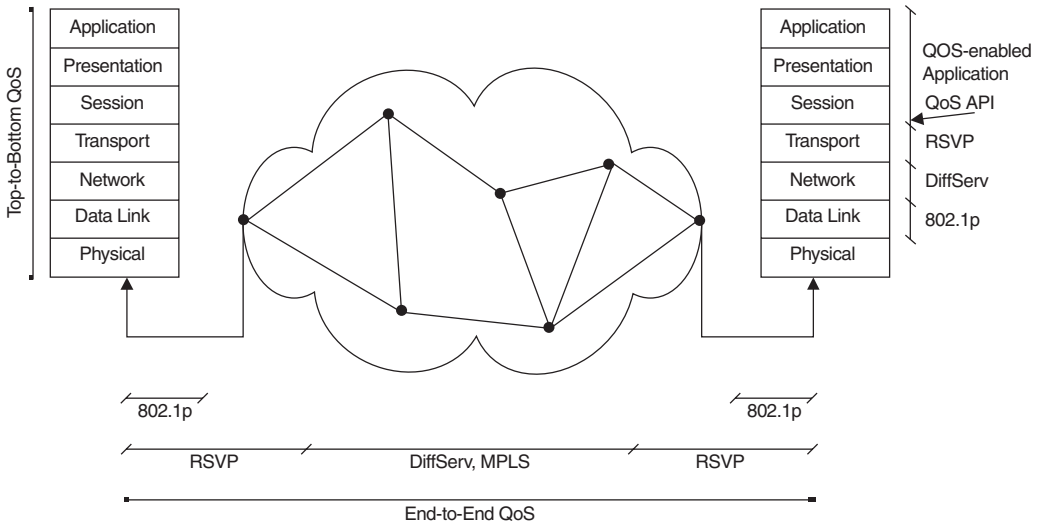

FIGURE 14.5 QoS Architecture.

flows. The strength of a combination is the fact that it gives network operators another opportunity to customize their network and fine-tune it based on QoS and scalability demands, as stated in [19].

Until now, IP has provided a best-effort service in which network resources are shared equitably. Adding QoS support to the Internet raises significant concerns, since it enables differentiated services that represent a significant departure from the fundamental and simple design principles that made the Internet a success. Nonetheless, there is a significant need for IP QoS, and protocols have evolved to address this need. The most viable solution today is a trade-off between protocol complexity and bandwidth "scarcity" with the following result:

- different QoS levels are used in the core network (e.g., four MPLS levels),
- applications at the user side are distinguished by DiffServ mechanisms, and
- and the marked user traffic is mapped to the appropriate core layers.

Finally, we should always bear in mind that an "application-to-application" guarantee not only depends on network conditions but also on the overall performance of each end-system.

15.2 Basic Operation of The Internet Protocol
15.3 IP Addressing
15.4 IP Fragmenting
15.5 Internet Protocol Header
15.6 ICMP — Internet Control Message Protocol

Jürgen Falb
Vienna University of Technology

15.1 Motivation

The Internet Protocol (IP) was designed for use in interconnected packet-switched computer networks. It fulfills two different tasks. First, the IP provides for transmitting blocks of data called IP datagrams from a source host to a destination host. The second task is fragmentation and reassembly of datagrams for packet-switched networks able to handle only small packets. These two functions are named addressing and fragmentation.

The IP is not intended to provide additional services like reliability, flow control, or other common services provided by host-to-host protocols. In the TCP/IP suite, TCP provides these services. The IP only delivers datagrams from one host to another host with the use of interconnected networks.

A comparison of the Internet World with the ISO/OSI model places the IP on layer 3 — the network layer — of the ISO/OSI model. This comparison is often made, but is not sufficient because the IP itself does not define many functionalities of the network layer. For example, the IP does not define mechanisms for routing or congestion control. Therefore, the IP itself only implements a small part of the network layer. The IPs (such as IP, TCP, or UDP) are vendor-independent, and their specification is controlled by open public discussion. The results of the public discussions are written down in so-called "Request For Comments — RFCs." The Internet protocols are widely implemented by a variety of vendors and hence the definition of "open" as used in OSI is fulfilled.

15.2 Basic Operation of The Internet Protocol

The IP delivers datagrams throughout interconnected networks. Its operation makes it necessary that an IP module resides on each host involved in the transmission path as shown in Figure 15.1. Each IP module interfaces with one or more application programs and one or more underlying local networks. Typical application programs are TCP and UDP modules. The most commonly used type of local networks in the IP world is Ethernet. Nevertheless, the setup of IP upon other types of networks like ATM or fieldbus networks is possible.

The basic transmission scenario is as follows: an IP module receives data and a destination address from an application program. Then, the IP module encapsulates the data in IP datagrams, fragmenting

© 2005 by CRC Press LLC

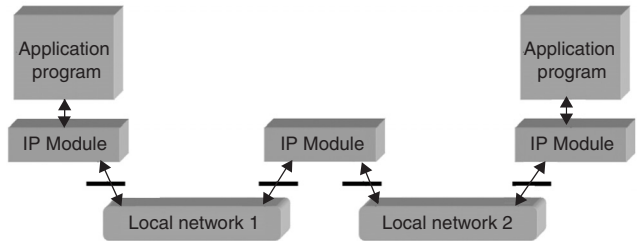

FIGURE 15.1 Interfacing of the IP.

them if necessary, and adding IP headers containing all necessary information to transmit the datagrams. Based on the destination address, the IP module transmits the packets over the local network to the next host. The receiving host decides if the datagrams belong to it by using the same addressing algorithm as the sender. In case the datagrams do not belong to the host, the receiving host forwards them to the next host. If the next local network is only able to transmit smaller datagrams then the prior one, the host fragments the datagrams again. This process is repeated until the datagrams reach their final destination. On the destination host, fragmented datagrams are reassembled. All hosts involved in the transmission make up the transmission path. The selection of a transmission path is called routing. Furthermore, all transmissions are stateless. This means that there is no relationship between subsequent IP datagrams such as a logical connection.

The IP uses four key mechanisms to fulfill its tasks: Type of Service, Time to Live, Options, and Header Checksum.

The *Type of Service* indicates the desired quality of service. Based on the indicated type of service, a host within the transmission path (often named gateway or router) can decide the proper routing and forwarding strategy.

The *Time to Live* mechanism indicates the lifetime of a datagram. The sender of a datagram chooses an initial value for the Time to Live. At each hop the datagram passes, the Time to Live will be decremented. If the Time to Live reaches zero before the datagram reaches its final destination, the datagram destroys itself. This mechanism ensures that a datagram cannot travel though the interconnected networks indefinitely.

Options provide a mechanism for control functions like timestamps, security, or recording of routes. Options are not necessary for normal operation.

The *Header Checksum* provides means for detecting errors. If a datagram was transmitted incorrectly, it will be discarded by the entity detecting the error. Errors are indicated to the sender using the Internet Control Message Protocol (ICMP) as described in section "ICMP".

15.3 IP Addressing

The IP only deals with addressing; finding a path to a destination host has to be done by higher-level protocols. Additionally, the Internet module supports mapping Internet addresses to local network addresses.

An Internet address is an address of fixed-length (32 bits). In the commonly used IP address notation, decimal numbers separated by dots (e.g., 128.131.80.33) represent the four bytes. Each Internet address consists of a network number and a local host address. A common notation for indicating the length of the network number part is the addition of a slash followed by a number specifying the number of bits (e.g., 128.131.80.0/24 refers to 256 IP addresses within the 24-bit network 128.131.80.). The Internet addressing scheme provides three classes of addresses and two classes of special-purpose addresses as shown in Figure 15.2. This original model for distributing IP addresses, based on classful addressing strategies, does not take into account the massive expansion of Internet use and is unable to scale to meet this expansion. Therefore, the authorities responsible for distributing IP address do not use this

© 2005 by CRC Press LLC

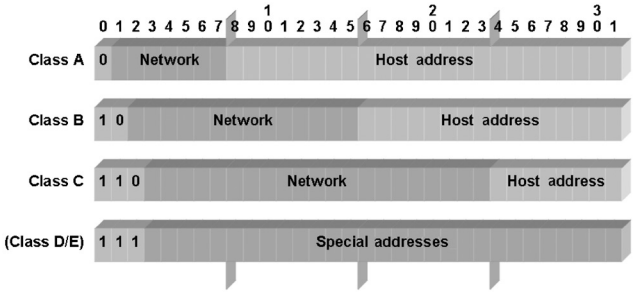

FIGURE 15.2 IP addresses.

class-based terminology anymore. Nowadays, IP addresses are only distributed for requested quantities if there is a documented need for this quantity of IP addresses. Nevertheless, many of the rules applied to the class hierarchy are still valid and discussed in the following paragraphs.

- *Class A*: A Class A address consists of a 7-bit network number and a 24-bit host number. That means there are 128 networks with 16,777,214 hosts. Only 125 of them are available for use, because the other three IP addresses are used for special purposes. The addresses in the network 0.0.0.0/8 refer to hosts on the local network. The special address 0.0.0.0 can be used as a source address for the own host. Addresses in the network 127.0.0.0/8 are used as loopback addresses, but usually in most IP stacks only the address 127.0.0.1 is implemented as a loopback address. Addresses in the network 10.0.0.0/8 can be used for private purposes and should not appear on the public Internet.
- *Class B*: A Class B address consists of a 14-bit network number and a 16-bit host number. Therefore, there are 16,384 networks with 65,532 hosts available. Addresses in the networks 172.16.0.0/12 to 172.31.0.0/12 are used for private purposes and should not appear on the public Internet. The network 169.254.0.0/16 is used as "link local" block. It is used for communication between hosts on a single link. Hosts obtain these addresses by autoconfiguration. This is the case if no DHCP server is available.
- *Class C*: A Class C address consists of a 21-bit network number and an 8-bit host number. Therefore, 2,097,152 Class C networks with 254 hosts exist. The networks 192.168.0.0/24 to 192.168.255.0/24 are reserved for private use and should not appear on the public Internet. The block 192.88.99.0/24 is used for routing between IPv6 and IPv4 networks. The block 192.0.2.0 /24 is called "TEST-NET" and is valid for use in documentation and examples. Addresses in this block should not appear on the public Internet. The last reserved block 198.18.0.0/15 is dedicated to benchmark tests of interconnected network devices.
- *Class D/E*: Classes D and E addresses are used for special purposes. Class D addresses in the range from 224.0.0.0 to 239.255.255.255 are used as IPv4 multicast addresses to address a group of hosts in the Internet for a special purpose. Class E addresses in the range from 240.0.0.0 to 255.255.255.254 are reserved for future use. The special address 255.255.255.255 is used for broadcasts in the local network and should never be forwarded outside the local network.

More on IP addressing can be found in [1].

15.4 IP Fragmenting

If a large packet originates in a local network and it has to traverse another network that only allows smaller packets to get to its destination host, the packet must be fragmented into smaller packets to enable transportation over this particular network. Hereby, each fragment is a valid IP packet again and can be transmitted independent of the other fragments. IP defines an *n*-way fragmentation algorithm to allow

© 2005 by CRC Press LLC

further fragmentation of already fragmented packets to enable transportation of fragmented packets that are still too large for some networks. The maximum packet size of a local network is usually called *Maximum Transfer Unit* (MTU). A local network must be able to transport packets with at least 68 octets. This value results from the fact that the maximum IP header length amounts to 60 octets and the minimal fragment block length is 8 octets.

Based on the example in Figure 15.3 the fragmentation algorithm will be explained in this paragraph.

1. First, the Internet module, which has to forward a packet from a local network 1 to a local network 2, has to compare the *total length* (TL) of the packet with the MTU of the local network 2. If the TL is less than or equal to the MTU, it simply can forward the packet without fragmentation. If the TL is greater than the MTU, the packet has to be fragmented. In the example of Figure 15.3, the TL of 124 octets is greater than the next MTU (88 octets). If the packet has to be fragmented, the *don't fragment flag* has to be checked. If this flag is set, the packet should not be fragmented and therefore has to be discarded because forwarding is not possible. In this case, the IP module usually creates an ICMP message to indicate the error to the originator of the packet.
2. In the next step, the Internet module creates the first fragment by copying the original IP header to the new packet. For subsequent fragments, some option headers can be omitted while copying the original IP header to the new packet [2]. Based on the MTU and the *Internet Header Length* (IHL), the Internet module has to compute the *number of fragment blocks* (NFB) it can insert into the new packet: $NFB = (MTU - IHL \ast 4)/8$. The IHL is given in a multiple of 4 octets within the Internet header and each fragment block consists of 8 octets data, except the last one of the last fragment, which can be less than 8 octets.
3. In the third step, the Internet header has to be corrected. If the fragment is not the last one, the *more fragments flag* (MF) has to be set to indicate to the receiver that at least one more fragment will follow. The *fragment offset* (FO) of the Internet header has to be set to the original fragment offset plus the sum of the NFBs of prior fragments. Since the FO field is 13-bit long, the maximum length of the overall packet data (all fragments together) is $2^{13} \ast 8 = 65{,}536$ octets. The third field to compute is the total length (TL), which is the sum of the new header length and the fragment data length. Based on the new header values, the *Header Checksum* has to be recomputed for the fragment.
4. The last step is the transmission of the new fragments to the next host in the transmission path. The receiver of the fragments again applies this fragmentation algorithm to the received packets.

The reassembly of the packets occurs only at the final destination host of the original packet. All fragments belonging to one packet are identified by the combination of source address, destination address, identification header field, and protocol header field. The fragments are ordered by the fragment offset header field. Based on the fragment length and the more fragment bit, the IP module on the destination host can decide if all fragments have arrived. If a packet is fully reassembled, it is handed over to the next module for further processing of the data.

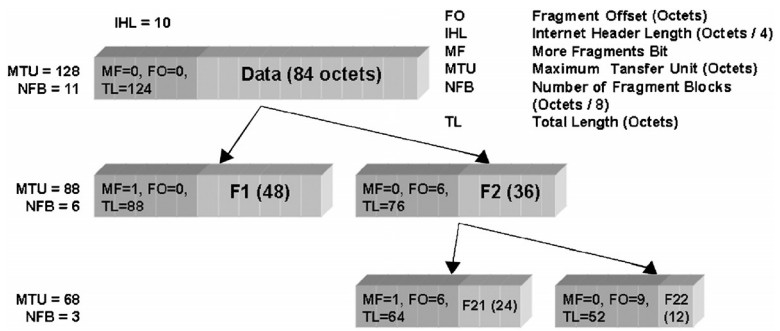

FIGURE 15.3 IP fragmentation example.

© 2005 by CRC Press LLC

15.5 Internet Protocol Header

The IP header contains all information for transmitting a packet from a source host to a destination host and for fragmentation and reassembly of packets. An IP header consists of at least 20 octets up to 60 octets. The structure of the IP header is shown in Figure 15.4. For each field in Figure 15.4 the bit with the lowest number is the most significant bit.

- *Version*: 4 bits. The version field indicates the version of the IP protocol. In this case, the version field contains the value 4.
- *Internet Header Length*: 4 bits. This field denotes the overall length of the IP header in a multiple of 4 octets. Since the IP header consists of at least 20 octets, the minimal value is 5.
- *Type of Service*: 8 bits. The Type of Service field is used to provide different levels of transmission quality. The three most significant bits define the priority of the packet. Packets with higher priority should be processed first. The next three bits define the network parameters to be considered in the packet processing. The three bits represent the following network parameters: delay, throughput, and reliability. Usually, only one of these three bits is set to one. It does not make sense to set more than two bits to one because the improvement of network parameters occurs at the cost of the other network parameters. The last two bits are reserved for future use. More details can be found in [3].
- *Total Length*: 16 bits. The total length field specifies the length of a packet consisting of header and data block in octets. Due to the 16 bits, a maximal length of 65,536 octets is possible. A host must be prepared to accept at least packets with a length of 576 octets. The value is based on a data block of 512 octets and a typical IP header of 20 octets and a reserve for higher-level protocol overhead.
- *Identification*: 16 bits. This field should contain a value unique with respect to the originating host. It is used in the reassembly procedure to identify fragments that belong to a particular packet.
- *Flags*: 3 bits. These bits are used for the fragmentation procedure. Bit 0 is reserved and must be zero. Bit 1 is the Don't Fragment Flag and Bit 2 is the More Fragment Bit indicating that more fragments belonging to this packet will follow.
- *Fragment Offset*: 13 bits. The Fragment Offset field indicates the position of the fragment data within the whole packet. The fragment offset is measured in units of 8 octets.
- *Time to Live*: 8 bits. The Time to Live field indicates the maximum time a packet is allowed to travel through the networks. At each host passed by the packet, this field has to be decremented by at least one. If this field contains the value 0, it has to be discarded. The TTL field represents the maximum time in seconds a packet can live within networks. If a host needs more than a second for processing a packet, the value of the TTL should be decremented by the corresponding value. Since the TTL field is decremented at least by 1 at each host, it just represents an upper bound for the time a packet lives.

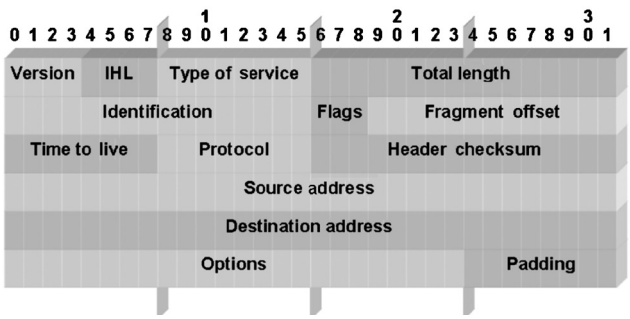

FIGURE 15.4 IP header.

© 2005 by CRC Press LLC

- *Protocol*: 8 bits. The Protocol field identifies the next higher-level protocol used within the data block of the IP packet. The values for this field are maintained by the "Internet Assigned Numbers Authority" [4] and are updated at regular intervals. TCP, for example, has the value 6.
- *Header Checksum*: 16 bits. This field contains a checksum for the header only. Therefore, there is no mechanism in IP for verifying the correctness of the data. Since some header fields change at each host (e.g., TTL), the checksum has to be recomputed at every host in the transmission path.

Source Address: 32 bits. The source address is a structured 32-bit address as defined in section "IP Adressing" identifying the originating source host.

Destination Address: 32 bits. The destination address is also a structured 32- bit address as defined in section "IP Addressing" identifying the final destination host.

Options: Variable. Options are mainly used for control, debugging, and measurement. The IP protocol defines options for recording and supplying route information, transmitting timestamps, and for sending security information. A detailed description of the possible options can be found in [2].

Padding: Variable. The Internet header padding ensures that the Internet header ends at 32-bit boundary. The padding bits are filled with zeros.

One success factor of the Internet is mentioned in the following quote of the originator of the Internet Protocol Jon Postel: "*In general, an implementation must be conservative in its sending behaviour, and liberal in its receiving behaviour. That is, it must be careful to send well-formed datagrams, but must accept any datagram that it can interpret*." This fact is not as apparent as in the HyperText Transfer Protocol (HTTP), the basis for the World Wide Web, but makes the protocol implementations robust and supports the interoperability of different IP implementations.

15.6 ICMP — Internet Control Message Protocol

The purpose of the ICMP (specified in RFC 792 [5]) is to provide information about problems in the Internet communication environment. To transport the error information to its destination, it uses the IP as a transport mechanism. ICMP is not designed to make the IP reliable; it only provides feedback about problems to the source host. It is not designed for control purposes between routers and hosts.

The ICMP is an integral part of every IP module and therefore must be implemented together with IP. With respect to the datagram structure, it can be seen as a higher-level protocol since it is transported by IP. To avoid too many errors in reporting traffic, there will be no ICMP messages sent about errors in the transmission of other ICMP messages. Also, there is only an error reporting for the first fragment of a fragmented packet (The first fragment is denoted by the fragment offset value 0.)

ICMP is used to provide information about the following network situations:

Destination unreachable: An ICMP message of this type is sent either if a network or a particular host is unreachable or if there is a problem in the next level protocol module. Reasons are the unavailability of the protocol module itself or of the corresponding port. The third case for the generation of a destination unreachable message is the necessity to fragment a packet with the "don't fragment" flag set.

Time Exceeded: This message is generated either if the Time to Live field is zero and the packet has to be dropped or if a timeout occurs during the reassembly procedure of IP fragments at the destination host.

Parameter Problem: A Parameter Problem ICMP message is generated if a host has to drop a packet because it cannot complete processing the packet due to an error in the IP header.

Source Quench: A Source Quench ICMP message should be sent if either the buffer of a host is full or the packets arrive to fast for processing and the host discards the packets. A host can send a Source Quench message for every packet it discards. A source host receiving Source Quench messages should cut back its transmission rate until it does not receive Source Quench messages anymore.

Redirect: If there are more than one gateways present on the local network and a gateway receives a packet that should rather be forwarded by another gateway due to its routing table, it sends a Redirect ICMP message back to the source host containing the address of the other gateway.

© 2005 by CRC Press LLC

Echo or Echo Reply: These messages are primarily used to verify the connectivity between hosts. The data sent in an Echo ICMP message have to be returned in the Echo Reply ICMP message. A common application based on these ICMP message types is the "ping" command.

Timestamp or Timestamp Reply: These two message types are used to record time information. A host sends a Timestamp ICMP message and receives the echoed Timestamp Reply ICMP message. The echoed Timestamp Reply message contains the sent time and received time of the Timestamp message and the sent time of the Timestamp Reply message. With this information, it is possible to calculate the transmission time and the processing time at the destination host.

Information Request or Information Reply: These message types can be used by a host to find out the network number of the network it is on. The sender can set the network part of the source and destination address within the IP header to zero. A network part of zero in an IP addresses identifies "this" network. The destination host, which has to send the Information Reply message, has to specify the full IP addresses within the IP header. By examining the IP addresses in the Information Reply message, the original host can determine its network number.

A typical application based on ICMP messages is the traceroute command. The traceroute command tries to figure out the route a packet will take most probably to get to the destination host. It is not guaranteed that subsequent packets will take the same route as printed out by the traceroute command. Figure 15.5 shows an example traceroute output. The traceroute command works as follows: first, it sends an IP packet to the destination host with a Time to Live of one. The next host in the transmission path has to decrease the TTL header field to zero and therefore has to discard the IP packet. To inform the sender about the error, it sends a Time Exceeded ICMP message (Type 0x0b) back to the sender. The traceroute command recognizes the originator of the ICMP message as the first hop. In the next step, it sends the same IP packet again, but with a TTL field increased by one. This time, the first receiving host decreases the TTL to one and forwards the packet to the second host that decreases the TTL to zero and sends a Time Exceeded ICMP message back to the sender. This procedure is repeated until a packet reaches the final destination host. In this example, the final destination host sends a Destination Unreachable ICMP

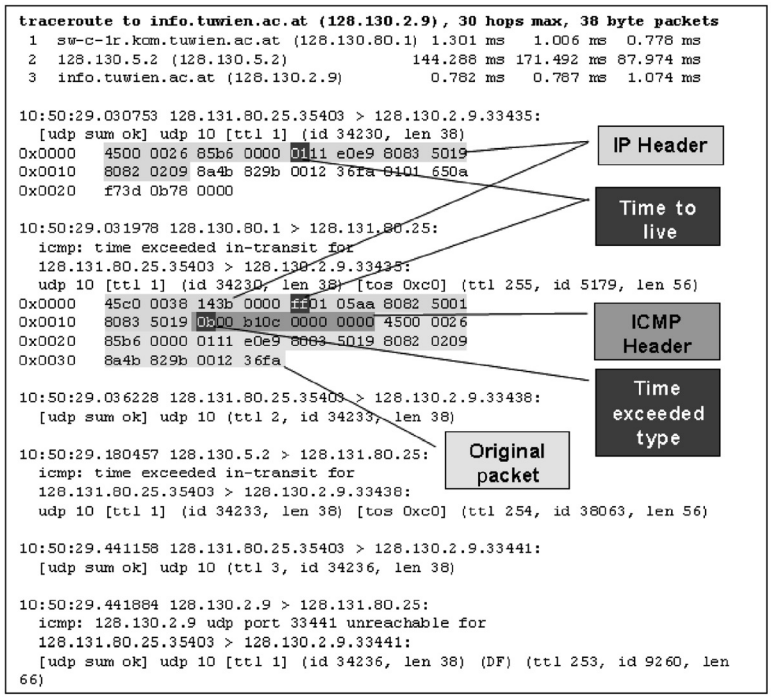

FIGURE 15.5 Example usage of ICMP messages by traceroute.

© 2005 by CRC Press LLC

message, because the IP packet is addressed to port 33,441 unavailable at the final destination host. The ports used by traceroute are usually in the range of 33,434 – 33,600 and are increased by one for each packet. Commonly, three packets are sent with the same TTL value for each hop in case a packet gets dropped or the port is in use.

16.1 Introduction
16.2 Protocol Operation
TCP Segment • Port Number Assignments • Connection Establishment • Maintaining the Open Connection • Connection Termination
16.3 State Diagram

16.1 Introduction

Transmission Control Protocol (TCP) is a part of the TCP/IP protocol suite. It provides full transport layer services to applications. It belongs to the transport layer in the OSI model as shown in Figure 16.1. TCP is more complicated than User Datagram Protocol (UDP) and provides a reliable connection between both ends of transmission. This connection needs to be set up, maintained, and torn down. The protocol divides a stream of data into units of limited size that are called segments. These segments are reassembled together in a reliable manner at the other end. Reliability is achieved by assembling segments by preserving their original sequence, and arranging for retransmission of lost or corrupted data. While the underlying IP protocol provides logical addressing of segments and is responsible for their transmission through networks, TCP provides additional addressing that allows setting up connections for multiple applications and services on the same end. Each application seeking TCP connection is assigned one or more numbers (one number per connection) that are called port numbers. Figure 16.2 illustrates the concept of port numbers.

TCP provides a logical full duplex connection between two application layer processes. The connection is perceived as a connection-oriented, reliable, in-sequence byte-stream service. The protocol also allows the recipient of the data to control the rate at which the sender transmits data to avoid buffer overflow.

Connection-oriented means that the connection needs to be established and its parameters negotiated between the two processed. This negotiation is performed by sending transmission control blocks (TCB). At the end of transmission, the connection must be torn down. TCP terminates each direction of the connection separately. This allows the data flow to continue even after the other direction has been closed.

Reliable means that either all data are delivered or the connection is broken. TCP is designed to work over the Internet Protocol (IP) and thus it does not assume that underlying network services are reliable. To ensure reliability, each chunk of data is numbered, and a selective automatic repeat request (ARQ) is used to request the retransmission of lost or corrupt data chunk.

In-sequence means that all data are guaranteed to be received by the end receiving process in the same order that they were sent in. Sequencing is implemented by the same mechanism that is used for missing

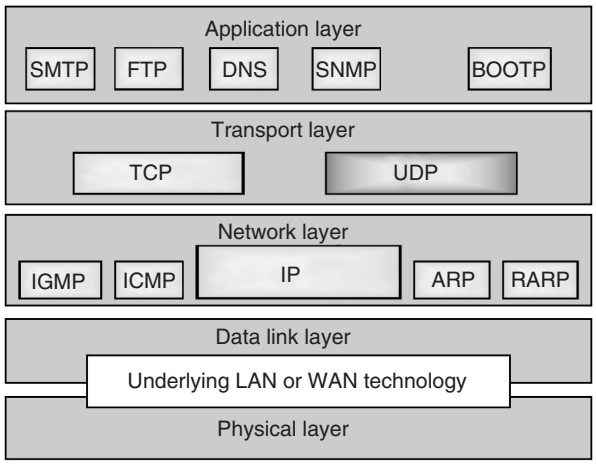

FIGURE 16.1 UDP and TCP/IP in the OSI model.

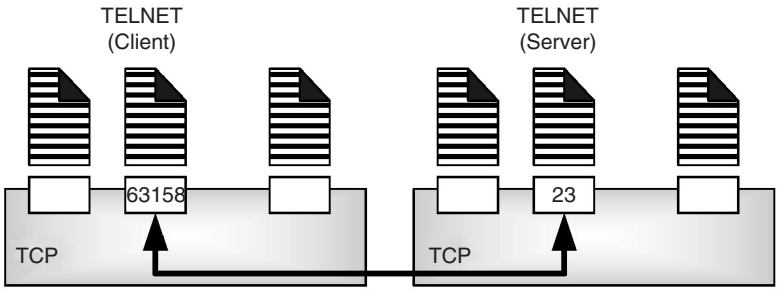

FIGURE 16.2 Process-to-process communication.

data chunk detection. All received data are placed in a receiving buffer in a location corresponding to the data chunk number. The process that receives data reads it from that buffer in the correct sequence.

Byte-stream oriented means that the connection can be perceived as a continuous stream of data regardless of the fact that the underlying network services may transmit data in chunks. These data chunks may be of various sizes and may have a maximum size limit. The sending process, however, may send data either continuously or in bursts. All data to be sent are placed in the sending buffer. Data from the buffer are partitioned into chunks that are called segments according to algorithms of TCP and sent over the network. On the receiving side, the data are placed in the receiving buffer in an appropriate sequence as mentioned earlier. The receiving process may read data in either chunks or byte after byte.

Full duplex means that each party involved in the transmission has control over it. For example, any side can send data at any time or terminate the connection.

16.2 Protocol Operation

Before data transfer begins, TCP establishes a connection between two application processes by setting up the protocol parameters. These parameters are stored in a structure variable called TCB. Once the connection is established, the data transfer may begin. During the transfer, parameters may be modified to improve the efficiency of transmission and prevent congestion. In the end, the connection is closed. Under certain circumstances, connection may be terminated without formal closing.

© 2005 by CRC Press LLC

TCP Segment

Although TCP is a byte-stream-oriented connection and buffering takes care of the disparities in the speed of preparing data for sending, speed of sending data, and the speed of consuming data at the other end, one more step is necessary before data are sent. The underneath IP layer that takes care of sending data through the entire network sends data in packets, and not as a stream of bytes. Sending one byte in a packet would be very inefficient due to the large overhead caused by headers. Therefore, data are grouped into larger chunks that are called segments. Each segment is encapsulated in an IP datagram and then transmitted. Each TCP segment follows the same format as shown in Figure 16.3. Each segment consists of a header that is followed by options and data. The meaning of each header field will be discussed now, and its importance will be illustrated in the following sections, which shows phases of a typical TCP connection.

Source Port Address — this is a 16-bit field that contains a port number of the process that sends options or data in this segment.

Destination Port Address — this is a 16-bit field that contains a port number of the process that is supposed to receive options or data carried by this segment.

Sequence Number — this is a 32-bit field that contains the number assigned to the first byte of data carried by this segment. During the establishment of connection, each side generates its own random initial sequence number (ISN). The sequence number is then increased by one with each one byte of data sent. For example, if a previous segment had a sequence number 700 and had 200 bytes of data, then the next segment has sequence number 900.

Acknowledgement Number — this is a 32-bit field that contains the sequence number for the next segment that is expected to be received from the other party. For example, if the last received segment had a sequence number 700 and had 200 bytes of data, then the acknowledgement number is 900.

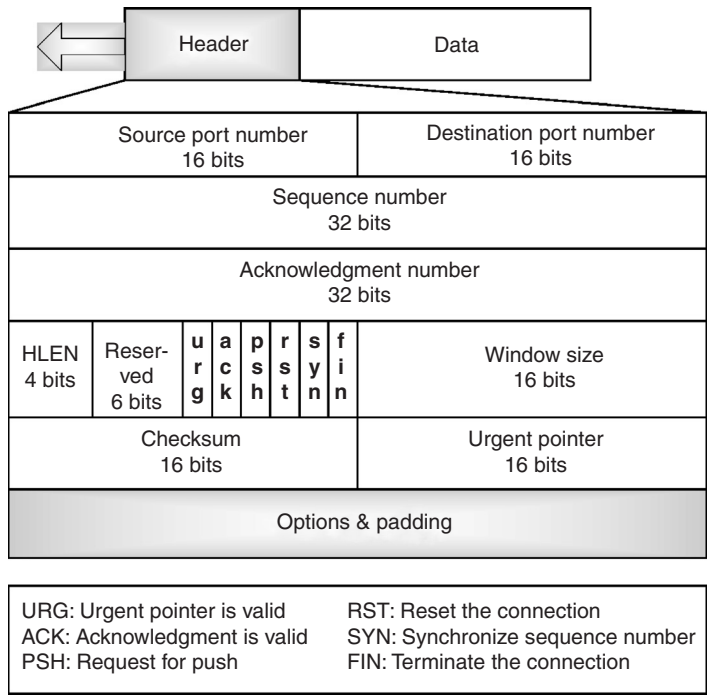

FIGURE 16.3 TCP segment format.

© 2005 by CRC Press LLC

Header Length — this 4-bit field contains the total size of the segment header divided by 4. Since headers may be 20 to 60 bytes long, the value is in the range of 5 – 15.

Reserved — this 6-bit field is reserved for future use.

Control — this 6-bit field contains transmission control flags:

URG — urgent. If the bit is set, then the urgent pointer is valid.

ACK — acknowledgement. If the bit is set, then the acknowledgement number is valid.

PSH — push. If the bit is set, then the other party should not buffer outgoing data but send it immediately, as it becomes available, without buffering.

RST — reset. If the bit is set, then the connection should be aborted immediately due to abnormal condition.

SYN — synchronize. The bit is set in the connection request segment when the connection is being established.

FIN — finalize. If the bit is set it means that the sender does not have anything more to send, and that the connection may be closed. The process will still accept data from the other party until the other party also sends FIN.

Window Size — this 16-bit field contains information about the size of the transmission window that the other party must maintain. Window size will be explained and illustrated later.

Checksum — this 16-bit field contains the checksum. The checksum is calculated by

Initially filling it with 0's.

Adding a pseudoheader with information from IP protocol as illustrated in Figure 16.4.

Treating the whole segment with the pseudoheader prepended as a stream of 16-bit numbers. If the number of bytes is odd, 0 is appended at the end.

Adding all 16-bit numbers using 1's complement binary arithmetic.

Complementing the result. This complemented result is inserted into the checksum field.

Checksum verification — the receiver calculates the new checksum for the received packet, which includes the original checksum, after adding the pseudoheader (see Figure 16.4). If the new checksum is nonzero, then the packet is corrupt and is discarded.

Urgent Pointer — this 16-bit field is used only if the URG flag is set. It defines the location of the last urgent byte in the data section of the segment. Urgent data are data sent out of sequence. For example, a telnet client sends a break character without queuing it in the sending buffer.

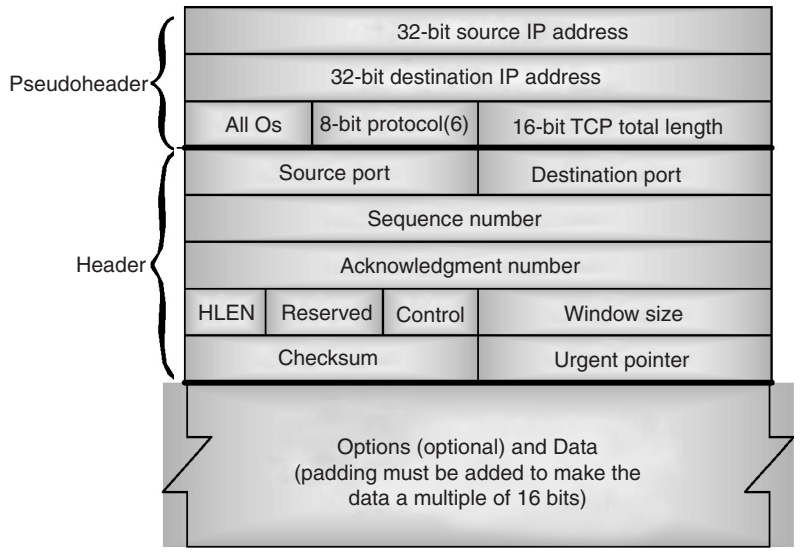

FIGURE 16.4 Pseudoheader added to the TCP datagram.

© 2005 by CRC Press LLC

Options — there can be up to 40 bytes of options appended to the header. The options are padded inside with 0's so that the total number of bytes in the header is divisible by four. The possible options are listed below and are illustrated in Figure 16.5.

No Operation — 1-byte option used as a filler between the options and as padding.

End of Options — 1-byte option used as a padding at the end of options filed. Data portion of the segment follows immediately.

Maximum segment size — option defines the maximum size of a chunk of data that can be received. IT refers to the size of data and not the whole segment. It is used only during the establishment of the connection. The receiving party defines the maximum size of *r* the sender. If not specified, the default maximum is 536.

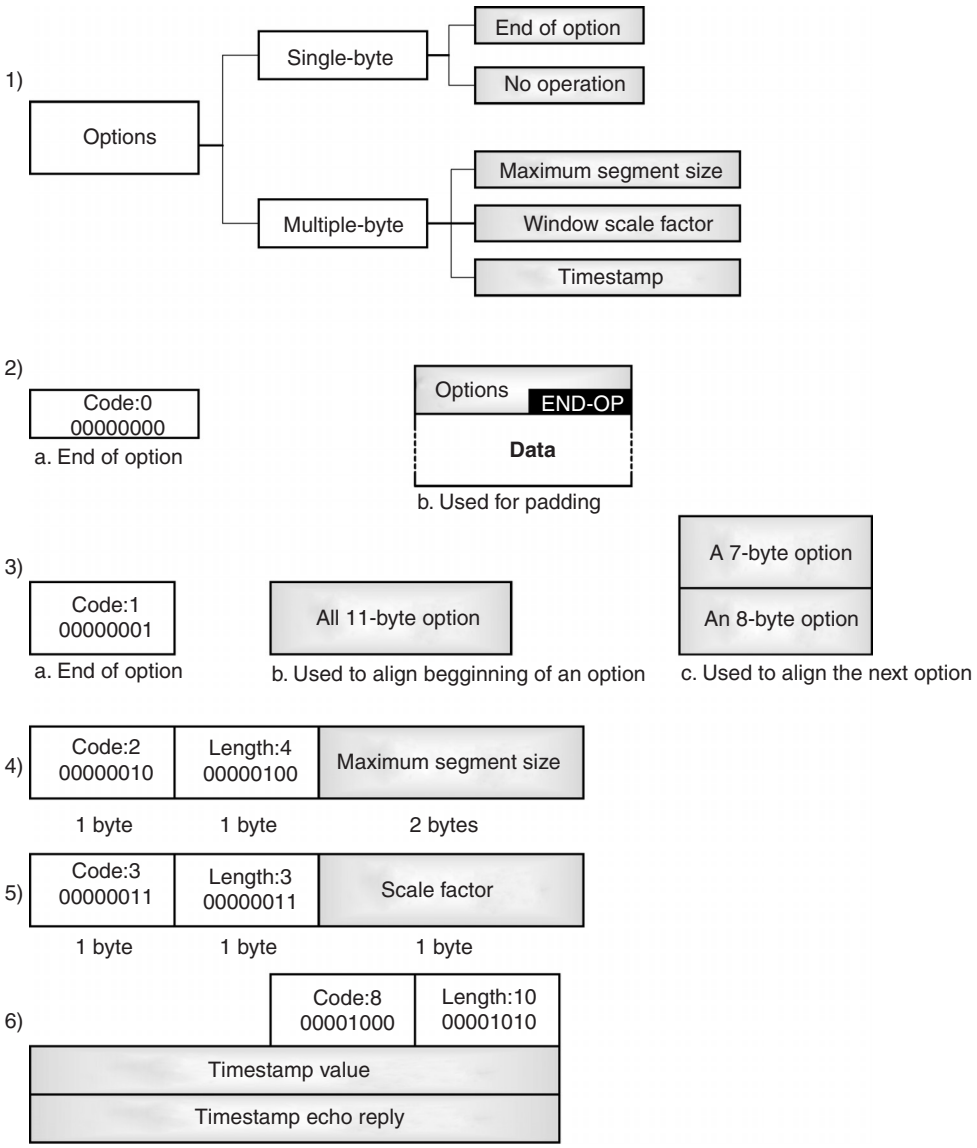

FIGURE 16.5 TCP options: classification — 1, end of options — 2, no operation (used for padding) — 3, setting maximum segment size — 4, setting window scale factor — 5, time stamp — 6.

© 2005 by CRC Press LLC

Window scale factor — for the high throughput channels, the window size from the segment header (16-bit, maximum 65,535) may not be sufficient. This 3-byte option defines the multiplication factor for the window size. The actual window size is computed suing the following formula:

$$ActualWindowSize = WindowSize \cdot 2^{WindowScale\ eFactor}$$

Time stamp — this is a 10-byte option that holds the time stamp value of transmitted segment. When an acknowledgement is sent, the same value is used. This allows the original sender to determine the optimal retransmission time based on the packet round-trip time.

Port Number Assignments

In order to provide platform-independent process addressing on a host, each connection of the process to the network is assigned a 16-bit number. There are three categories of port numbers: well-known (0–1023), registered (1024–49,151) and ephemeral (49,152–6553). *Well-known ports* have been historically assigned to common services. Some operating systems require that the process that utilizes those ports must have administrative privileges. This requirement was historically created to avoid hackers running server imposters on multi-user systems. Well-known ports are registered and controlled by Internet Assigned Numbers Authority (IANA). Table 16.1 shows well-known ports commonly used by TCP. *Registered ports* are also registered by IANA to avoid possible conflicts among different applications attempting to use the same port for listening to incoming connections. *Ephemeral* ports are also called dynamic ports. These ports are used by outgoing connections that are typically assigned the first available port above 49,151. Some operating systems may not follow IANA recommendations, and treat the registered ports range as ephemeral.

For example, a Web Server usually uses well-known port 80, a proxy-server may typically use registered port 8080, a Web browser uses multiple ephemeral ports, one for each new connection open to download a component of a Web page. Ephemeral ports are eventually recycled.

Connection Establishment

Before data transfer begins, TCP establishes a connection between two application processes by setting up the protocol parameters. These parameters are stored in a structure variable called TCB.

TABLE 16.1 Well-known Ports Used with TCP

Port	Protocol	Description	RFC/STD #
7	Echo	Echoes received data back to its sender	STD20
9	Discard	Discards any data that are received	STD21
11	Users	Active users	STD24
13	Daytime	Returns the date and the time in ASCII string format	STD25
17	Quote	Returns a quote of the day, ASCII string up to 512 characters	STD23
19	Chargen	Returns a string of characters of random length 0 to 512 characters	STD22
20	FTP Data	File Transfer Protocol (data transmission connection)	STD9
21	FTP Control	File Transfer protocol (control connection)	STD9
23	Telnet	Telnet	STD8, STD27-STD32
25	SMTP	Simple Mail Transfer Protocol (sending email)	STD10
37	Time	Returns the current time in seconds since 1/1/1900 in a 32-bit format	STD26
53	Nameserver	Domain Name Service	STD13
67	Bootps	Bootstrap Protocol Server	RFC951
68	Bootpc	Bootstrap Protocol Client	RFC951
79	Finger	Finger	RFC1288
80	HTTP	Hypertext Transfer Protocol	RFC2616
110	POP3	Post Office Protocol 3 (email download)	STD53
111	RPC	SUN Remote Procedure Call	RFC1831
143	IMAP	Interim Mail Access Protocol v2 (email access)	RFC2060
443	SHTTP	Secure Hypertext Transfer Protocol	RFC2660

© 2005 by CRC Press LLC

Before the two parties, called here hosts A and B, can start sending data, four actions must be performed:

1. Host A sends a segment announcing that it wants to establish connection, which includes initial information about traffic from A to B.
2. Host B sends a segment acknowledging the request received from A.
3. Host B sends a segment with information about traffic from B to A.
4. Host A sends a segment acknowledging the request received from B.

The second and the third steps can be combined into one segment. Therefore, the connection establishment described is also called *three-way handshaking*. Figure 16.6 illustrates an example of segment exchange during connection establishment. Among the two programs that are involved in the connection, the server program is the one that passively waits for another party to connect. Hereafter, it will be called the server. It informs the underlying TCP library in its system that it is ready to accept a connection. The program that actively seeks connection is called a client program. Hereafter, it will be called the client. The client informs the underlying library in its system that it needs to connect to a particular server that is defined by the computer IP address and the destination port number.

1. The client sends the first segment that includes the source and destination port with SYN bit set. The segment also contains the initial value of Sequence Number that is also called the initialization sequence number (ISN) that will be used by the client in this connection. The client may also send some options as necessary, for example, to alter the window size, or maximum segment size in order to change their values from default.
2. The server sends the second segment that has both ACK and SYN bits set. This is done in order to both acknowledge receipt of the first segment from the client (ACK) and to initialize the sequence number in the direction from the server to the client (SYN). The Acknowledgement number is set to the client ISN plus one. The server ISN is set to a random number. The option to define client window size must also be sent.
3. In reply to the segment from the server, the client sends as segment with ACK bit set and the segment number set to its ISN plus one. The acknowledgement number is set to the server ISN plus one.

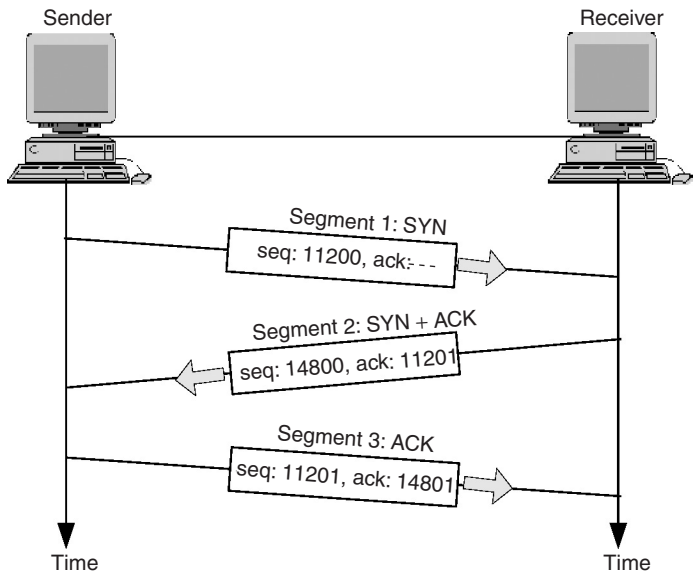

FIGURE 16.6 Three-way handshaking during connection establishment.

© 2005 by CRC Press LLC

4. In very rare situations, the two processes may want to start connection at the same time. In that case, both will issue an active open segment with SYN and ISN, and then both would send the ACK segment. A situation when one of the segments is lost during the transmission and needs to be resent after time out may also be analyzed.

Maintaining the Open Connection

After a connection is established, each process can send data. Each segment has its sequence number increased by the number of bytes sent in the previous segment, with the previous sequence number. The number rolls over at 2^{32}. The process expects to receive segments with ACK bit set and acknowledgement numbers that confirm that data are received. Acknowledgement number is not merely the repetition of the received sequence number. It indicates the next expected sequence number of a segment to be received by the acknowledging process. Acknowledgements must be received within a certain time frame; not every segment that is sent needs to be acknowledged. Sending acknowledgment of a certain segment also acknowledges receiving all previous segments. More segments are usually sent ahead before the sender expects to receive an acknowledgement. Sending an acknowledgement can be combined with sending data in the other direction (*piggybacking*).

Flow Control and Sliding Window Protocol

A certain amount of data are sent before waiting for an acknowledgment from the destination. In extreme situations, the process may wait for an acknowledgement for each segment; but this would make the long-distance transmission very slow due to long latency. On the other hand, the process may send all data without waiting for the confirmation. This is also impractical because a high volume of data may need to be retransmitted in case a segment in the middle of the transmission is lost.

Sliding window protocol is a solution in between the two extreme situations described above that TCP implements in order to speed up the transmission. TCP sends as much data as allowed by a so-called sliding window before waiting for an acknowledgement. After receiving an acknowledgement, it moves (slides) the window ahead in the outgoing data buffer as illustrated in Figure 16.7.

On the receiving side, incoming data are stored in the receiving buffer before data are consumed by the communicating process. Since the size of the buffer is limited, the number of bytes that can be received at a particular time is limited. The size of the unused portion of the buffer is called the *receiver window*. In order to maintain the flow control, the sender must be prevented from sending excessive amount of data and overflowing the incoming data buffer. This is implemented by controlling the timing when the acknowledgements are sent.

If the receiving process consumes data at a faster rate than they arrive, then the receiver window expands. This information is passed to the sender as an option included in a segment so that the sender may synchronize the size of its *sender window*. This allows more data to be sent without receiving an acknowledgement. If the receiving process consumes data slower than they arrive, then the receiver buffer shrinks. In that case, the receiver must inform the sender to shrink the sender window as well. This causes transmission to wait for more frequent acknowledgements and prevents data from being sent without the possibility of storing. If the receiving buffer is full, then the receiver may close (set to zero) the receiver window. The sender cannot send any more data until the receiver reopens the window.

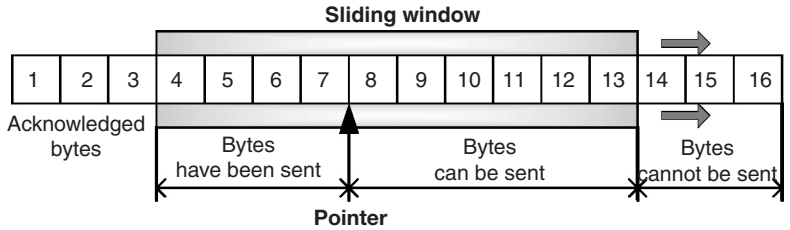

FIGURE 16.7 Sender buffer and sliding window protocol.

© 2005 by CRC Press LLC

Improving Flow Control

In the case when one or both communicating processes process data slowly, a problem leading to significant bandwidth waste may arise. In case of slow transmission caused by the receiving processes, the sliding window may be reduced even as low as to one byte. In case of slow transmission caused by the sender, data may be sent as soon as they are produced even with a large window, one byte at a time as well. This produces segments carrying small data payload, and lowers the ration of carried data size to the total segment size, and to the total packet size in the underlying protocols.

To prevent this situation, data should not be sent as soon as they becomes available; but should be combined in larger chunks provided that this approach is suitable for a particular application. Nagle found a very good and simple solution for the sender that is called *Nagle's Algorithm*. The algorithm can be described by the following three steps:

- The first piece of data is sent immediately even if it is only one byte.
- After sending the first segment, the sender waits for the acknowledgement segment or until enough data are accumulated to fill in the segment of the maximum segment size, whatever happens first. Then, it sends the next segment with data.
- The previous step is repeated until the end of transmission.

On the receiving side, two different solutions are frequently used. *Clark* proposed to send the acknowledgement as soon as the incoming segment arrives but to set the window to zero if the receiving buffer is full (Figure 16.8b), and then to increase the buffer only after a maximum size of a segment can be received or half of the buffer becomes empty. The other solution is to delay the acknowledgment, thus preventing the sender form sending more segments with data. The latter of the two solutions creates less network traffic; but it may cause unnecessary segment retransmission if the delay is too long.

Error Control

TCP as a reliable protocol that uses unreliable underlying IP protocol must implement error control. This error control includes detecting lost segments, out-of-order segments, corrupted segments, and duplicated segments. After detection, the error must be corrected. The error detection is implemented by using three features: segment checksum, segment acknowledgement, and time-out. Segments with *incorrect checksum* (Figure 16.9a) are discarded. Since TCP uses only positive acknowledgement, no negative acknowledgement can be sent, and both the corrupted segment error and the *lost segment* (Figure 16.9b) error are detected by time-out for receiving an acknowledgement by the sender.

The error correction is implemented by establishing a *time-out counter* for each segment sent. If the acknowledgement is received, then the particular and all preceding counters and the segments are disposed. If the counter reaches time-out, then the segment is resent and the timer is reset.

A *duplicate segment* can be created if acknowledgement segment is lost or is delayed too much, since data are reassembled into a byte-stream at the destination data from the duplicate segment is already in the buffer. The duplicate segment is discarded. No acknowledgement is sent.

An *out-of-order segment* is stored but not acknowledged before all segments that precede it are received. This may require resending the segments. The duplicates are discarded.

In case of *lost acknowledgement* (Figure 16.9c), the error is corrected when the acknowledgement for the next segment is sent since an acknowledgement to the next segment also acknowledges all previous segments. Therefore, a lost acknowledgement may not be noticed at all. This could generate a deadlock in case the acknowledgment is sent on the last segment and for a time there are no more segments to send. This deadlock is corrected by a sender who uses a so-called *persistence timer*. If no acknowledgment comes within a certain time frame, then the sender sends a one-byte segment called probe and resets the persistence counter. With each attempt, the persistence timer time-out is doubled until 60 sec time are reached. After receiving an acknowledgement, the persistence timer time-out is reset to the initial value.

Keep-alive timer is used to prevent a long idle connection. If no segments are exchanged for a given period of time, usually 2 h, the server sends a probe. If there is no response after 10 probes, the connection is reset and thus terminated.

© 2005 by CRC Press LLC

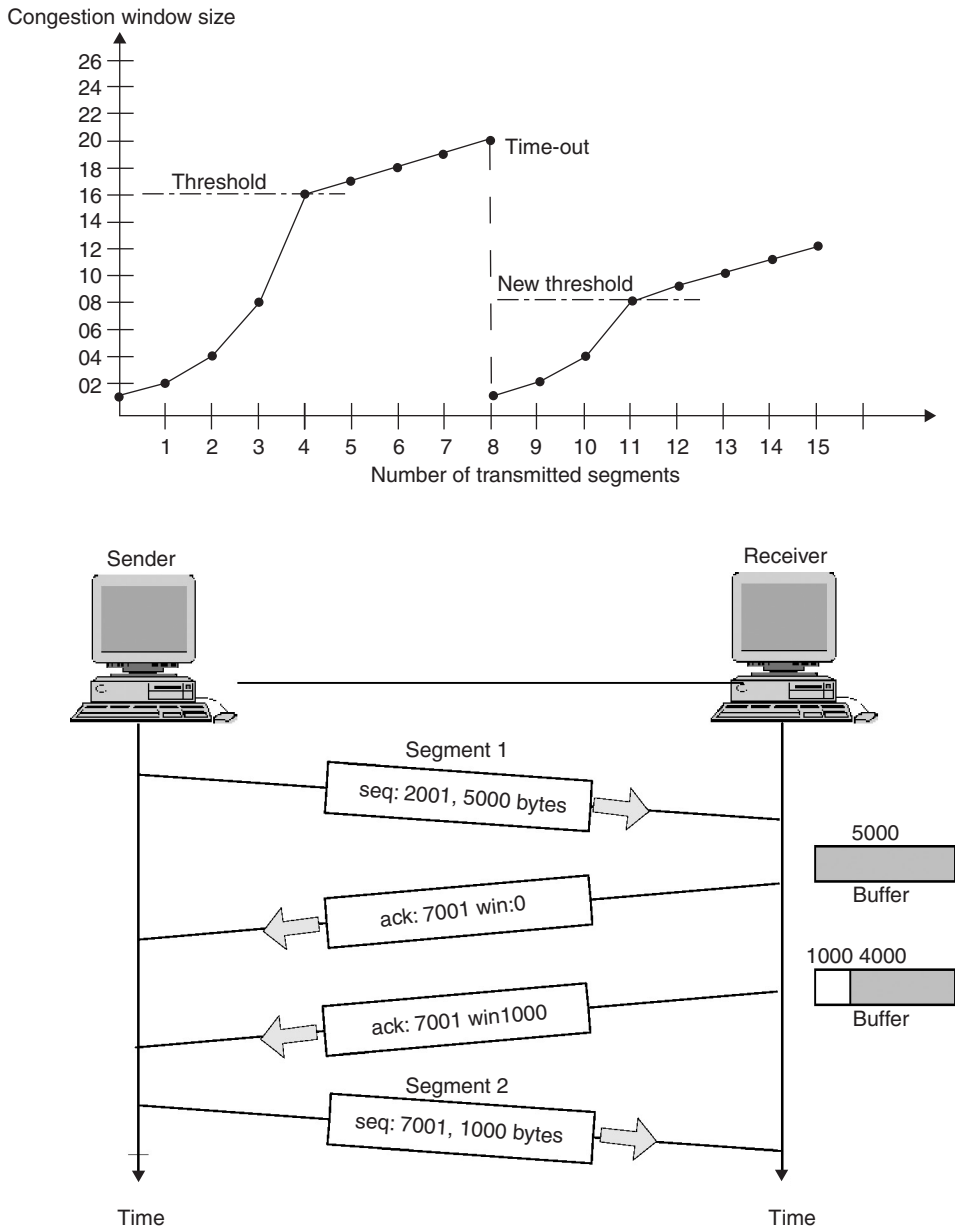

FIGURE 16.8 Congestion Control Window Size. Sender-side A (upper/left), receiver-side control B (lower/right).

Time-waited timer is used during the connection termination procedure that is described later. If there is no acknowledgment to the FIN segment, the FIN segment is resent after time-waited timer expires. Duplicate FIN segments are discarded by the destination.

Congestion Control

In case of congestion on the network, packets could be dropped by routers. TCP assumes that the cause of a lost segment is network congestion. Therefore, an additional mechanism is incorporated into TCP to prevent prompt resending of packets and creating even more congestion. This mechanism is implemented by additional control of the sender window as described below and is illustrated in Figure 16.8a.

© 2005 by CRC Press LLC

- The sender window size is always set to the smaller of the two values: the receiver window size and the *congestion window size*.
- The congestion window size starts at the size of two maximum segments.
- With each received acknowledgement, the congestion window size is doubled until a certain threshold. After reaching the threshold, further increase is additive.
- With each acknowledgement timed out, the threshold is reduced by half and the congestion window size is reset to the initial size of two maximum segment sizes.

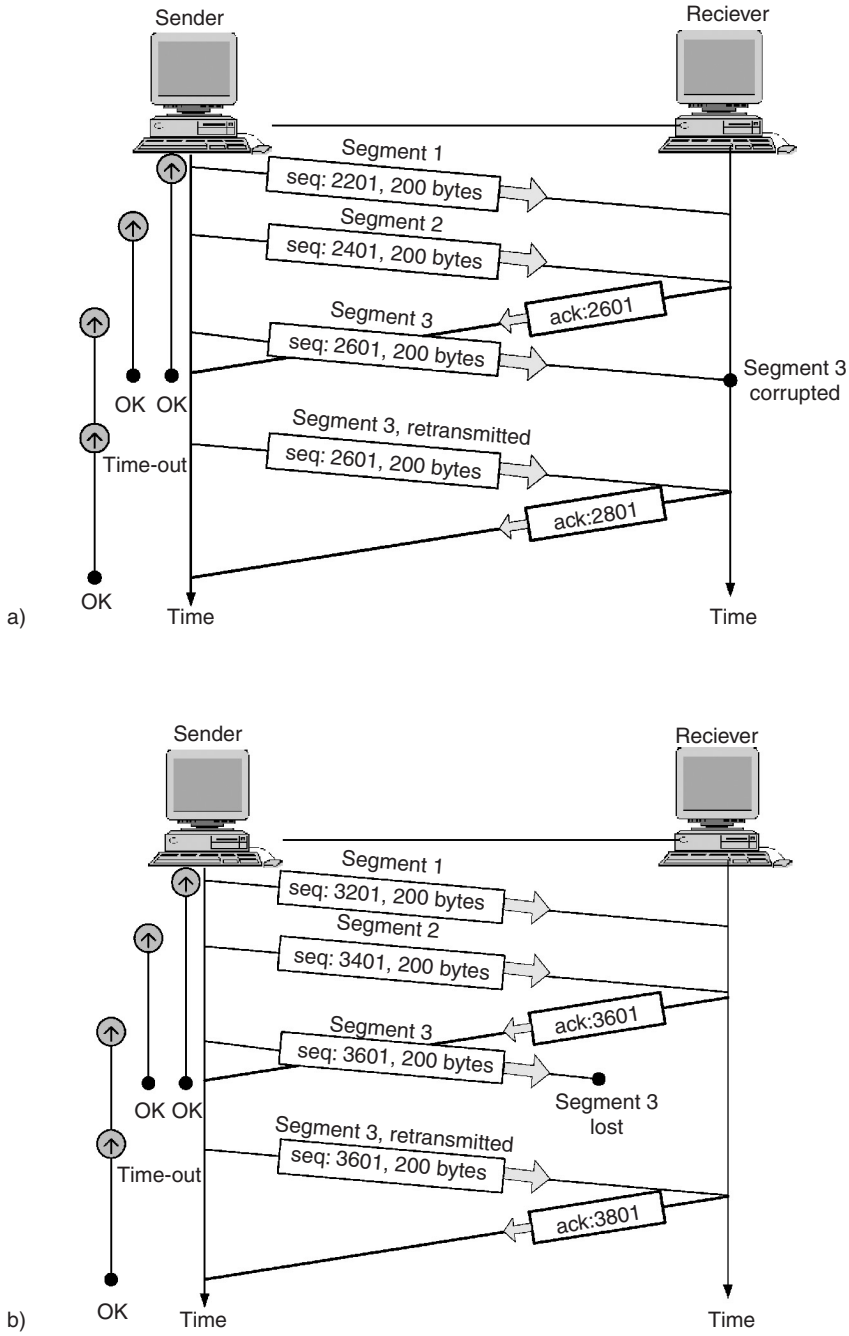

FIGURE 16.9 Corrupted segment (a), Lost segment (b), Lost Acknowledgement (c).

© 2005 by CRC Press LLC

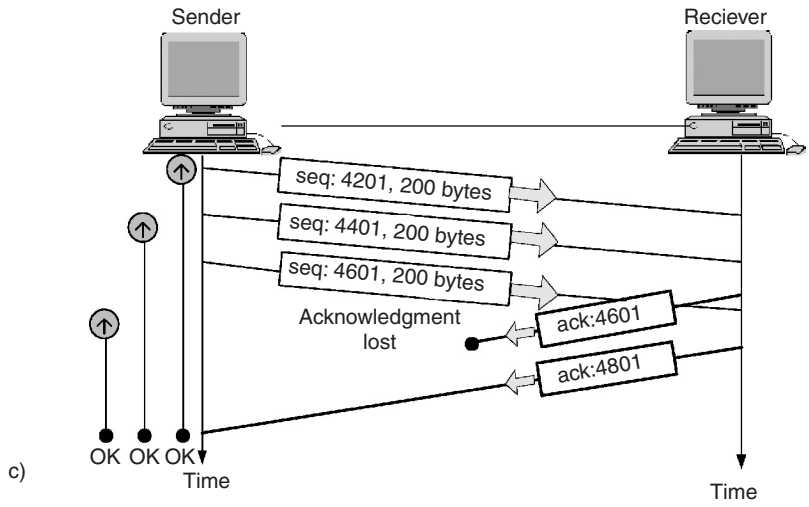

FIGURE 16.9 (Continued).

Connection Termination

Any of the two application processes that established a TCP connection can close that connection. When connection in one direction is terminated, the other direction is still functional, until the second process also terminates it. Therefore, four actions must be performed to close the connection in both directions:

1. Host A (either client or server) sends a segment announcing that it wants to terminate the connection.
2. Host B sends a segment acknowledging the request of A. At that moment, the connection from A to B is closed, but that from B to A is still open.
3. When host B is ready to terminate the connection, for example, after sending remaining data, it sends a segment announcing that it wants to terminate the connection as well.
4. Host A sends a segment acknowledging the request of B. At this moment, the connection in both directions is closed.

Unlike in the case of opening the connection, none of the steps can be combined into one segment. Therefore, the connection termination described is also called *four-way handshaking*. Figure 16.10 illustrates an example of segment exchange during connection termination. Because it does not matter as to which host is a server and which is a client, they are denoted only as A and B.

1. Host A sends a segment with an FIN bit set.
2. Host B sends a segment with ACK bit set to confirm receiving the FIN segment from host A.
3. Host B may continue to send data and expect to receive acknowledgement messages with no data from host A. Eventually, when there is nothing more to send, it sends a segment with FIN bit set.
4. Host A sends the last segment in the transmission with ACK bit set to confirm receiving the FIN segment from host B.

The connection termination procedure described above is so-called graceful termination. In certain cases, the connection may be terminated abruptly by resetting. This may occur in the following cases:

- The client process requested a connection to a nonexistent port. The TCP library on the other side may send a segment with the RST bit set to indicate connection refusal.
- One of the processes wants to abandon the connection because of an abnormal situation. It can send the RST segment to destroy the connection.

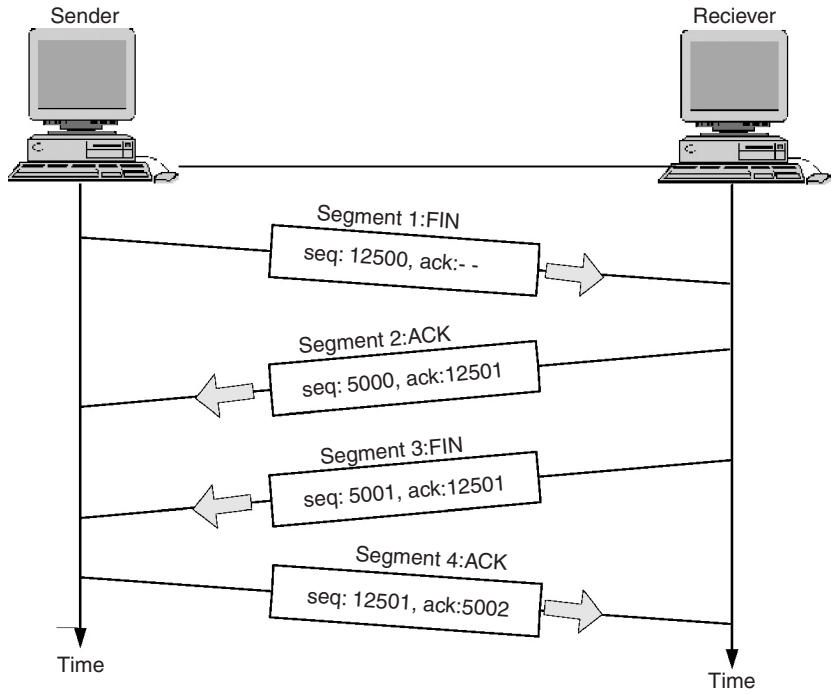

FIGURE 16.10 Four-way handshaking during connection termination.

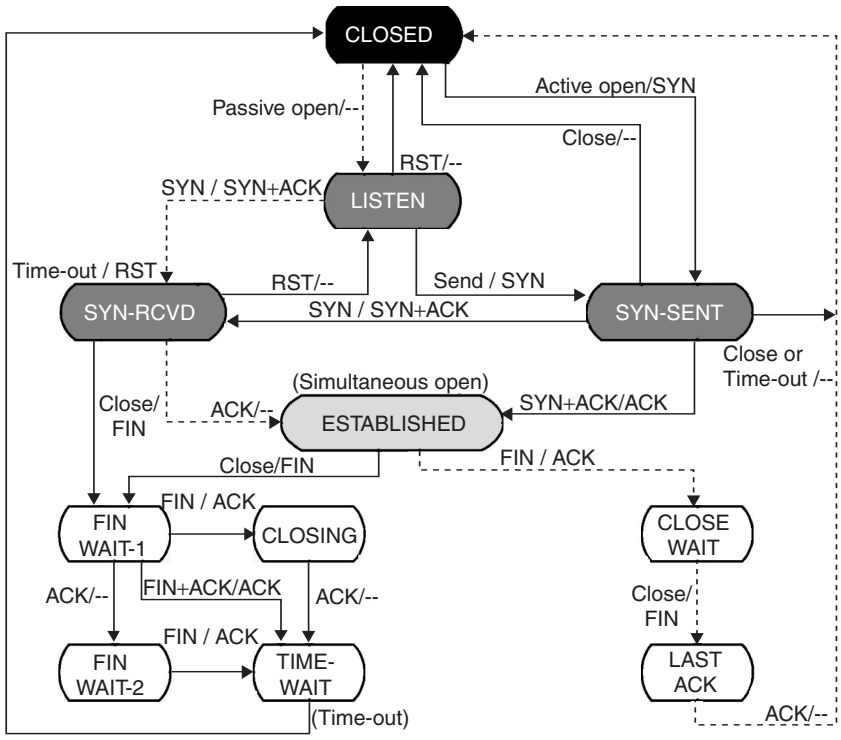

FIGURE 16.11 TCP State Transition Diagram.

© 2005 by CRC Press LLC

- One of the processes determines that the other side is idle for a long time. The other system is considered idle if it does not send any data, any acknowledgements, or keep-alive segments. The awaiting process may send the RST segment to destroy the connection.

16.3 State Diagram

The state transition diagram for software that implements TCP is presented. Figure 16.11 shows the state transition diagram for the server and for the client. The dashed lines indicate transitions in a server. The solid lines indicate transitions in a client.

The User Datagram Protocol

Aleksander Malinowski
Bradley University

Bogdan M. Wilamowski
Auburn University

17.1 Introduction
17.2 Protocol Operation
UDP Datagram • Port Number Assignments • Connectionless Service, Flow, and Error Control

17.1 Introduction

User Datagram Protocol (UDP) is a part of TCP/IP protocol suite. It provides full transport layer services to applications. It belongs to the transport layer in the OSI model as shown in Figure 17.1. UDP provides a connection between two processes at both ends of the transmission. This connection is provided with minimal overhead, without flow control or acknowledgement of received data. The minimal error control is provided by ignoring (dropping) received packets that fail the checksum test.

17.2 Protocol Operation

The underlying IP protocol facilitates data transport through the network between two hosts. UDP allows addressing particular processes at each host so that incoming data are handled by a particular application. Addressing the processes is implemented by assigning each connection to the network a number that is called a port number, Figure 17.2 illustrates the concept of port numbers and shows the difference between IP and UDP addressing. UDP packets are also called *datagrams*. Each datagram is characterized by four parameters: the IP address and the port number at each end of the connection. Certain classes of destination IP addresses may not describe individual computers but a group of processes on multiple hosts that are to receive the same datagram. This particular case of *multicasting* is described in another article entitled "UDP multicasting routing."

Although the term connection is used here, unlike in the case of Transmission Control Protocol (TCP), there is no persistent connection between the two processes. The data exchange may follow a certain pattern or protocol; but there is no guarantee that all data may reach the destination and that the order of their receiving would be the same as the order they were sent. The client–server approach that is usually used to describe the interaction between two processes can still be used. The process that may be identified as waiting for the data exchange is called the *server*. The process that may be identified as one that initializes that exchange is called the *client*.

UDP Datagram

UDP datagrams have a constant size 8-byte header prepended to the transmitted data as shown in Figure 17.3. The meaning of each header field is described below.

© 2005 by CRC Press LLC

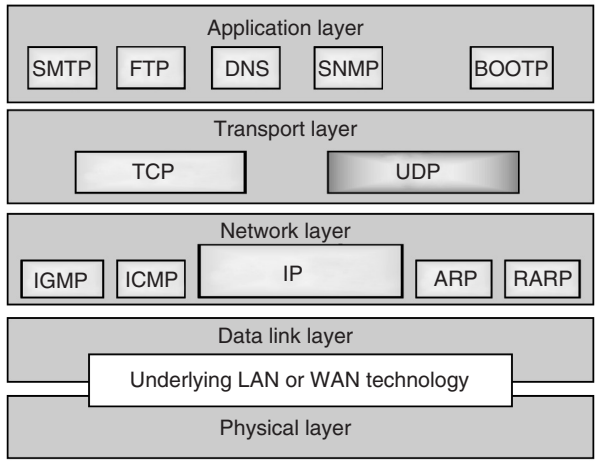

FIGURE 17.1 UDP and TCP/IP in the OSI model.

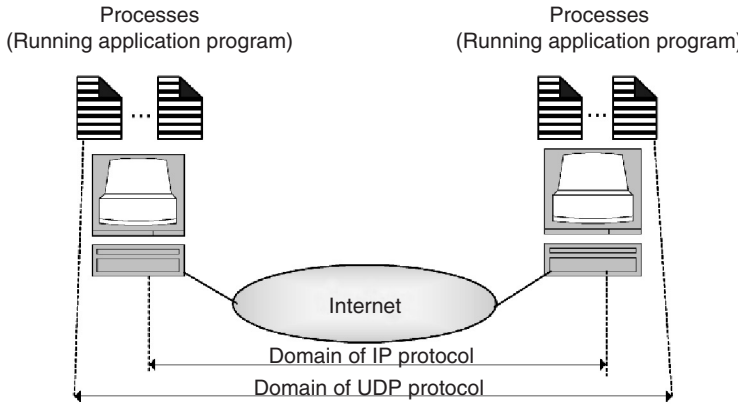

FIGURE 17.2 Comparison of IP and UDP addressing.

Source Port Address — this is a 16-bit field that contains a port number of the process that sends options or data in this segment.

Destination Port Address — this is a 16-bit field that contains a port number of the process that is supposed to receive options or data carried by this segment.

Total Length — this is a 16-bit field that contains the total length of the packet. Although the number could be in the range from 0 to 65,535 the minimum length is 8 bytes, which correspond to the packet with the header and no data. The maximum length is 65,507 because 20 bytes are used by the IP header and 8 bytes are used by the UDP header. Thus, this information is redundant to the packet length stored in the IP header.

Checksum — this 16-bit field contains the checksum. The checksum is calculated by

Initially filling it with 0's.

Adding a pseudoheader with information from the IP protocol as illustrated in Figure 17.4.

Treating the whole segment with the pseudoheader prepended as a stream of 16-bit numbers. If the number of bytes is odd, 0 is appended at the end.

Adding all 16-bit numbers using 1's complements binary arithmetic.

Complementing the result. This complemented result is inserted into the checksum field.

© 2005 by CRC Press LLC

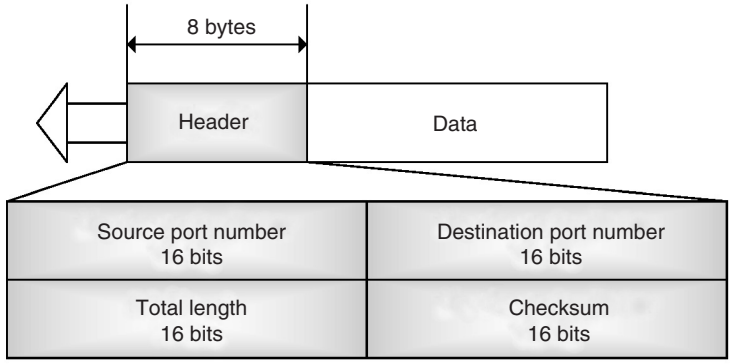

FIGURE 17.3 User datagram format.

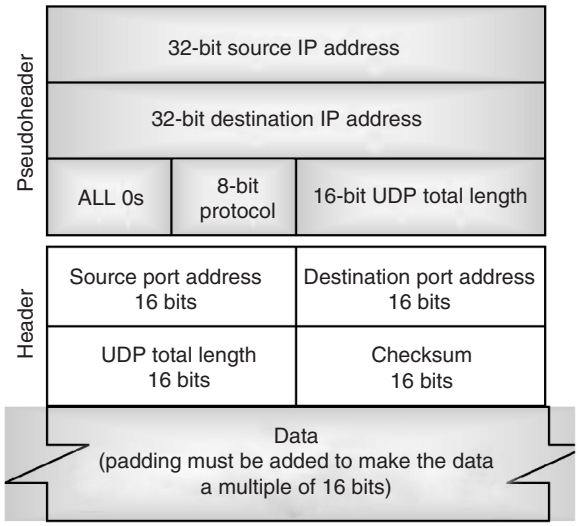

FIGURE 17.4 Pseudoheader added to the UDP datagram.

Checksum verification — the receiver calculates the new checksum for the received packet that includes the original checksum, after adding the so-called pseudoheader (see Figure 17.4). If the new checksum is nonzero, then the datagram is corrupt and is discarded.

In case of UDP, the use of checksum is optional. If it is not calculated, then the field is filled with 0's. The receiver can determine whether checksum was calculated by inspecting the field. Even in case the checksum is 0, the field does not contain 0 as the calculated checksum is complemented at the end of the process, and negative 0 (the field filled with 1's) is stored.

Port Number Assignments

In order to provide platform-independent process addressing on a host, each connection of the process to the network is assigned a 16-bit number. There are three categories of port numbers: well-known (0–1023), registered (1024–49,151), and ephemeral (49,152–6553). *Well-known ports* have been historically assigned to common services. Table 17.1 shows well-known ports commonly used by UDP. Some operating systems require that processes utilizing those ports must have administrative privileges. This requirement was historically created to prevent hackers from running server imposters on multi-user systems. Well-known ports

© 2005 by CRC Press LLC

TABLE 17.1 Well-known Ports Used with UDP

Port	Protocol	Description	RFC/STD #
7	Echo	Echoes a received datagram back to its sender	STD20
9	Discard	Discards any datagram that is received	STD21
11	Users	Active users	STD24
13	Daytime	Returns the date and the time in ASCII string format	STD25
17	Quote	Returns a quote of the day, ASCII string up to 512 characters	STD23
19	Chargen	Returns a string of characters of random length 0 to 512 characters	STD22
37	Time	Returns the current time in seconds since 1/1/1900 in a 32-bit format	STD26
53	Nameserver	Domain Name Service	STD13
67	Bootps	Bootstrap Protocol Server	RFC951
68	Bootpc	Bootstrap Protocol Client	RFC951
69	TFTP	Trivial File Transfer	STD33
111	RPC	SUN Remote Procedure Call	RFC1831
123	NTP	Network Time Protocol	STD12
161	SNMP	Simple Network Management Protocol	STD62
162	SNMP	Simple Network Management Protocol (trap)	STD62

are registered and controlled by Internet Assigned Numbers Authority (IANA). *Registered ports* are also registered by IANA to avoid possible conflicts among different applications attempting to use the same port for listening to incoming connections. *Ephemeral* ports are also called dynamic ports. These ports are used by outgoing connections that are typically assigned the first available port above 49,151. Some operating systems may not follow IANA recommendations and treat the registered ports range as ephemeral.

Connectionless Service, Flow, and Error Control

As already outlined, UDP provides connectionless communication. Each datagram is not related to another datagram coming earlier or later from the same source. The datagrams are not numbered. There is no need for establishing or tearing down the connection. In the extreme case, just one datagram might be sent in the process of data exchange between the two processes.

UDP does not provide any flow control. The receiving side may overflow with incoming data. Unlike in TCP, which has a windowing mechanism, there is no way to control the sender. There is no error control other than the checksum discussed above. The sender cannot be requested to resend any datagram. However, an upper-level protocol that utilizes UDP may implement some kind of control. In that case, unlike in TCP, no data are repeated by resending the same datagram. Instead, the communicating process sends a request to send some information again. Trivial File Transfer Protocol (TFTP) is a very good example of that situation. Since it has its own higher level flow and error control, it can use UDP as a transport-layer protocol instead of TCP. Other examples of UDP utilization are Simple Network Management Protocol (SNMP) or any other protocol that requires only a simple short request-response communication.

18.4 ARP Problems
18.5 Proxy ARP
18.6 Possible ARP Attacks
18.7 RARP — Reverse Address Resolution Protocol
18.8 InARP — Inverse Address Resolution Protocol
18.9 Summary

Jürgen Falb
Vienna University of Technology

In every network, datagrams have to be transmitted over a physical network medium. At this level, network interface cards use MAC addresses (MAC = Media Access Control) for addressing the communication partner. This is necessary because MAC layer protocols support methods of sharing the physical line among a number of computers in contrast to point-to-point protocols like Point-to-Point Protocol (PPP) or Serial Line Interface Protocol (SLIP). The MAC address is used by the MAC sublayer of the Data-Link Layer (layer 2 of the ISO/OSI model responsible for a reliable data transmission over a physical link) to unambiguously identify a host on the physical line. Different physical media use different types of MAC addresses. For example, Ethernet uses 48-bit Ethernet addresses.

By using higher-level protocols like TCP/IP, it is necessary to map protocol addresses (e.g., IP addresses) to MAC addresses (e.g., Ethernet addresses) to be able to transport a datagram to the next host connected to the same physical line. Earlier, a table manually configured on each network node did this mapping. Increasing node numbers and frequent network changes (e.g., notebooks) made it necessary to define a mechanism for automatically configuring the mapping table. The Address Resolution Protocol (ARP) defined in RFC 826 [1, 8] was designed to convert protocol addresses into MAC addresses by solving the prior-mentioned problem. The subsequent sections will describe ARP by concentrating on the most common case: the conversion of IP addresses into Ethernet addresses.

18.1 Operation of The Address Resolution Protocol

If an IP module wants to send a datagram to another host, it looks up the desired IP address in a mapping table called ARP cache. If it finds a corresponding entry in the ARP cache, it uses the associated MAC address to send the datagram to the MAC address. Is there no suitable entry in the ARP cache, the ARP mechanism will be invoked, as explained in the following paragraph.

© 2005 by CRC Press LLC

First, the ARP module builds an ARP datagram containing the required IP address it wishes to resolve. It sends this packet to all hosts connected to the physical line by using a broadcast MAC address (ff:ff:ff:ff:ff:ff in case of 48 bit Ethernet addresses). Each host on the local network reads the datagram and compares the requested IP address with its own IP address. The host identified by the requested IP address then generates an ARP response datagram to convey its MAC address to the sender. The original sender now knows the MAC address of the desired target host on the local network and inserts the mapping information into his ARP cache. In the final step, the host is now able to send IP datagrams to the host with the desired IP address.

The described process relies on the constraint that the underlying local network has to support broadcasts. Ethernet supports broadcast as well as multicast and unicast using special addresses.

To increase efficiency and reduce the network load, the host generating the ARP response caches the address mapping of the originator of the ARP request. Thus, there is no ARP resolution dialog necessary for sending IP datagrams in the opposite direction.

18.2 The Address Resolution Protocol in Detail

The ARP message structure is simple and was designed for use in all kinds of networks. The only constraint of the Address Resolution Protocol is the requirement of broadcast support on the network side.

ARP operates directly on the Data Link Layer, and therefore is directly embedded in the network frame (Ethernet frame). To distinguish ARP from other network protocols, it uses the value 0x0806 for the "Ethernet Type" field within an Ethernet frame. An ARP datagram itself is structured as shown in Figure 18.1.

ARP datagrams consist of the following header fields:

- *Hardware Type*: The hardware type field specifies the network hardware used by the ARP datagram originator. The most important value is "1" for Ethernet. Another typical value is "6" for FDDI (Fiber Distributed Data Interface; for more details, see [3, 4]). This field is most important for switches combining different networks (e.g., Ethernet and FDDI or TokenRing).
- *Protocol Type*: The protocol type field specifies the protocol type of the address to be resolved. A receiving ARP module has to determine if it supports the protocol for the address mapping process.
- *Hardware Address Length*: This header field specifies the length of the hardware address in bytes. For Ethernet addresses, this field has the value "6."
- *Protocol Address Length*: The protocol address length field determines the address length of the higher-level protocol. In case of the Internet Protocol, the value of this field is "4" (32 bit IPv4 addresses).

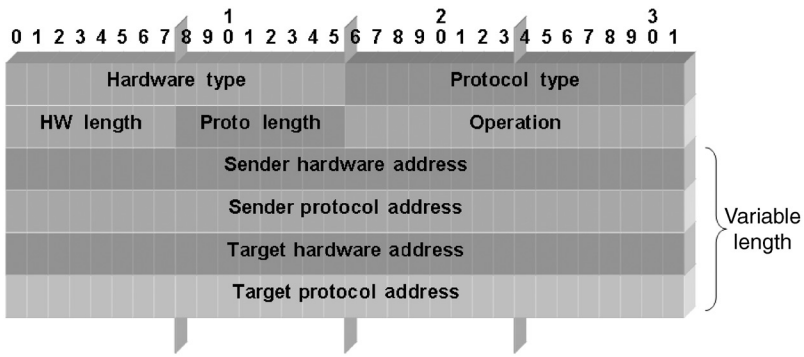

FIGURE 18.1 ARP header.

© 2005 by CRC Press LLC

- *Operation*: The operation field determines if the datagram is a request or a response. There are different values for the different address resolution protocols:
  - 1 — ARP request
  - 2 — ARP response
  - 3 — RARP request (RARP = Reverse Address Resolution Protocol)
  - 4 — RARP response
  - 5 — Dynamic RARP request
  - 6 — Dynamic RARP response
  - 7 — Dynamic RARP error
  - 8 — InARP request (InARP = Inverse Address Resolution Protocol)
  - 9 — InARP response

- *Sender Hardware Address*: This field contains the hardware address of the ARP datagram sender. The length of this field corresponds to the value of the "Hardware Address Length" field. Within an ARP response, this address is the requested hardware address.
- *Sender Protocol Address*: This field contains the protocol address of the ARP datagram sender. This address is typically an IP address. The length of this field corresponds to the value of the "Protocol Address Length" field.
- *Target Hardware Address*: Within an ARP request, this address is unknown and therefore the target address is a broadcast address (Ethernet: ff:ff:ff:ff:ff:ff). An ARP response is always conveyed directly to the originator of the request and contains the hardware address of the ARP request originator.
- *Target Protocol Address*: Within an ARP request, the target protocol address reflects the address that the sender wants to resolve. All hosts on the local network compare this target protocol address with its own protocol address and react by sending an ARP response if they are equal.

An example ARP dialog is shown in Figure 18.2. In this example, the host having the IP address 192.168.1.67 wants to resolve the hardware address belonging to the IP address 192.168.1.142. The sender host broadcasts an ARP request (operation code 0x0001). The hardware type identifies the underlying local network as an Ethernet (0x0001). In the ARP response, the concerned host replies with its MAC address (00:a0:cc:c5:a8:aa).

A problem of ARP lies in the fact that the receiver of the ARP response always assumes that ARP responses are valid. This allows ARP spoofing as explained later.

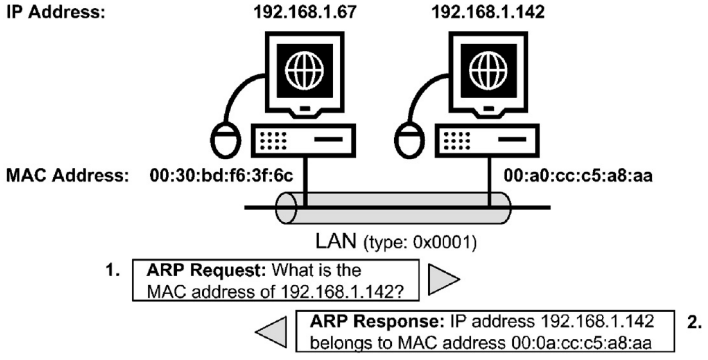

FIGURE 18.2 Example ARP dialog.

© 2005 by CRC Press LLC

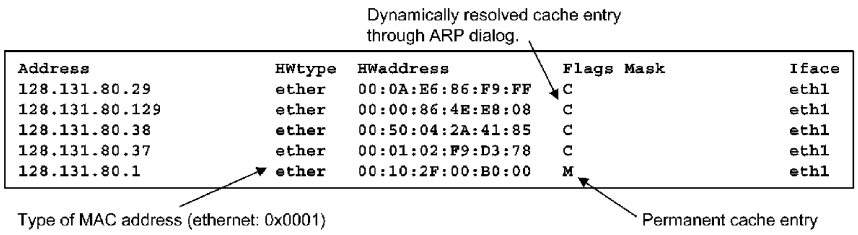

FIGURE 18.3 ARP cache.

18.3 The ARP Cache

The ARP cache contains statically configured mappings and dynamically resolved MAC addresses to reduce the network load and the response time. Figure 18.3 shows a sample output of the "arp" command, which can be used to display and modify the ARP cache of a system. The flag "C" marks an entry as dynamically resolved. Most systems keep the entries in the cache until either the cache is full or the entry is aged out because it was not used for a specified time. Typical aging times are 15 min. Common cache sizes are 128–512 entries. This implies that in usual subnets, entries need not be removed from the cache.

Furthermore, the ARP cache expects a positive feedback from higher-level protocols to mark an ARP entry as valid. For example, a positive feedback can be retrieved from a successful TCP ACK packet. If the cache cannot receive a positive feedback, it marks the entry as stale and removes it after a specified time if it still does not receive a positive feedback.

18.4 ARP Problems

The most common error in conjunction with ARP is based on the situation that two hosts get the same IP address. Let us examine the following scenario:

Hosts A and B get the same IP address. Host A starts a communication with host C by sending an ARP request to resolve the MAC address of host C. Host C sends back an ARP response to host A and inserts the MAC address of host A into its ARP cache. After a while of communication between host A and host C, host B initiates a communication with host C by sending an ARP request to resolve host C's MAC address. Since host C gets an ARP request from host B with the identical IP address, it replaces the MAC address of host A with the MAC address of host B. From now on, host C sends all datagrams intended for host A to host B. Host B discards these unknown datagrams and probably generates error messages. Host A will get a timeout because it does not receive any more datagrams from host C and will restart its communication by sending an ARP request. Now the whole described procedure restarts again. This effect caused by IP address conflicts is often called "flip-flop."

An example "flip-flop" notification message generated by an "arpwatch" daemon can be seen in Figure 18.4. This example shows a time span of about 1 min between the changes of the MAC address in the ARP cache. Network administrators often use such tools to identify changes and problems in the network structure.

The second problem with ARP occurs if a central component like a switch or a physical line fails. The failure of a switch leads to the removal of all ARP entries in the ARP caches of all hosts connected to this switch if there is no communication possible for some minutes. This results in a heavy network load caused by ARP broadcasts in the beginning when the switch is operating again.

18.5 Proxy ARP

Proxy ARP was used for large IP networks (e.g., Class B network) with routers and gateways in between. Nowadays, Proxy ARP has become less important due to the use of subnets and switches.

© 2005 by CRC Press LLC

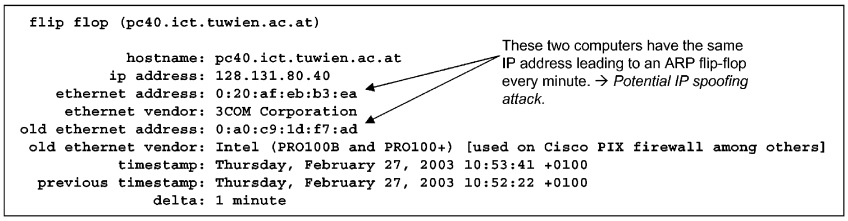

FIGURE 18.4 Ethernet address flip-flop.

In a large IP network that has not been split into subnets, it is not possible to connect all hosts to one physical medium since Ethernet, for example, only allows 1024 hosts on one physical line. Therefore, routers are needed, which forward the ARP requests and responses to the other network segments. In this case, the router replaces the sender MAC addresses with its own MAC addresses while forwarding ARP requests and responses and stores the original mapping between protocol address and MAC address together with the network interface in a routing table. A host trying to communicate with a host on the other side of the router now sends all datagrams to the router because it got the MAC address of the router in the ARP request or response. The router forwards datagrams to the other host, which sends IP datagrams back to the router, since it got the router's MAC address in the ARP request or response, too.

Nowadays, using subnets, it is not necessary to forward ARP datagrams since hosts will look up a suitable IP gateway on the local network in their IP routing table and therefore it is not necessary to look up MAC addresses of hosts behind a router. Nevertheless, switches forward ARP datagrams to the involved ports; but they need not rewrite the ARP datagrams if the network interface type is the same on all ports.

18.6 Possible ARP Attacks

The following sections describe the two most common kinds of possible ARP attacks.

Denial of Service Attack by ARP Storms: This attack tries to overload a network component or a whole network segment by broadcasting ARP requests for nonexistent IP addresses. If the system contains Proxy ARP routers, they will start forwarding the broadcasts to all network segments. The effect can be amplified by generating synthetic ARP responses for the ARP requests. Routers forwarding these responses using broadcasts further increase the network load.

ARP Spoofing: An attacker retains his MAC address but tries to acquire the IP address of a trusted host. To achieve this goal, he has to modify the mapping of the spoofed host remotely. This can be done by different methods, for example, being the first answering an ARP request. From this time, all IP traffic belonging to this IP address goes to the attacker. This kind of attack is not very attractive for the attacker. The drawback is that on the one hand, entries in the ARP cache can age quite fast, making it necessary to keep the ARP cache updated with the hackers MAC address and on the other intelligent hardware that can suppress such attacks.

18.7 RARP — Reverse Address Resolution Protocol

The Reverse Address Resolution Protocol was designed for devices that are not able to store their IP addresses. These are, for example, diskless workstations. In contrast to ARP, RARP is designed to look up an IP address for a particular MAC address. RARP is specified in RFC 903 [2].

ARP and RARP are different operations. ARP assumes that every host knows the mapping between its own hardware address and protocol address(es). Information gathered about other hosts is accumulated in a small cache. All hosts are equal in status; there is no distinction between clients and servers.

On the other hand, RARP requires one or more server hosts to maintain a database of mappings from hardware address to protocol address and respond to requests from client hosts.

© 2005 by CRC Press LLC

The datagram format of RARP messages is identical to ARP messages. The differences from ARP are: by using 0x8035 as Ethernet Type Code, it is possible to distinguish RARP from ARP and other higher-level protocols like IP. If the same module handles ARP and RARP messages, the operation code can be used to distinguish between ARP requests, ARP responses, RARP requests, and RARP responses (see Operation Header field on page 2).

By using RARP, one or more RARP servers are needed, maintaining large tables containing the mapping between MAC addresses and network addresses.

If a host needs to know its protocol address (e.g., IP address), it sends an RARP request to an RARP server by unicast or broadcast with its MAC address set in the "Sender Hardware Address" field and the desired protocol type (e.g., IP) set in the "Protocol Type" field. The RARP server sends back an RARP response with all address fields filled out. Therefore, the host knows its IP address and the IP address of the RARP server, which can be used to save an additional ARP request to figure out the RARP server's IP address.

Actually, RARP is not widely used, since it has strong competitors in the Bootstrap Protocol (BOOTP) [5,8] and Dynamic Host Configuration Protocol (DHCP) [6–8] protocols having a richer feature set.

There are some extensions available defined in RFC1931 [9] and called Dynamic RARP (DRARP). The main difference is that a DRARP server always sends an answer back to the originating host. An RARP server, on the other hand, only returns a response if it finds a suitable protocol address for the senders MAC address. In contrast, a DRARP server returns at least an error response if no protocol address was found. Additionally, a DRARP server can return temporary protocol addresses not configured in the mapping table. DRARP was never really used, because it was immediately replaced by DHCP.

18.8 InARP — Inverse Address Resolution Protocol

InARP, specified in RFC 2390 [10], can be seen as an extension to ARP to be able to look up protocol addresses for a given MAC address. InARP originates from Frame Relay [11]. Frame Relay has the following problem: in Frame Relay data are transmitted over so-called "virtual circuits." These virtual circuits will be established by signaling messages and are identified by Data Link Connection Identifier (DLCI). The DLCI can be seen as a MAC address. During communication, the virtual circuits together with their DLCIs can change. Now, the problem is that a host recognizes the reconfigured "MAC addresses," but is not able to associate it with a protocol address again. For this purpose, InARP was developed.

Reverse ARP, for example, seemed like a good candidate; but the response to a request is the protocol address of the requesting host, not the host receiving the request. IP-specific mechanisms were limiting since they would not allow the resolution of protocols other than IP. For this reason, the ARP protocol was expanded.

Basic InARP operates essentially in the same manner as ARP with the exception that InARP does not broadcast requests. This is because the hardware address of the target host is already known. InARP can be distinguished from ARP by the use of different operation codes for InARP requests and InARP responses. After looking up a particular protocol address, the hosts can insert the mapping into their ARP caches.

18.9 Summary

Address resolution protocols are inevitable for using higher-level protocols like IP on physical point-to-multi-point networks like Ethernet. It must be able to associate a protocol address with a hardware address to convey a higher-level protocol datagram to the correct next host.

The most widely used address resolution protocol is ARP in conjunction with Ethernet and IP. It is used for looking up a MAC address belonging to an IP address. RARP is used to look up the requester's own IP address by providing a MAC address; but it is almost substituted by DHCP. InARP is used to look up the protocol address of a destination host and is mainly used in connection-oriented networks transporting IP datagrams.

Although all protocols are mainly used for IP networks, they are specified independent of the protocol and physical network used.

19.1 Introduction

There is growing interest in the use of VPNs as a cost-effective means of building and deploying private networks for multi-site communication over the Internet. In this context, a VPN may be defined as the emulation of a secure, private wide area network over the public Internet. The challenge in developing a VPN for today's global business environment is to utilize the public Internet backbone for both intra- and inter-company communications, while still providing the security of a traditional private, self-administered corporate network.

Within the Internet Engineering Task Force (IETF), the IP Security (IPSec) working group has developed a framework for network layer security over the Internet [11]. IPSec is a flexible framework, enabling a company to configure secure end-to-end solutions that can accommodate both locally attached users and remote-access users, and can support communications both within the company and between different companies [8].

Note that, although VPNs are mostly used over the Internet, they are not restricted to this environment. VPNs can be used over any public network to provide secure communications [1, 10]. The purpose of this article is to give a brief overview of VPNs based on the IPSec protocol, with special emphasis on the forthcoming IP version 6 of the Internet Protocol [4].

19.2 Security Requirements

Types of Security

The security of an organization's electronic information requires a comprehensive plan of action, including the following aspects:

© 2005 by CRC Press LLC

Host security: Controlling access to, and processing on each computer.

Network security: Securing a network, where the network itself acts as an access medium.

Administration: Ensuring that proper functional procedures and operational rules are put in place and adhered to.

Personnel: Making sure that personnel are properly trained, authorized, and alerted to security awareness.

Physical security: Cont\rolling physical access to assets and infrastructure.

Security Framework

Virtual private networks are intended to provide suitable cryptographic services and mechanisms to protect a network. The ITU-T Recommendation X.800, *Security Architecture for OSI*, defines a comprehensive framework in terms of security *threats*, *services,* and *mechanisms* of networks.

Security threat: A threat is anything that poses some form of danger to a network and related resources.

Security service: A service that counters security threats and attacks and enhances the security of a network, by applying a range of available security mechanisms.

Security mechanisms: A mechanism that is intended to detect, prevent, or recover from a security attack.

Security Services

A security service enhances the security of the network and its related components. In general, services function in one of the following categories:

- Prevention
- Detection or
- Recovery

X.800 lists the following five categories of security services:

Authentication: Ensure the authenticity of the identity of all communicating entities, as well as the origin of data or information.

Data Confidentiality: Protect transmitted data or information against eavesdropping or leakage to unauthorized entities.

Data Integrity: Prevent the unauthorized creation, alteration, replay, or destruction of transmitted data.

Access Control: Limit and control access to resources to legitimate users.

Accountability: Ensure the maintenance of a complete record of the actions of every user in the system.

19.3 IP Version 6 (IPv6)

Introduction

The Internet Protocol (IP) is part of the TCP/IP suite, and is the most widely used internetworking protocol [2]. For decades, the keystone of the TCP/IP protocol architecture has been IP version 4 (IPv4). However, IPv4 has several shortcomings and limitations, which prompted the IETF to start working on a next version of IP. In 1995, the specification for a next-generation IP protocol, then known as IPng, was issued. In 1996, this specification was turned into a standard, referred to as IPv6 [4].

IPv6 provides a number of functional enhancements over the existing IPv4, designed to accommodate the higher speeds of today's networks and the mix of data streams, including graphic and video, which are becoming more prevalent. But the prime driving force behind the development of IPv6 was the need for more addresses. IPv4 uses a 32-bit address to specify the source or destination. With the explosive growth of the Internet, and the private networks attached to the Internet, this address length is rapidly becoming insufficient. Ultimately, all installations using TCP/IP are expected to migrate from the current IPv4 to IPv6; but this process may take many years, if not decades.

© 2005 by CRC Press LLC

As shown in Figure 19.1, IPv6 contains 128-bit source and destination address fields (compared to the 32-bit address space of IPv4). Also, instead of the dotted decimal notation used in IPv4, IPv6 uses a different notation to depict an Internet address, that is, hexadecimal numbers separated by colons:

0123:4567:89ab:cdef:0123:4567:89ab:cdef

The IPv6 header has a length of 40 octets, consisting of the following fields:

Version (4 bits): Internet Protocol version number; for IPv6, the value is 6.
Traffic Class (8 bits): To distinguish between different classes or priorities of IPv6 packets.
Flow Label (20 bits): The flow label is intended to assist with resource reservation and real-time traffic processing.
Payload Length (16 bits): Gives the total length of all of the extension headers plus the transport-level payload.
Next Header (8 bits): Identifies the type of header immediately following the IPv6 header.
Hop Limit (8 bits): The hop limit is set to some desired maximum value by the source and decremented by 1 by each node that forwards the packet.
Source Address (128 bits): The address of the originator of the packet.
Destination Address (128 bits): The address of the intended recipient of the packet.

IPv6 Packet Format

An IPv6 packet has the following general form, as shown in Figure 19.2:

The only mandatory header is simply referred to as the IPv6 Header, and has a fixed length of 40 octets. Although the IPv6 Header is longer than the mandatory portion of the IPv4 header (20 octets), the IPv6 packet contains fewer fields (8 vs. 12). Thus, routers have less processing to carry out per packet, which should speed up routing.

The following extension headers are defined for IPv6:

Hop-by-Hop Options Header: Defines special options that require hop-by-hop processing.
Routing Header: Provides extended routing, similar to IPv4 source routing.
Fragment Header: Contains fragmentation and reassembly information.
Authentication Header: Provides packet integrity and authentication (required for IPSec).
Encapsulating Security Payload Header: Provides privacy (required for IPSec).
Destination Options Header: Contains optional information to be examined by the destination node.

FIGURE 19.1 Illustration of the IPv6 header.

© 2005 by CRC Press LLC

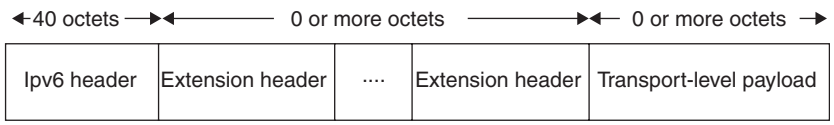

FIGURE 19.2 General form of an IPv6 packet.

Figure 19.3 shows an example of an IPv6 packet that includes an instance of each nonsecurity header. Observe that each extension header includes a Next Header field. This field identifies the type of subsequent header. If the subsequent header is an extension header, then this field contains the type identifier of that header.

19.4 IPSec

Introduction

In 1994, the Internet Architecture Board (IAB) issued a report entitled "Security in the Internet Architecture" (RFC 1636) [11]. The report stated the need for security on the Internet, and identified the following three functional areas for security mechanisms:

Authentication: To ensure that a received packet was transmitted by the claimed source in the packet header, and also that the packet was not altered in transit.

Confidentiality (encryption): Provide encryption of packets to prevent eavesdropping by third parties, as well as the unauthorized monitoring and control of network traffic.

Key management: Establish an infrastructure for the secure management and exchange of cryptographic keys.

In response, the IPSec working group was formed within the IETF, and a framework for network layer security was developed that is usable both with the current IPv4 and the future IPv6.

What is IPSec?

The acronym IPSec, a short form of the term "Internet Protocol Security," is an evolving standard for security at the network or packet layer of network communication. In essence, IPSec is a set of protocols that may be used to implement VPNs that operate over the Internet [5, 8]. The principal feature of IPSec is that it can encrypt and/or authenticate all traffic at the IP level, so that all distributed higher-layer applications, including remote logon, client/server, e-mail, file transfer, Web access, etc. can be secured, as shown in Figure 19.4.

Thus, IPSec is transparent to end users and applications and facilitates a general-purpose solution. Furthermore, IPSec includes a filtering capability so that only selected traffic is affected by the overhead of IPSec processing.

The IPSec specification consists of numerous documents. The most important of these, issued in November 1998, are:

- *RFC 2401*: An overview of a security architecture.
- *RFC 2402*: Description of a packet authentication extension to IPv4 and IPv6.
- *RFC 2406*: Description of a packet encryption extension to IPv4 and IPv6.
- *RFC 2408*: Specification of key management capabilities.

Support for IPSec is mandatory for IPv6 and optional for IPv4. In both cases, the security features are implemented as two extension headers that follow the main IP header.

IPSec Services

The following security services are provided by IPSec:

Data origin authentication: Verifies that each datagram was originated by the claimed sender.

© 2005 by CRC Press LLC

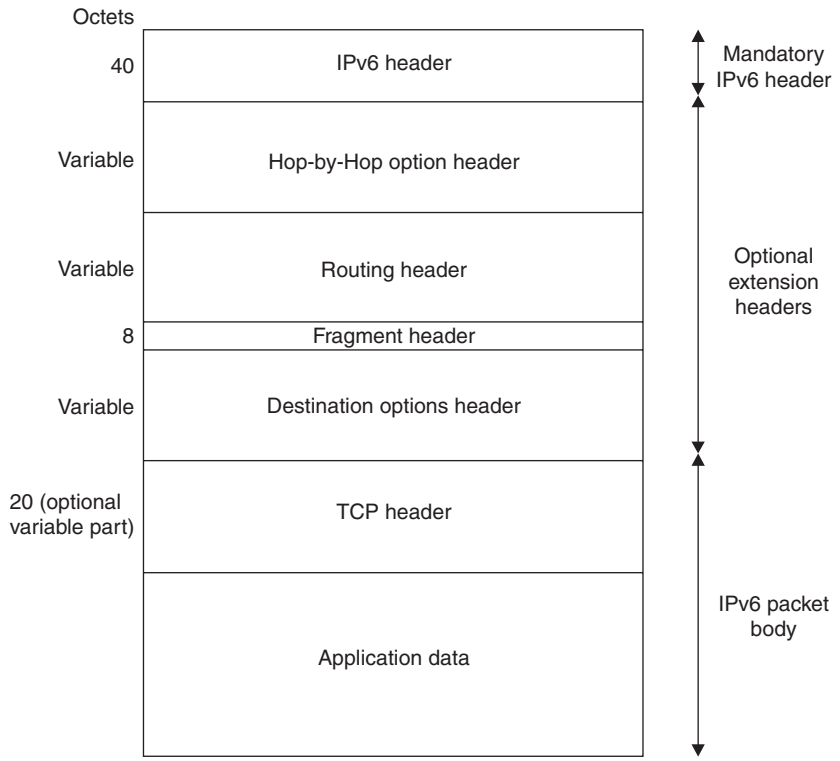

FIGURE 19.3 Illustration of an IPv6 packet with Extension Headers.

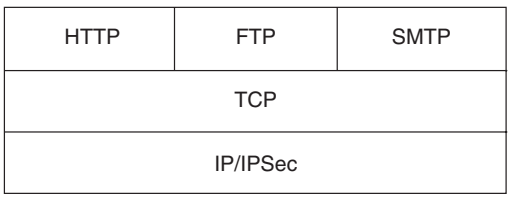

FIGURE 19.4 Placement of security in the TCP/IP stack.

Data integrity: Verifies that the contents of the datagram were not changed in transit, either deliberately or due to random errors.

Data confidentiality: Protects the plaintext of a message by means of encryption.

Replay protection: Assures that an attacker cannot intercept a datagram and send it back at some later time.

Key management: Generation and distribution of cryptographic keys across a distributed network environment.

IPSec provides these security services by means of two protocols: an authentication protocol designated by the *header* of the protocol, Authentication Header (AH), and a combined encryption/authentication protocol designated by the *format of the packet* for that protocol, Encapsulating Security Payload (ESP).

Authentication Header (AH): Provides data origin authentication, data integrity, and replay protection.

Encapsulating Security Payload (ESP): Provides data confidentiality, data origin authentication, data integrity, and replay protection.

Internet Security Association and Key Management Protocol (ISAKMP): Provides a framework for the generation, distribution, and management of cryptographic keys.

In the sequel, each of these protocols will be discussed in some detail.

© 2005 by CRC Press LLC

Transport and Tunnel Modes

AH and ESP support two modes of use: the transport mode and the tunnel mode.

- The transport mode provides protection primarily for upper-layer protocols. Typically, the transport mode is used for end-to-end communication, for example, between client and server or between two workstations.
- The tunnel mode is normally used between two entities when at least one of them is not a connection end-point. For example, if secure communication is desired between two gateways that are located between a client and a server, these gateways would utilize IPSec in the tunnel mode.

Authentication Header (AH)

The Authentication Header provides connectionless integrity and data origin authentication for IP datagrams, as well as protection against replay [7]. The format of the AH header is illustrated in Figure 19.5.

The data integrity feature prevents undetected modification of a datagram. Data authentication enables an end system or network device to authenticate the user, and also prevents address spoofing attacks. The AH protects the entire contents of an IP datagram except for certain fields in the IP header, called *mutable fields*, that are being modified while the datagram is in transit. A checksum, generated by means of a (keyed) message authentication code (MAC), is included in the AH header. Hence, the two communication parties must share a secret key. The checksum is calculated using the HMAC algorithm, based on either MD5 or SHA-1. During calculation of the checksum, the mutable fields are treated as if they contained all zeros. Replay is prevented by including a sequence number field within the AH Header, which is increased for each transmitted package.

AH can be applied in the transport or tunnel mode, as shown in Figure 19.6.

In the transport mode, the AH is inserted after the original IP header and before the IP payload. The AH is viewed as an end-to-end payload, that is, it is not examined or processed by intermediate routers. Therefore, the AH appears after the IPv6 base header and the hop-by-hop, routing, and fragment extension headers. Authentication covers the entire packet, excluding mutable fields, which are set to zero for MAC calculation. Note that all information in the datagram is in plaintext form, and therefore is subject to eavesdropping while in transit.

In tunnel mode, a new IP header is generated; the AH is inserted between the new, outer IP header and the original (inner) IP header. The inner IP header carries the ultimate source and destination addresses, while a new IP header may contain intermediate IP addresses (e.g., VPN address). The entire new datagram (new IP Header, AH Header, IP Header, and IP Payload) is protected by the AH protocol. Any change to any field (except the mutable fields) in the tunnel mode datagram can be detected.

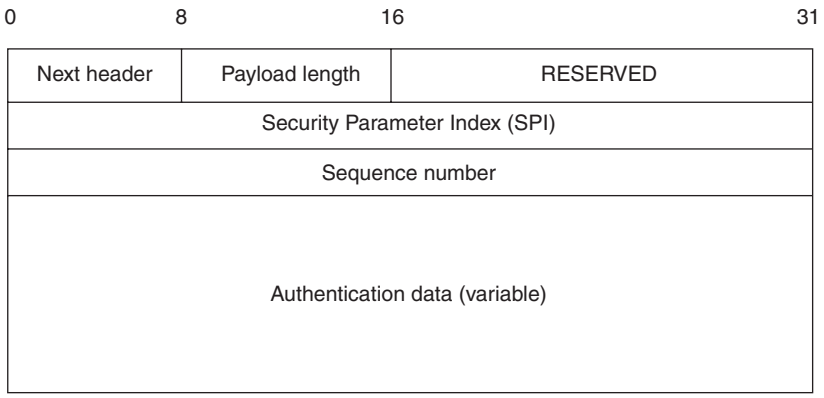

FIGURE 19.5 IPSec Authentication Header.

© 2005 by CRC Press LLC

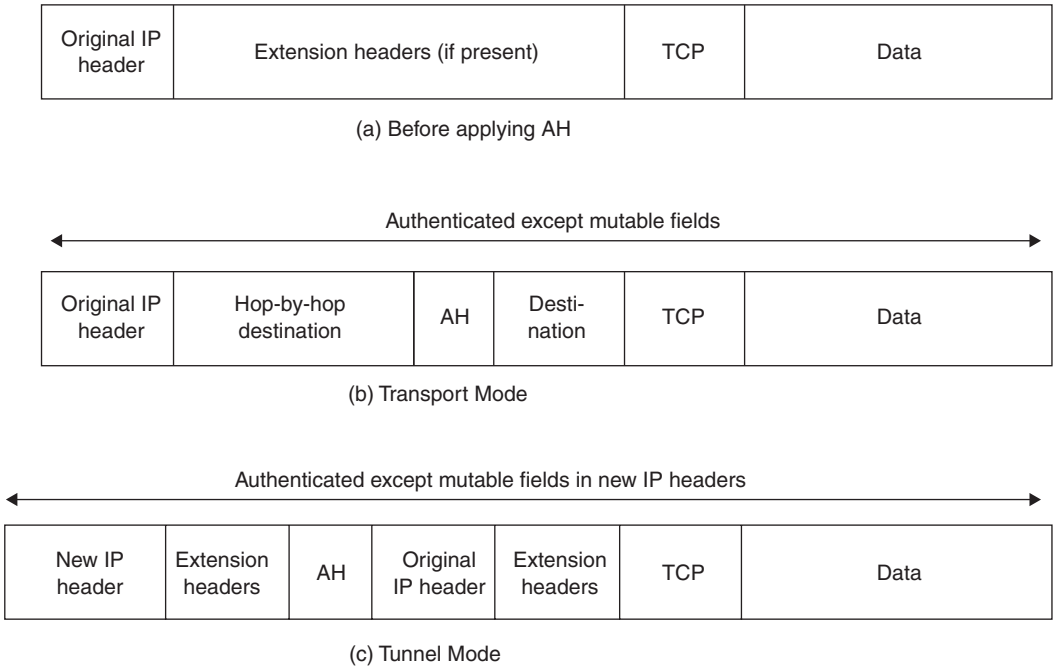

FIGURE 19.6 Illustration of the AH modes.

AH may be applied alone or in combination with the ESP header. The primary difference between the authentication provided by ESP and AH is the extent of the coverage. Specifically, ESP does not protect any IP header fields unless those fields are encapsulated by ESP (tunnel mode).

ESP

The ESP provides data confidentiality, and protection against replay; it can also optionally provide data origin authentication and data integrity checking, similar to AH. The current IPSec specification mandates the use of the Data Encryption Standard (DES) in cipher block chaining (CBC) mode for encryption. Several other algorithms are also accepted, including triple DES, RC5, IDEA, CAST, and Blowfish. When ESP is required to provide authentication as well, it uses the same HMAC algorithms (HMAC-MD5 or HMAC-SHA-1) as the AH protocol. The format of an ESP package is shown in Figure 19.7.

ESP can be applied in either transport or tunnel mode. Transport mode may be used, for example, to provide encryption (and optionally authentication) between two directly connected hosts. On the other hand, a VPN may be established over the Internet between various private, corporate networks by implementing ESP tunnel mode on the security gateways that connect the internal networks to the Internet. In this way, implementation of security on every internal host is avoided. This is illustrated in Figure 19.8.

- In the transport mode, ESP is viewed as an end-to-end payload, that is, it is not examined or processed by intermediate routers. Therefore, the ESP header appears after the IPv6 base header and the hop-by-hop, routing, and fragment extension headers. Encryption covers the entire transport-level segment plus the ESP trailer. Note that the IP Header itself is neither authenticated nor encrypted. Hence, the addressing information in the outer header is visible to an attacker while the datagram is in transit.
- In the tunnel mode, a new IP header is generated. The entire original IP datagram (including both IP Header and IP Payload) and the ESP Trailer are encrypted. Because the original IP Header is encrypted, its contents are not visible to an attacker while it is in transit. Tunneling offers the advantage of hiding original source and destination addresses from users on the Internet, thus diminishing

© 2005 by CRC Press LLC

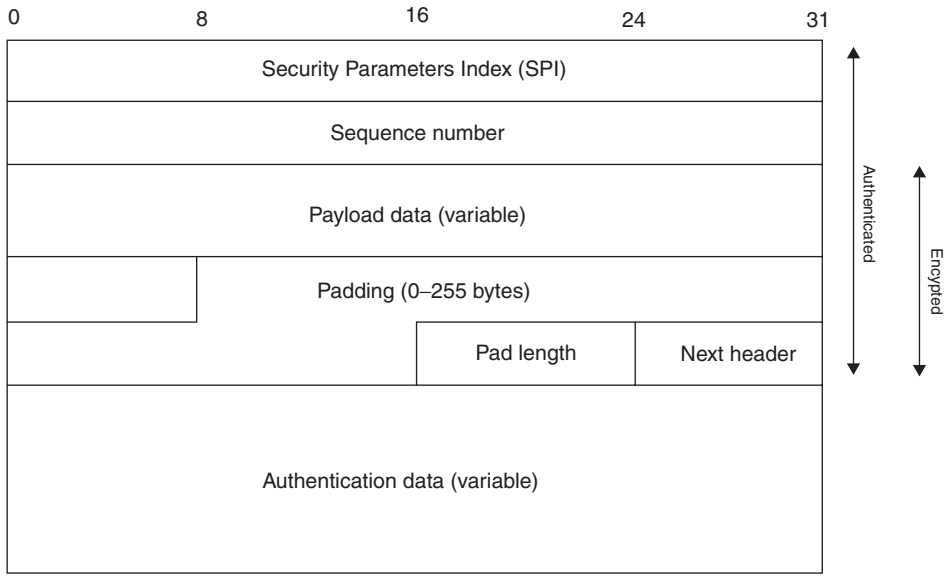

FIGURE 19.7 ESP header format.

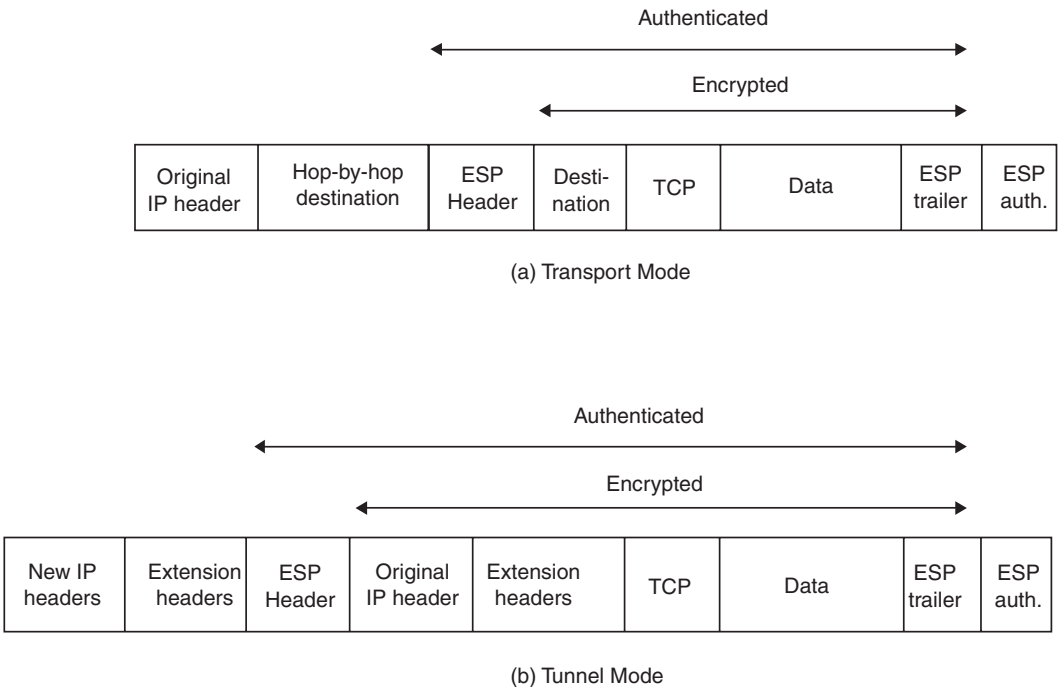

FIGURE 19.8 Illustration of ESP modes for encryption and authentication.

the threat of traffic analysis attacks. A common use of tunnel mode is to protect a datagram that is *tunneled* between two gateways. This relieves hosts on the internal network of the processing burden of encryption and simplifies the key distribution task by reducing the number of required secret keys.

The security services provided by the two IPSec protocols are shown in Table 19.1.

© 2005 by CRC Press LLC

TABLE 19.1 An overview of IPSec Security Services

Security service	AH	ESP(encryption only)	ESP(encryption and authentication)
Access control	Yes	Yes	Yes
Connectionless integrity	Yes		Yes
Data origin authentication	Yes		Yes
Rejection of replayed packets	Yes	Yes	Yes
Confidentiality		Yes	Yes
Limited traffic flow confidentiality		Yes	Yes

Security Association

A Security Association (SA) is a relationship between two or more entities that describes how the entities will use security services to communicate securely. The security association is unidirectional, meaning that for each pair of communicating systems, there are at least two security connections — one from A to B and one from B to A. The security association is uniquely identified by three parameters:

Security Parameters Index (SPI): A randomly chosen unique number that is carried in AH and ESP headers to enable the receiving system to select the SA under which a received packet will be processed.

IP Destination Address: This is the address of the destination endpoint of the SA, which may be an end-user system or a network system such as a fire wall or router.

Security Protocol Identifier: This indicates whether the association is an AH or ESP security association.

In an SA, ESP may be applied alone, in combination with AH, or even nested within another instance of itself. With these combinations, authentication can be provided between a pair of communicating hosts, between a pair of communicating firewalls, or between a host and a firewall. An SA contains all the relevant information that communicating systems need in order to execute the IPSec protocols, such as:

- The mode of the authentication algorithm used in the AH, and the keys for the algorithm.
- The encryption algorithm mode for ESP, and the required keys.
- Authentication algorithm-related information used in the ESP.
- Key management information, such as key lifetime.
- The SA lifetime.

Key Management in IPSec

The operation of IPSec in either AH or ESP mode requires the availability of shared secret keys between communicating entities. Typically, four keys are required for communication between two applications: transmit and receive pairs for both AH and ESP. The IPSec Architecture document mandates support for two types of key management:

Manual: A system administrator manually configures each system with its own keys and with the keys of other communicating systems. This is practical for small, relatively static environments.

Automated: An automated system enables the on-demand creation of keys for SAs and facilitates the use of keys in a large distributed system with an evolving configuration.

The default automated key management protocol for IPSec consists of the following elements:

ISAKMP: ISAKMP defines a standardized framework to support negotiation of SA, initial generation of all cryptographic keys, and subsequent refreshing of these keys [6, 9].

Oakley Key Determination Protocol: This key exchange protocol is based on the Diffie–Hellman algorithm, modified to provide security against known attacks.

ISAKMP by itself does not dictate a specific key exchange algorithm, but consists of a set of message types that enable the use of a variety of key exchange algorithms. Oakley is the specific key exchange algorithm mandated for use with the initial version of ISAKMP. The ISAKMP/Oakley protocol combination was named *Internet Key Exchange (IKE)*, and is specified in RFC 2409.

© 2005 by CRC Press LLC

The ISAKMP methods have been designed with the explicit goal of providing protection against several well-known threats:

Denial of Service: The messages are constructed with unique *cookies* that can be used to quickly identify and reject invalid messages without the need to execute processor-intensive cryptographic operations.

Man-in-the-Middle: Protection is provided against common attacks such as deletion of messages, modification of messages, reflecting messages back to the sender, replaying of old messages, and redirection of messages to unintended recipients.

Perfect Forward Secrecy: Compromise of past keys provides no useful clues for breaking any other key, whether it occurred before or after the compromised key. That is, each refreshed key will be derived without any dependence on predecessor keys.

IKE functions in two phases. Phase one involves two IKE peers establishing a secure channel for performing phase two. Phase two involves the two peers negotiating general-purpose SAs. IKE provides three modes for the exchange of keying information and setting up of IKE SAs. Two modes are for IKE phase-one exchanges, and one mode is for phase-two exchanges.

Main Mode

This mode provides a way to establish the first phase of IKE SA, which is then used to negotiate future communications. The first step, securing an IKE SA, occurs in three two-way exchanges between the sender and the receiver. In the first exchange, the sender and receiver agree on basic algorithms and hashes. In the second exchange, public keys are sent for a Diffie–Hellman exchange. Nonces (random numbers each party must sign and return to prove their identities) are then exchanged. In the third exchange, identities are verified, and each party is assured that the exchange has been completed.

Aggressive Mode

The aggressive mode provides the same services as the main mode. It establishes the phase one SA, and operates in much the same manner as the main mode except that it is completed in two exchanges instead of three. However, the aggressive mode does not provide identity protection for communicating parties. In other words, in the aggressive mode, the sender and recipient exchange identification information before they establish a secure channel where the information is encrypted.

Quick Mode

After two parties have established a secure channel using either aggressive mode or main mode, they can use quick mode. Quick mode has two purposes: to negotiate general IPSec security services and to generate newly keyed material. Quick mode is much simpler than both main and aggressive modes. Quick mode packets are always encrypted under the secure channel (or IKE SA established in phase one) and start with a hash payload that is used to authenticate the rest of the packet.

Perfect Forward Secrecy

For perfect forward secrecy, it is required to generate a new key that does not depend on the current or any previous key. Diffie–Hellman allows the generation of new shared keys that are independent of older keys, thus providing perfect forward secrecy. The derived Diffie–Hellman key can be used either as a session key for subsequent exchanges, or to encrypt another randomly generated key.

19.5 Virtual Private Networks

Introduction

A VPN can best be described as follows:

A Virtual Private Network provides secure, private communications by utilizing an existing public, insecure network infrastructure, such as the Internet.

Within this context, we observe the following:

© 2005 by CRC Press LLC

- A public network is any network that is under the control of another party, or that is accessible by other parties. The term *other parties* is used to refer to other people or organizations that are not part of the relevant organization.
- A *private* network is a network belonging to a specific organization, and is accessible only to authorized members (e.g., employees) of that organization.
- The network is termed *virtual* because it uses a logical connection that is built on the physical connections. Client applications are unaware of the actual physical connection and route traffic securely across the public network in much the same way in which traffic on a private network is securely routed.

In other words, a VPN enables the use of part of a public network for private, confidential purposes [1, 10, 12]. A VPN is intended to give an organization the same capabilities as a private network that is based on leased lines, but at a much lower cost. Privacy is maintained through the use of security services and mechanisms, based on tunneling protocols.

A secure and effective VPN deployment should provide the following functions:

- enforce an overall network security policy,
- ensure that VPN traffic is subject to network access control,
- protect the VPN gateway from security threats,
- provide an overall architecture that optimizes VPN and firewall performance,
- accommodate highly dynamic and growing network environments.

The key technologies that comprise the security component of a VPN are:

- access control to guarantee the security of network connections,
- encryption (confidentiality) to protect the privacy of sensitive data,
- authentication to verify the user's identity as well as the integrity of the data, and
- procedures for exchanging keys and digital certificates (credentials) among different users.

VPN Configurations

User-to-site VPN

A VPN provides an easy mechanism to allow remote access to an organization's private network. In the past, users working at off-site locations such as their homes (telecommuting) or while traveling (mobile or roaming users) had to connect to the company network via dial-up links to a modem pool. The Internet provides a cheaper alternative since the user can connect to the nearest ISP and access the company network via the Internet. Figures 19.9 and 19.10 compare two different scenarios.

Site-to-site VPN

A VPN using a public infrastructure such as the Internet can replace the traditional wide area network (WAN) architecture (using point-to-point leased lines) between offices. WANs are usually privately owned networks that span a large geographical area, typically across a country or even a continent, and interconnect LANs in different locations.

The example in Figure 19.11 shows a company with three offices situated in different locations. Each office requires access to the Internet, as well as being connected to the other offices. Traditionally, connectivity between the offices is obtained by means of a dedicated WAN, based on leased lines. However, if a VPN is used, as shown in Figure 19.12, only one Internet connection is required at each office.

Extranet

An extranet is a network configured to allow specific trusted parties access to selected regions of an organization's internal network. Trusted parties may, for example, include clients and other organizations collaborating on a project. Figure 19.13 shows an example where a company provides access to customers via a dedicated line.

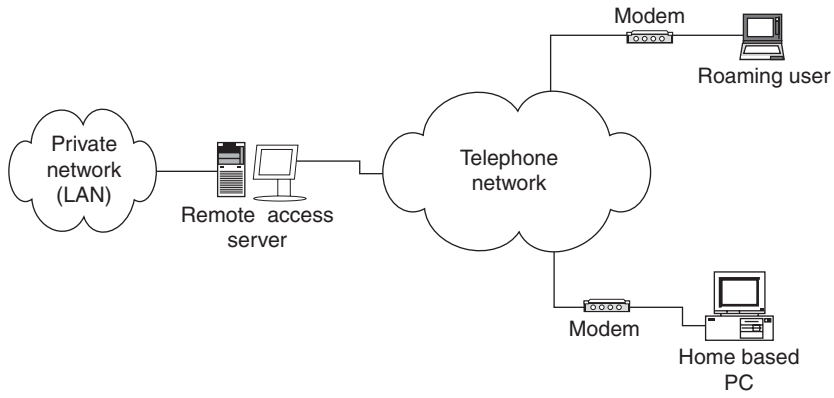

FIGURE 19.9 Remote access using a Remote Access Server.

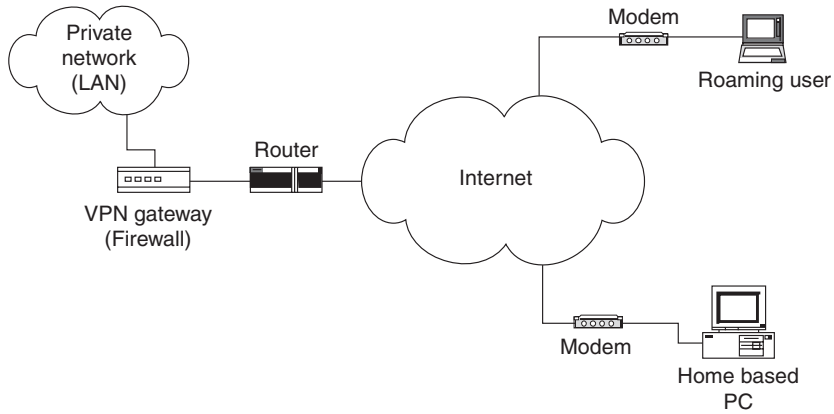

FIGURE 19.10 Remote access via the Internet.

Figure 19.14 shows how an external customer can gain access by means of a VPN connected to the Internet. The access control and authentication services of the VPN are utilized to grant discretionary access to customers and partners to information and resources on the organization's private network.

Internal VPN or Private LANs

A VPN implementation can be used for internal network partitioning. This enables different logical networks on the same network infrastructure. Figure 19.15 shows a LAN configuration with unrestricted access. In the example shown in Figure 19.16, VPN technology can be used to partition the company LAN to restrict Workstation 1 access to Server A and C only, while allowing Workstation 2 access to Server B and C. The partitioning will prevent a user at Workstation 1 from intercepting and reading the traffic between Workstation 2 and Server B.

Methods of VPN Deployment

Some form of VPN gateway is necessary to connect a private network to the Internet. The gateway can be a stand-alone hardware device, or a software component integrated into an existing firewall or router. In the case of remote access, remote users typically run software applications on their own computers.

© 2005 by CRC Press LLC

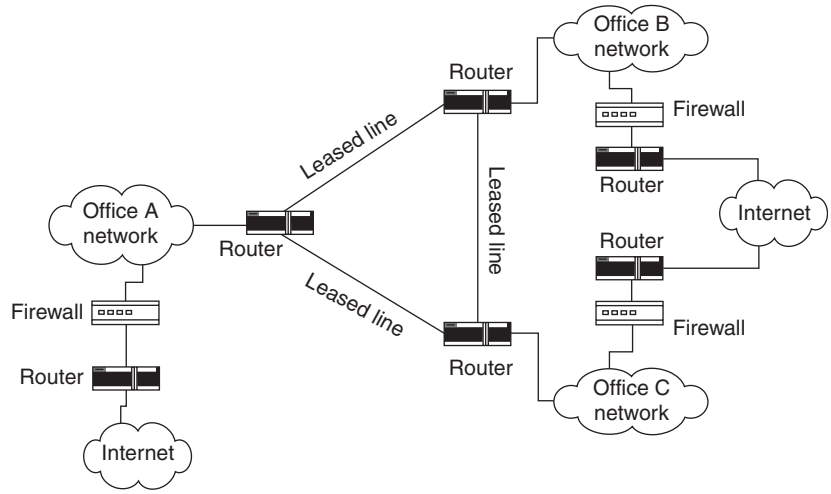

FIGURE 19.11 Traditional site-to-site communication.

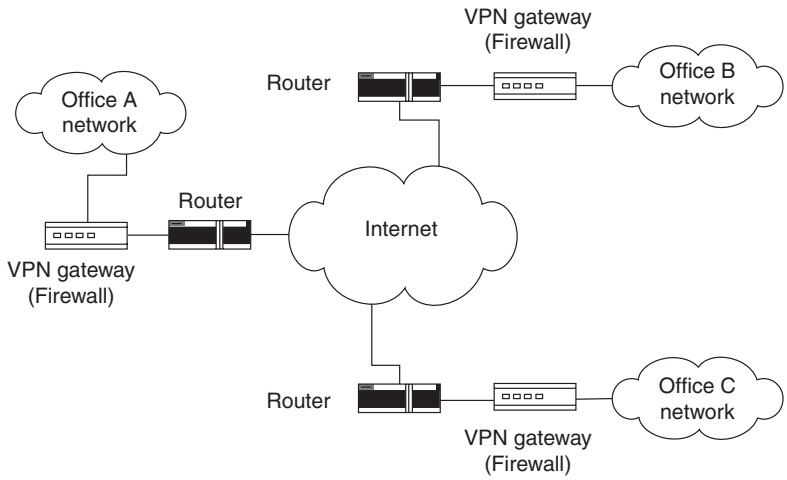

FIGURE 19.12 Site-to-site VPN.

Software Integration

This type of deployment involves the installation of software on existing equipment. In all cases, performance degradation may be a problem.

Routers: Many commercial routers support the addition of VPN software. The processing required for tunneling, etc. may reduce the throughput of the router in cases where the traffic load is high, since all processing is done in software.

Firewalls: Many companies view their firewall as the central component of their network security plan. Firewalls often make provision for the addition of a VPN capability. Again, because of the high processing requirement for both the firewall functionality and VPN service, the throughput may be severely degraded [3].

Servers: Another way to deploy a VPN is to install a software-based VPN on a server. Operating system suppliers and third-party vendors offer VPN applications that are able to link users via a VPN. The software can be installed on existing servers, allowing the existing network configuration to remain intact.

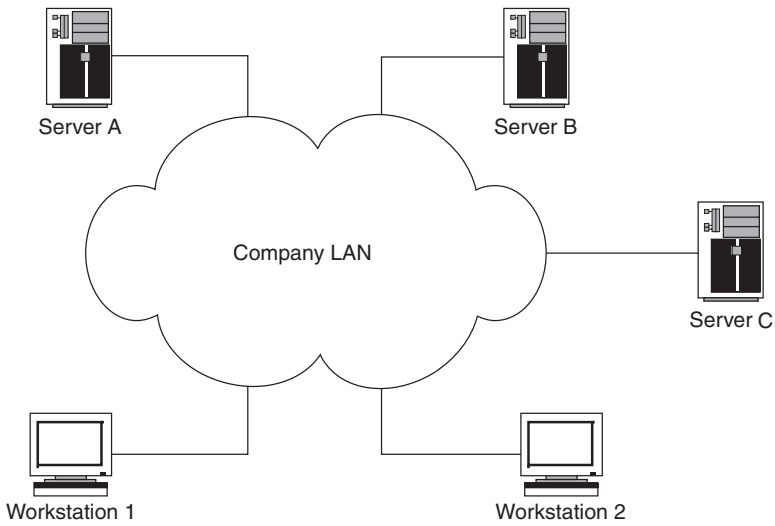

FIGURE 19.15 Company LAN with no access restrictions.

Stand-alone Hardware

As an alternative, VPNs may be implemented on dedicated, stand-alone devices that are specifically designed for tunneling, encryption, and user authentication. These devices are easier to install than to modify existing firewalls or routers, and, in general, they are much more efficient in terms of throughput than software-based solutions.

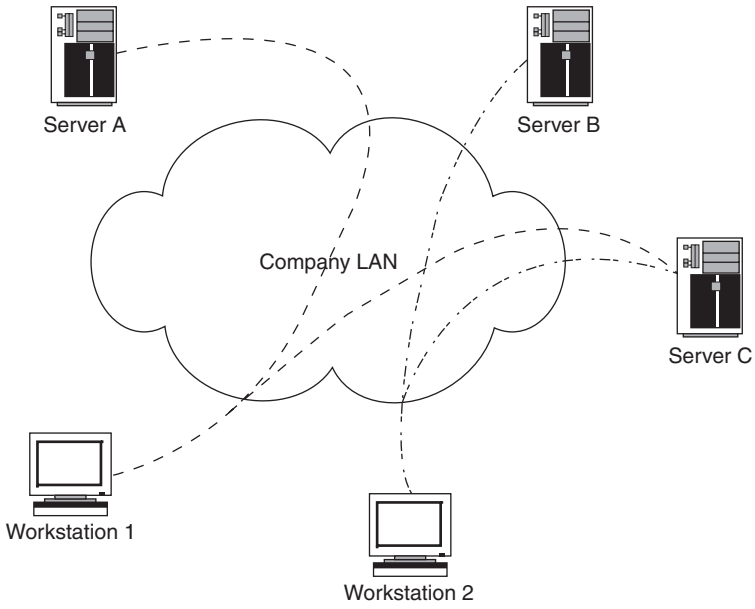

FIGURE 19.16 Virtual private LANs.

Advantages of a VPN

The advantages of using a VPN for connectivity all hinge on one aspect — saving money while employing strong security. A few of the advantages are:

- *Existing infrastructure*: The Internet can be used to provide distributed network services over long distances, and this eliminates the need to create WANs based on expensive leased lines. Using the Internet for remote access leads to substantial savings, since remote users can dial in to a local service provider and gain access to the company network via the Internet.
- *Simpler connectivity*: It is much easier and cheaper to connect offices using the existing Internet infrastructure than to install leased lines.
- *Availability*: In general, the availability of the Internet's communication infrastructure is much higher than with dedicated leased lines. The Internet has a high degree of redundancy — if one link fails, another link is available to carry the traffic.
- *Maintenance*: The cost, time, and resources necessary to maintain and administer a VPN are much less than for a WAN. Furthermore, an organization typically does not need to maintain a dial-in facility to accommodate remote users.
- *Flexibility*: By using the Internet as part of the network infrastructure, companies are no longer bound by long-term contracts as required by leased-line providers. In general, it is easier to change Internet service providers.
- *Extranet applications*: Organizations can allow trusted parties access to certain resources on the private network through an extranet facility. This promotes customer relations and enhances communication with partner organizations, etc.

Competing VPN Deployment Protocols

In recent years, four different protocols have been suggested for creating a VPN over the Internet:

- point-to-point tunneling protocol (PPTP),
- layer-2 forwarding protocol (L2F),

© 2005 by CRC Press LLC

- layer-2 tunneling protocol (L2TP), and
- IP security protocol (IPSec).

One reason for the number of protocols is that, for some companies, a VPN is a substitute for remote-access servers, allowing mobile users and branch offices to dial into the protected corporate network via their local ISP. For others, a VPN may consist of traffic traveling in secure tunnels over the Internet between protected LANs. The protocols that have been developed for VPNs reflect this dichotomy. PPTP, L2F, and L2TP are largely aimed at dial-up VPNs, while IPSec's main focus has been on LAN-to-LAN solutions.

PPTP: Currently, the most commonly used protocol for remote access to the Internet is the point-to-point protocol (PPP). PPP provides a standard method for transmitting IP datagrams over serial point-to-point links, and provides three functions:

- A method for encapsulating IP Datagrams over serial links.
- An extensible Link Control Protocol (LCP).
- A family of Network Control Protocols (NCP) for establishing and configuring different network-layer protocols.

The PPTP is an extension of PPP, to provide remote access that can be tunneled through the Internet to a destination site. PPTP was developed primarily by Microsoft, and at one time enjoyed the status of a *de facto* standard. PPTP creates a secure tunnel in which encrypted PPP packets are sent as IP datagrams over the Internet.

PPTP utilizes the authentication mechanisms within PPP, namely the password authentication protocol (PAP) and Challenge/Handshake Authentication Protocol (CHAP). For encryption, PPTP derives a 40-bit encryption key from the hashed password stored on the client and the server.

Besides the relative simplicity of client support for PPTP, one of the protocol's main advantages is that PPTP is designed to run at open systems interconnection (OSI) Layer 2, or the link layer, as opposed to IPSec, which runs at Layer 3. By supporting data communications at Layer 2, PPTP can transmit protocols other than IP over its tunnels. As currently implemented, PPTP encapsulates PPP packets using a modified version of the generic routing encapsulation (GRE) protocol, which gives PPTP the flexibility of handling protocols other than IP, such as Internet packet exchange (IPX) and network basic input/output system extended user interface (NetBEUI).

PPTP does have some limitations: it does not provide strong encryption for protecting data, nor does it support any token-based methods for authenticating users. Hence, it is not likely that PPTP will become a formal standard endorsed by any of the standard bodies, like the IETF.

L2F: L2F emerged during the early stages of VPN development, and was designed by Cisco Systems. Like PPTP, L2F is intended as a protocol for tunneling traffic from users to their corporate sites. L2F provides tunneling for the encapsulation of non-IP packets, and thus it is able to work directly with other media such as frame relay, X.25, or asynchronous transfer mode (ATM).

Similar to PPTP, L2F uses PPP for authentication of the remote user, but it also includes support for terminal access controller access control system (TACACS)+ and RADIUS for authentication. L2F also differs from PPTP in that it allows tunnels to support more than one connection.

L2TP: In an effort to combine the different functionalities of PPTP and L2F, the IETF has proposed the Layer Two Tunneling Protocol (L2TP). This protocol is able to tunnel PPP traffic over a variety of networks (e.g., IP, X.25, SONET, frame relay, and ATM), using its own tunneling protocol.

Because it uses PPP for dial-up links, L2TP includes the authentication mechanisms within PPP, namely PAP and CHAP. However, PPTP, L2F, and L2TP do not all include encryption, or facilities for management of cryptographic keys. The current L2TP draft standard recommends that IPSec be used for encryption and key management over IP networks.

IPSec: IPSec emerged from efforts to secure IP packets, when the next generation of IP (i.e., IPv6) was being developed; it can now be used with IPv4 protocols as well. IPSec is generally considered the best VPN solution for IP environments, since it provides strong security measures — notably encryption, authentication, and key management.

However, IPSec is mainly intended to handle IP packets, and therefore PPTP and L2TP will probably remain the first choice for a multi-protocol non-IP environment, such as NetBEUI, IPX, and AppleTalk.

© 2005 by CRC Press LLC

Benefits of IPSec

Applying IPSec in a firewall gives the following benefits:

- Strong security can be applied to all traffic crossing a firewall if IPSec is implemented on the firewall.
- If IPSec is implemented on the firewall, traffic on the private network does not incur the overhead of security-related processing.
- IPSec in a firewall is resistant to bypassing if all traffic from the untrusted network must use IP and the firewall is the only access point to the local (trusted) network.
- IPSec operates below the transport layer (e.g., TCP) and is thus transparent to applications. There is no need to change software on a user or server system when IPSec is implemented in the firewall or router. Even if IPSec is implemented in end systems, application-layer software is not affected.

19.6 Conclusion

This article provides a short overview of VPN and the IPsec protocol, one of the technologies available for implementing VPNs. IPSec provides a powerful and flexible security framework for secure communication over the Internet, by means of the following security functions:

- *Authentication:* Ensures that a packet comes from the claimed source and was not altered in transit.
- *Confidentiality*: Prevents unauthorized disclosure of packet contents as well as the monitoring of network traffic.
- *Key management:* Establish an infrastructure for the secure management and exchange of cryptographic keys over insecure links.

IPSec provides two modes of operation, transport and tunnel modes, that are implemented by means of the Authentication Header and Encapsulating Security Payload protocols. The transport mode is generally used for secure end-to-end communication, while the tunnel mode can be used for host-to-host or network-to-network communication.

It is important to note that although VPNs are mostly used for the Internet, they are not restricted to this environment. VPNs can be used over any public network to give secure, private communication. Furthermore, IPSec can provide robust security services for other popular protocols, such as PPTP or L2TP.

20.1 Introduction

The Internet Protocol (IP) is the building block of the Internet. Nowadays, IP is also becoming the single technology used to support the different kinds of traffic present in a number of enterprise internetworks. This chapter covers the basics of routing technology and protocols for IP networks. After a review of routing algorithms and design issues, a classification of IP routing protocols is presented, together with details of the different protocols and comparative assessments.

The chapter ends with a case study addressing the routing technologies and design criteria of a global IP network for a large-scale enterprise. The scenario refers to a manufacturing company, which extends over three macro-regions — Europe, North America, and the Asia-Pacific region. The case study provides an overview of the architecture of this global IP network and highlights both technical issues and design approaches toward a large-scale, high-availability infrastructure.

20.2 A Review of Routing

Routers

Routers are an example of Layer 3 Intermediate Systems (ISs), which are generally defined as network devices with the ability to forward packets between portions of a network. More specifically, routers allow IP packets [1] to be switched between interconnected networks. Originally called *gateways* in many early Internet Engineering Task Force (IETF) standards, routers play a crucial role in modern enterprise internetworking, providing transparent connectivity over heterogeneous technology subnetworks. Even routers from different vendors can cooperate to create a holistic view of the network in the form of routing tables.

Routing Protocols

An *internetwork*, also called an internet, consists of two or more networks joined together. In an internetwork, network layer *routing protocols* implement *path determination* and *packet switching*. Path determination consists of choosing which path (or *route*) the packets are to follow across the internetwork from a sending host to a destination, while packet switching refers to transporting them.

Path determination is accomplished by *routing algorithms*. In general terms, the purpose of routing algorithms is to determine, given a set of routers and links connecting them, the best (i.e., least-cost) path from source to destination. In order to support the calculation of the best path for individual packets, routing protocols have to enable routers to communicate with each other exchanging both *topology* information (e.g., about neighbors and routes) and *state* information (e.g., costs). This information is used to build a *routing table* that is consulted whenever a routing decision has to be made.

A routing table consists of a list of *routing entries* indicating which outgoing link should be used to forward packets to a given destination. When a router receives an incoming packet, it checks the routing table in order to find a destination/next hop association for the destination address specified in the packet. Figure 20.1 shows the basic structure of a simplified routing table.

A number of routing algorithms exist, with different characteristics, targets, and metrics. The following subsection presents a classification of the routing protocols used in the IP environment, together with some main design issues.

Destination network	Next Hop	Nhops	Interface
160.4.0.0	160.4.5.2	–	Ethernet0
151.5.0.0	160.4.5.2	5	Ethernet0
192.166.30.0	160.7.3.1	3	Ethernet1

FIGURE 20.1 A simplified routing table.

Routing Design Issues

The first design issue of routing algorithms is *optimality*, as their purpose is to find the optimal (i.e., least-cost) path from source to destination according to a given metric. Paths can be weighted according to a single metric or multiple metrics combined to form a single hybrid one. Metrics give a measure of the overall degree of "goodness" of a path.

The most common routing metric is *path length*. In the simplest case, it is expressed in terms of hop count, that is, the number of hops that a packet must make on its path from a source to a destination. Alternatively, network administrators may assign arbitrary costs (expressed as integer values) to each network link and calculate the path length as the sum of the costs associated with each link traversed.

These costs may be due to several link characteristics, such as:

- *bandwidth;*
- *routing delay,* which gives the length of time required to move a packet from source to destination through the internetwork;
- *load,* which gives the degree of utilization of a router, obtained by monitoring variables such as CPU utilization or packets processed per second;
- *reliability*, which depends on the link's fault probability or recovery time in the event of failure.

Some protocols combine these metrics into a single composite one, which encompasses all these costs according to weighting factors that can be configured by the network administrator.

Different routing protocols generally adopt different metrics and algorithms that are not compatible with each other. In a network where multiple routing protocols are present, it is important to find a way to exchange route information to determine the best path across the multiple protocols.

Administrative distance is the feature used by routers to select the best path when there are two or more different routes to the same destination from two different routing protocols. Each protocol is therefore assigned an administrative distance, that is, an integer value that defines the "trustworthiness" of the protocol. Each routing protocol is prioritized in order of most to least "reliable" using an administrative distance value, and routers will select the route supplied by the protocol with the shortest administrative distance. As an example, Table 20.1 gives the administrative distance assigned to various routing protocols [2]. In some cases, *link monetary cost* also has to be taken into account. For example, companies may prefer to send packets over their own lines, even though slower, rather than through faster but expensive external lines charging money for usage time.

Apart from optimality, another important design issue for routing algorithms is fast *convergence*.

Convergence is the process of agreement, by all routers, on optimal routes. When a router detects a topology change, this information must be propagated through the network and a new routing topology

TABLE 20.1 Administrative Distances for IP Protocols

Protocol	Administrative distance
Unknown	255*
Internal BGP	200
External EIGRP	170
Exterior Gateway Protocol (EGP)	140
Routing Information Protocol (RIP)	120
Intermediate System-to-Intermediate System (IS–IS)	115
OSPF	110
IGRP	100
Internal EIGRP	90
External Border Gateway Protocol (BGP)	20
Enhanced Interior Gateway Routing Protocol (EIGRP) summary route	5
Static route	1
Connected interface	0

*This value indicates that the router does not trust the source of that route and will not insert the route into its routing table.

© 2005 by CRC Press LLC

should be calculated. This is achieved by distributing *routing update* messages to the other routers, thus stimulating recalculation of optimal routes and eventually causing all routers to agree on these routes. The time taken to detect changes in the network topology (such as new routes being added or existing routes changing state) and reconfigure the topology correctly, called *convergence time*, is a very important characteristic of routing algorithms. Slow convergence is undesirable, as it may cause routing loops or network interruption. A routing loop occurs when, due to slow convergence, a packet arriving at a router A or B and destined for a router C bounces back and forth between these two routers until either convergence is reached or the packet has been switched the maximum number of times allowed. Several factors may affect convergence time. Some depend on the network topology and size (e.g., number of routers, link speeds, routing delays), while others are strictly related to the routing protocol adopted and the setting of the relevant timing parameters.

Scalability is also a very important requirement for routing algorithms, especially in large size internetworks. Some routing algorithms behave well in small systems but scale poorly, so they cannot be used in larger internetworks.

Another important issue is *robustness*, that is, the ability of routing algorithms to perform correctly even in the presence of unusual or unforeseen events, such as router failures, misbehavior, or sabotage.

Moreover, routing algorithms should combine *flexibility*, which enables them to adapt to network changes (e.g., in bandwidth, router queue size, network delay) with *stability*, which means that they should not be too sensitive to changes in the network. For example, on a network featuring unstable links, frequent occurrences of changes and subsequent convergences would affect proper network operation.

Last but not the least, routing algorithms should be *simple*, in order to introduce a low overhead on routers (in terms of processing and storage), and *efficient* in resource utilization (especially when running on hosts with limited physical resources).

20.3 Classification of Routing Protocols

Routing protocols may be classified according to several different characteristics [3–5]. Here, we will address the most relevant. As it will be seen in the following, routing protocols may be *static* or *dynamic, global* or *decentralized, link-state* or *distance-vector, single path* or *multipath, flat* or *hierarchical*.

Static or Dynamic

Static algorithms are based on table mappings that are fixed by the network administrator. Static routes seldom change, and when changes do occur it is usually a result of human intervention (i.e., editing a router's forwarding table). Thanks to their simplicity, static routing algorithms introduce a low overhead and are suitable for stable environments where network traffic is predictable. Static routing is commonly adopted where there is no need for an alternate path, for example, in permanent point-to-point WAN links to remote sites or dial-up ISDN lines.

Dynamic routing algorithms, on the other hand, automatically generate the routing paths responding to the network traffic or topology changes. When a change occurs, the routing algorithm running on a router recalculates routes, reflects changes in the routing table, and then propagates updates throughout the network, thus stimulating recalculation in the other routers as well.

Dynamic algorithms sometimes have static routes inserted into their routing tables. This is the case, for instance, of *default* routers, to which all traffic should be forwarded when the destination address is unknown (i.e., not explicitly listed in the routing table).

Global or Decentralized

A *global* algorithm makes the routing decision on the basis of complete information about the network, in terms of connectivity and link costs. The calculation of the best path can be up to a single site or replicated over multiple ones.

© 2005 by CRC Press LLC

In a *decentralized* routing algorithm, no site has complete knowledge of the network, and route calculation is iterative and distributed. Each node only knows the status of the links directly connected to it. This information is then distributed to its neighbors, that is, nodes directly connected to it, and this iterative process of route calculations and exchanges enables a node to determine the least-cost path to a destination.

Link-state or Distance-vector

Link-state algorithms (also called Shortest Path First algorithms) compute the least-cost path using complete, global knowledge of the network in terms of connectivity, and link costs. Each router maintains a complete copy of the topology database in its routing table and floods routing information to all the nodes in the internetwork. At the beginning, each router will know only about its neighbors, but it will increase its knowledge through *link state* broadcasts received from all the other routers. The router does not send the entire routing table, but only the portion of the table that describes the state of its own links.

Distance-vector algorithms (also known as minimum hop or Bellman–Ford algorithms) require each router to keep track of its distance (hop count) from all other possible destinations.

Each node receives information from its directly connected neighbors, calculates the routing table, and then distributes the results back to the neighbors. When a change is detected in the link cost from a node to a neighbor, the router first updates its distance table and then, if the change also affects the cost of the least-cost path, it notifies its neighbors.

Distance-vector algorithms are distributed and iterative, as the routing table distribution process goes on until no more exchanges with neighbors occur. Routers can identify new destinations as they come into the network, learn of failures in the network, and calculate distances to all known destinations. Each router on a regular basis advertises all the destinations it is aware of with the relevant distances and sends update messages containing all the information maintained in the routing table to neighboring routers on directly connected segments. Each router can therefore build a detailed picture of the network topology by analyzing routing updates from all other routers. The best route for each destination is determined according to a minimum distance (minimum hop) rule.

Table 20.2 compares link-state and distance-vector routing algorithms.

As in link-state algorithms, all the routers share the same knowledge of the network; they have a consistent view of the best path to a given destination. This would entail a sudden change in the load on the least-cost link, and even congestion, if all the routes decide to send their packets through that link at the same time.

One way of avoiding such *oscillations* would be to ensure that all the routers do not run the algorithm at the same time. However, it has been noted that routers on the Internet can self-synchronize. Even though they initially execute the routing algorithm at the same rate, but at different times, the algorithm execution instance will eventually become synchronized at the routers [6]. To deal with this problem, randomization is introduced into the period between the execution instants of the algorithm at each router.

Single Path or Multipath

Routing protocols may be *single path* or *multipath*. The difference lies in the fact that multipath algorithms support multiple entries for the same destination in the routing table, while single path ones do not. The presence of alternative routes in multipath routing protocols allows traffic to be multiplexed over several circuits (LAN or WAN), thus providing not only greater throughput and topological robustness but also support for load balancing (i.e., splitting traffic between paths that have equal costs). In multipath algorithms, multiplexing may be *packet-based* or *session-based*. In the former case, a round-robin technique is typically used. In the latter case, load sharing is performed on a session basis, typically using a source–destination or destination hash function.

© 2005 by CRC Press LLC

TABLE 20.2 Link-state Vs. distance-vector Routing Algorithms

	Link-state	Distance-vector
Type	Global	Decentralized
Route Advertising	"Tell the world about the neighbors", that is, a router does not sent the entire routing table, but only the portion of the table that describes the state of its own links.	"Tell all neighbors about the world", that is router tend to distribute the entire routing table (or large portions of it) to their directly attached neighbors only
Robustness	More robust, as each router autonomously calculates its routing table	An incorrect node calculation can be spread over the entire network
Convergence	Fast	Slow (routing loops may occur)
Scalability	Good	Poor
Responsiveness to network changes	High	"Good news propagates fast, bad news propogates slowly", that is, a decrease in the cost of the best path propagates fast, while an increase goes slowly.
Message overhead	High: any change in a link cost entails the need to send all nodes the new cost.	Low: when link costs change, the results of the change will be propagatead only if the latter entails a change in the least-cost path for one of the nodes attached to the link.
Implementation complexity	High	Low
Processor and memory requirements	High	Low
Stability	Problematic, due to oscillation in routes	Good

Flat and Hierarchical

Another distinction can be made between *flat* and *hierarchical* routing algorithms. In a *flat* routing algorithm, all routers are peers. Each router is indistinguishable from the other as they all execute the same algorithm to compute routing paths through the entire network. This flat model has two main problems, that is, lack of scalability and poor administrative autonomy. The first derives from the growing computational, storing, and communication overhead that the algorithm introduces when the number of routers becomes large. The second arises from the need to conceal some features of a company's internal network from the outside, a crucial requirement for enterprise networks.

In *hierarchical routing*, logical groups of nodes, called *domains* or *autonomous systems* (ASs'), are defined. A routing domain is a collection of routers that coordinate their routing knowledge using a single routing protocol. An AS is a routing domain that is administered by one authority (person or group). Each AS requires a registered AS number (ASN) to connect to the Internet.

ASs may employ multiple *intradomain* routing protocols internally and interface to other ASs via a common *interdomain* routing protocol.

According to this hierarchy, some routers in an AS can communicate with routers in other ASs, while others can communicate only with routers within their own AS. In very large networks, additional hierarchical levels may exist, with routers at the highest hierarchical level forming a *routing backbone* (as shown in Figure 20.2). Packets from nonbackbone routers are conveyed along the backbone by *backbone routers* until a backbone router connected to the destination AS is found. Then, packets are sent through one or more nonbackbone routers within the AS until the ultimate destination is reached.

As compared to flat routing, a drawback of hierarchical routing is that suboptimal paths may sometimes be found. Nevertheless, hierarchical routing offers several advantages over flat routing. Firstly, the amount of information maintained and exchanged by routers is reduced, and this increases the speed of route calculation, thus allowing faster convergence. Secondly, unlike flat routing, where a single router problem can affect all routers in the network, in a hierarchical algorithm the scope of router misbehavior is limited. This increases the overall network availability. In addition, the existence of boundary

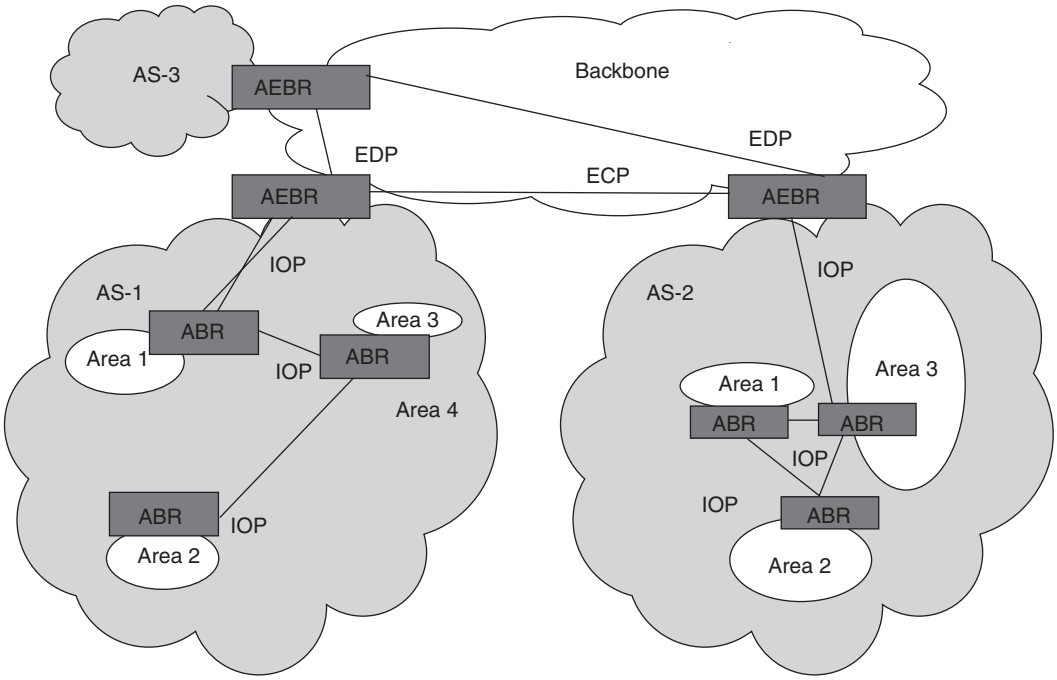

FIGURE 20.2 A Routing Architecture with three ASs connected through backbone routers.

interfaces between different levels in the hierarchy can be exploited to enforce security policies (e.g., access control lists or firewalls) on border routers. Hierarchical routing also improves scalability and protocol upgrades, thus making the task of the network manager easier. Thanks to the above-mentioned advantages, large companies generally adopt hierarchical routing.

20.4 Interior and Exterior Gateway Protocols

A very large internetwork in the IP domain is typically organized as a collection of ASs' (Figure 20.2). An AS is administered by a single entity and has its own routing technology, which may be different for different ASs. An AS can comprise one or more *areas*, composed of contiguous nodes and networks, which may be further split into subnetworks. Within an area, network devices without the capability to forward packets between subnetworks are indicated as *End Systems* (*ESs*'), while network devices equipped with this capability are called *Intermediate Systems* (*ISs*'). ISs' may be further classified into those that can communicate within routing areas only (*intra-area ISs*') and those that can communicate both within and between routing areas (*inter-area ISs*').

Figure 20.2 shows a typical structure of a large internetwork, where three ASs (AS-1, AS-2, and AS-3) are connected through a routing backbone to exchange information, while still retaining their own policies and controlling the routing updates received from the other internetworks.

Autonomous System Border Routers (ASBR) on the backbone are entrusted with routing traffic between different ASs, while Area Border Routers (ABR) deal with traffic between different areas within the same AS.

The routing protocol used within an AS is referred to as an *Interior Gateway Protocol* (IGP). A separate protocol is used to interface among the ASs, called the *Exterior Gateway Protocol* (EGP). EGPs are usually referred to as inter-AS routing protocols.

All routers within each AS will run one or more IGPs. Routing information between ASs is exchanged through the routing backbone via an EGP. The use of an EPG limits the amount of routing information exchanged among the three ASs and allows them to be managed differently.

© 2005 by CRC Press LLC

The main differences between IGPs and EGPs can be summarized in terms of *policy*, *scalability,* and *performance*.

When dealing with inter-AS routing, enforcing policy is crucial. For example, traffic originating from a given AS might be required not to pass through another specific AS. On the other hand, policy is less critical within an AS, where everything is under the control of a single administrative entity.

Scalability represents a more critical requirement in inter-AS routing, where a large number of internetworks may be involved, than in intra-AS routing. Conversely, performance is more important within an AS than in inter-AS, where it becomes of secondary importance as compared to policy. For instance, an EGP may prefer a more costly path to another one if the former complies with certain policy criteria which the second does not fulfil.

Among the IGPs that support IP, there are [7]:

- the Routing Information Protocol, RIPv1 and RIPv2,
- the Cisco Interior Gateway Routing Protocol, IGRP,
- the Cisco Enhanced Interior Gateway Routing Protocol, EIGRP,
- the Open Shortest Path First protocol, OSPF, and
- the Intermediate System-to-Intermediate System protocol, IS–IS.

Among EGP protocols in the IP domain, there are:

- the Exterior Gateway Protocol, EGP and
- the Border Gateway Protocol, BGP.

20.5 Interior Gateway Protocols for IP Networks

In the IP world, interior gateway protocols are used to deal with both intra- and inter-area routings within an AS. RIPv1, RIPv2, and IGRP are distance-vector protocols. OSPF and IS–IS are link-state, while EIGRP is a hybrid. Apart from the two Cisco protocols, all the others are open standards, that is, their specifications are publicly available.

Distance vector IGPs

This section describes and compares two popular distance vector protocols supporting IP, RIP, and IGRP.

RIP

The RIP was one of the first IGPs and has been used for routing computations in computer networks since the early days of the ARPANET. Formally defined in the XNS Internet Transport Protocols publications (1981), its widespread use was favored by its inclusion, as the *routed* process, in the Berkeley Software Distribution (BSD) version of Unix supporting TCP/IP (1982). Two RIP versions exist: Version 1 [8] and Version 2 [9].

In RIP, each router sends a complete copy of its entire routing table to all its neighbors on a regular basis (typical RIP update timer=30 sec). A single RIP routing update contains up to 25 route entries within the AS. Each entry contains the destination address of a host or network, the IP address of the next hop, the distance to the destination (in hops), and the interface. To obtain the cost to a given destination, a router can also send RIP request messages. After receiving an update, a router compares the new information with the information that it already possesses. If the routing update includes a new destination network, it is added to the routing table. If the router receives a route to an existing destination with a lower metric, it replaces the current entry with the new one. If an entry in the update message has the same next hop as the current route entry, but a different metric, the new metric will be used to update the routing table.

If a router does not hear from a neighbor for a given time interval, called a "dead interval" (an *invalid* timer is used for this purpose), it assumes that the neighbor is no longer available (either down or unreachable). As a result, the router modifies its local routing table and then notifies its neighbors of the

© 2005 by CRC Press LLC

unavailable route. After another predefined time interval (a *flush* timer is set for this purpose), if nothing is heard from the route, the information is flushed from the router's routing table.

Routers allow for configuration of an *active* or *passive* RIP mode on specific interfaces. The active mode means full routing capability, while the passive mode means a listen-only mode, that is, no RIP updates are sent out.

To speed up convergence, RIP uses *triggered updates*. That is, whenever an RIP router learns of a change, such as a link becoming unavailable, it sends out a triggered update immediately, rather than waiting for the next announcement interval. As it takes time for triggered updates to get to all the other routers in large networks, a gateway that has not yet received the triggered update may issue a regular update at the wrong time, thus causing a bad route to be reinserted in a neighbor that has already received the triggered update.

In order to prevent new routes from reinstating an old link, a *hold-down* period is enforced in the protocol: when a route is removed, no update for that route will be accepted for a given period of time, until the topology becomes stable. Hold-downs have the drawback of slowing convergence.

Besides hold-down, RIP implements other techniques to avoid routing loops between adjacent routers, called *split horizon* with *poison reverse*. The general split horizon algorithm prevents routes from being propagated back to the source, that is, down the interface from which they were learned. As an example, consider the case in Figure 20.3.

During normal operations, router A will notify router B that it has a route to network 1. According to the split horizon algorithm, when B sends updates to A, it will not mention network 1. Now let us assume that router A interface to network 1 goes down. Without split horizon, router B would inform router A that it can get to network 1. Since it no longer has a valid route, router A might select that route. In this case, A and B would both have routes to 1. But this would result in a *circular route*, where A points to B and B points to A.

Using split horizon with poison reverse, instead of not advertising routes to the source, routes are advertised back to the source with a cost of infinity (i.e., 16), which will make the source router ignore the route.

On the whole, RIP is quite robust and very easy to set up. It is the only routing protocol that Unix nodes universally understand and is therefore commonly used in Unix environments. RIP is also commonly used in end system routing as a *dynamic router discovery protocol*. Dynamic router discovery is an alternative to static configurations, which allows hosts to dynamically locate routers when they have to access devices external to the local network.

RIP was designed to work with moderate-sized networks using reasonably homogeneous technology. This makes it suitable for local networks featuring a small number of routers (about a dozen) and links with equal characteristics. RIP has a poor degree of scalability; thus, it is not recommended for use in more complex environments. The RIP protocol cannot be used to build a backbone larger than 15 hops in diameter,[1] as it specifies a maximum hop count of 15. A number of hops equal to 16 correspond to "infinity." This is useful to prevent packets that get stuck in rooting loops from being constantly switched back and forth between routers.

As it uses a simple, fixed metric to compare alternative routes, RIP can generate suboptimal routing tables resulting in packets sent over slow (or costly) links even in the presence of better choices. RIP is therefore not suitable for environments where routes need to be chosen based on dynamically varying parameters such as measured delay, reliability, or load (RIP does not support load balancing).

RIP version 1 (RIPv1) lacks Variable Length Subnet Mask (VLSM) support. The term VLSM refers to a design practice of creating subsubnets in a tree-structured network. In particular, VLSM is the ability to specify a different subnet mask for the same network number on different subnets. More details can be found in [10]. Protocols that do not allow VLSM, because in the update phase they do not propagate the subnet mask and distinguish between address classes, are classified as Classful. Thus, RIPv1 is Classful.

[1]RIP is usually configured in such a way that a cost of 1 is used for the outbound link. If a network administrator chooses to use larger costs, the upper bound of 15 can be quickly reached and will become a problem.

© 2005 by CRC Press LLC

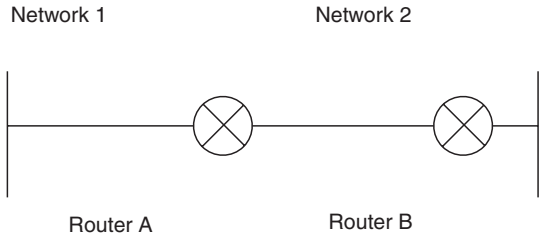

FIGURE 20.3 A simplified internetwork used to explain split horizon with poison reverse.

This may seriously deplete the available address space to the detriment of scalability. On the other hand, protocols that allow VLSM are called Classless. RIP version 2 (RIPv2) is Classless.

RIPv1 uses a broadcast mode to advertise and request routes, while RIPv2 has the ability to send routing updates via multicast addresses. RIPv2 also supports *route aggregation* techniques, that is, the use of a single network prefix to advertise multiple networks [11]. Moreover, RIPv2 provides some support for authorization data link security, implementing authentication support on a per message basis.[2]

RIPv2 also offers some support for ASs and IGP/EGP interaction by means of *external route tags.* External routes are learned from neighbors situated outside the AS, while internal routes lie completely within a given AS. In RIPv2, a Route Tag field is used to separate internal RIP routes from external routes imported from an EGP. Finally, RIPv2 scales better than RIPv1; but as compared to link-state protocols, it suffers from slow convergence and scalability limitations.

Interior Gateway Routing Protocol (IGRP)

The *Interior Gateway Routing Protocol (IGRP)* [12] was created by Cisco in the 1980s. Not being an open standard, it only runs on Cisco routers.

IGRP shares several features with RIP. IGRP sends out updates on a regular basis (every 90 sec) and uses *update*, *invalid,* and *flush* timers as well (with values different from RIP, depending on the implementation). Like RIP, IGRP uses triggered updates to speed up convergence and hold-down timers to enforce stability. However, while RIP only allows a network diameter of 15 hops, IGRP can support a network diameter of up to 255 hops; thus, it can be used in larger networks.

IGRP differs from RIP with respect to metrics, parallel route support, the reverse poisoning algorithm, and the use of a default gateway. Like RIPv1, IGRP does not support VLSM.

Unlike RIP, IGRP does not use a single metric, but a *vector* of metrics, which takes into account the topological delay time, the bandwidth of the narrowest bandwidth segment of the path, channel occupancy, and the reliability of the path. A single composite metric can be computed from this vector [12], which encompasses the effect of the various components into a single number representing how good a path is. The path featuring the smallest value for the composite metric will be the best path.

The hop count and Maximum Transmission Unit (MTU) that is, the maximum packet size that can be sent along the entire path without fragmentation) of each network are also considered in the best path calculation.

With IGRP, network administrators are supplied with a large range of metrics and they are also allowed to customize them. By giving a higher or lower weight to specific metrics, network administrators can therefore influence IGRP's automatic route selection. For example, suitable constants can be set to several different values to provide different "types of service" (interactive traffic, for instance, would typically yield a higher weight to delay, whereas file transfer would assign a higher weight to bandwidth).

[2]A whole RIP entry, denoted by a special Address Family Identifier (AFI) value of 0xFFFF, is used for authentication purposes, thus reducing the total number of routing entries per advertisement to 24.

© 2005 by CRC Press LLC

IGRP is more accurate than RIP in calculating the best path, as a vector of metrics instead of a single metric improves the description of the status of a network.

If, for instance, a single metric is used, several consecutive fast links will appear to be equivalent to a single slow link. While this would be appropriate for delay-sensitive traffic, it would not be so for bulk data transfer, which is more sensitive to bandwidth. This problem may arise with RIP, but not with IGRP, as it considers delay and bandwidth separately.

An interesting feature of IGRP is that it provides multipath routing and can perform load balancing, by splitting traffic equally between paths that have equal values for the composite metrics. To deal with the case of multiple paths featuring unequal values for the composite metrics, a *variance* parameter is defined as a multiplier of the best metrics. Only routes with metrics within a given variance of the best route can be used as multiple paths. In this case, traffic is distributed among multiple paths in inverse proportion to the composite metrics. The variance can be fixed by the network administrator. The default value is 1, which means that when the metric values of two paths are not equal, only the best route will be used. A higher variance value means that any path with a metric up to that value will be considered for routing purposes. However, variance values different from 1 should be carefully managed, as they may cause routing loops.[3]

Unlike RIP, which can only prevent routing loops between adjacent routers, the route poisoning algorithm used in IGRP prevents large routing loops between nonadjacent routers. This is achieved by poisoning routes, whose metrics increase by a factor of 10% or more after an update. The rationale behind this is that routing loops generate continually increasing metrics. It should be noted that if this poisoning rule is used, valid routes may be erroneously deleted from routing tables. However, if the routes are valid, they will be reinstalled by the next update. The advantage of the IGRP poisoning algorithm is that it safely allows a zero hold-down value, which significantly improves network convergence time. IGRP handles default routes differently from RIP. Instead of a single dummy entry for the default route, IGRP allows real networks to be flagged as candidates for being a default. IGRP periodically analyzes all the candidate default routes to choose the one with the lowest metric, which will be the actual default route. This approach is more flexible than the one adopted by typical RIP implementations. The default route can change in response to changes within a network.

A hybrid protocol: the Enhanced Interior Gateway Routing Protocol (EIGRP)

EIGRP was introduced by Cisco in the early 1990s as an evolution of IGRP [13]. As it offers support for multiple network layer protocols (e.g., IP, AppleTalk, and Novell NetWare), EIGRP is commonly used in mixed networking environments.

EIGRP is called a hybrid protocol as it combines a distance-vector routing protocol with the use of a Diffusing Update Algorithm (DUAL) [14], which has some of the features of link-state routing algorithms. The advantages of this combination are fast convergence and lower bandwidth consumption.

DUAL, based on distance information provided by route advertisements from neighbors, finds all loopfree paths to any given destination. Among all the loop-free paths to the destination, the neighbor with the best path is selected as the *successor*, while the others are selected as *feasible successors*, that is, eligible routes to be used if the primary route becomes unavailable. If, after a failure, one feasible successor is found, DUAL promotes it to primary route without performing recalculation, thus reducing the overhead on routers and transmission facilities. If, on the other hand, no feasible successors exist, a recomputation (called a *diffusing computation*) is performed to select a new successor. Unnecessary recomputations affect convergence; thus, they should be avoided.

EIGRP uses the same composite metrics as IGRP. However, it does not send periodic updates, but instead implements neighbor discovery/recovery, based on a hello mechanism, to assess neighbor

[3]It should also be pointed out that the load balancing performed by the IGRP may produce out-of-sequence packets. This should be taken into account when neither the Data Link nor Transport layer protocols have the capability of handling out-of-sequence packets.

© 2005 by CRC Press LLC

reachability. Routing updates are only sent in the event of topology changes or a failure in a router or link. Moreover, when the metric for a route changes, only partial updates are sent and they only reach the routers that really need the update. As a result, EIGRP requires less bandwidth than IGRP.

EIGRP relies on the Reliable Transport Protocol (RTP) [15] to achieve guaranteed and ordered delivery of EIGRP packets to all neighbors. It supports VLSM, thus providing more flexibility in internetwork design than RIPv1 or IGRP. This can be particularly useful when dealing with a limited address space.

EIGRP has a modular architecture that makes it possible to add support for new protocols to an existing network. On the whole, EIGRP is robust and easy to configure and use. EIGRP supports both internal and external routes, allowing tags to identify the source of external routes. This feature can be exploited by network administrators to develop their own interdomain routing policies [16,17].

Link-state Protocols

OSPF: The Open Shortest Path First Protocol

OSPF is a link-state IGP designed by the IETF in the late 1980s to overcome the limitations of RIP for large networks. The name of this protocol derives from the fact that it is an Open standard and that it uses the Shortest Path First (also called Dijkstra) algorithm [18,19]. It was specifically designed for the TCP/IP environment and runs directly over IP. OSPF is commonly used in medium-to-large IP networks and is implemented by all major router manufacturers. Several specifications have emerged since the first one [20]. The RFC for OSPF version 2 (OSPF v2) is [21], while OSFP specifications to support IPv6 are given in [22].

One of the most appealing features of OSPF is its support for hierarchical routing design within ASs (although it is purely an IGP). An AS running OSPF can therefore be configured into areas that are interconnected by one *backbone* area (as it is shown in Figure 20.4). There are two types of routing within OSPF, that is, intra- and inter-area routing.

In OSPF, each router monitors the state of its attached interfaces. If a topology change occurs, the router that has detected it distributes information about the change to all the other routers within its area, through broadcast messages called *Link State Advertisements* (LSAs). LSAs include metrics, interface address, and other data. A router uses this information to build a topological database in the form of a direct graph. The costs associated with the various edges (i.e., links) are expressed by a single dimensionless metric configured by the network administrator. A topological database is therefore present in each router.

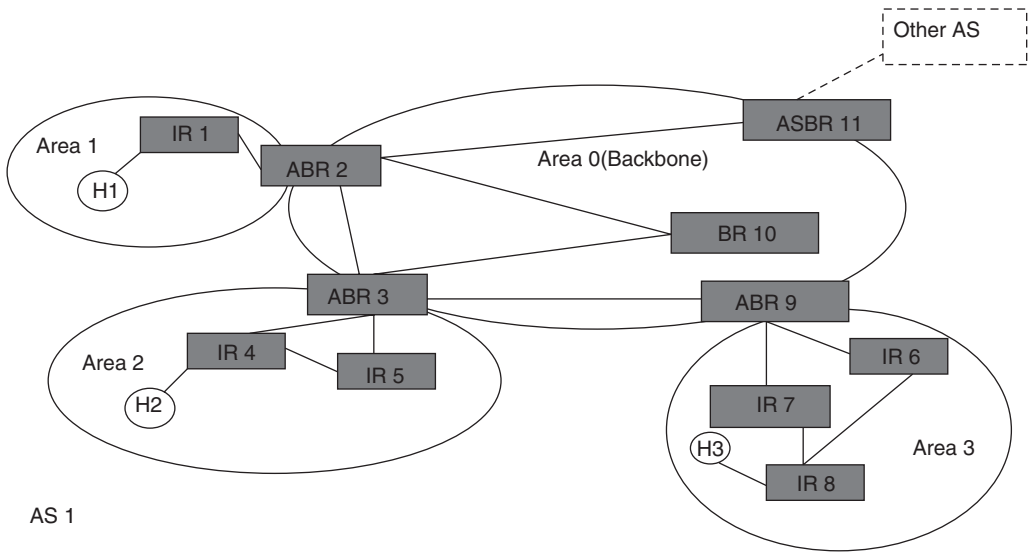

FIGURE 20.4 OSPF Routing Hierarchy.

© 2005 by CRC Press LLC

When two routers have identical topological databases, they become *adjacent.* This is important, as routing information can be exchanged only between adjacent routers. Locally, the router applies a Shortest Path Tree algorithm to all the networks, considering itself as the root node.

As mentioned above, each router sends LSAs only to all the routers in the same area. This prevents intra-area routing from spreading outside the area. Each router within an area will know routes to any destination within the area and to the backbone.

The internal topology of any area is hidden to every other area. Each router within a given area will know how to reach both every other router within its area and the backbone; but it does not have any clue about the number of routers existing or the way they are interconnected for any other area.

Inter-area routing is performed through the backbone (which must be configured as area 0). It should be pointed out that an OSPF backbone is a routing area and not a physical backbone network as the name might suggest. Four different types of router can be configured in OSPF: Internal Routers (IR), ABR, Backbone Routers (BR), and ASBR. All of them are depicted in Figure 20.4.

IRs are only entrusted with intra-area routing. All their interfaces are connected within an area. ABRs route packets between different areas within the AS. They interface to multiple areas (including the backbone); thus, they belong both to an area and the backbone, and maintain topological information about both of them.

BRs belong to the backbone (area 0), but are not ABR; that is, their interfaces are connected only to the backbone (e.g., BR-10). As the backbone operates an area itself, BRs maintain area routing information. ASBRs, also called Boundary Routers, are responsible for exchanging routing information with routers belonging to other ASs (e.g., ASBR-11 in Figure 20.4). They have an external interface to another AS and learn external routes from dynamic EGPs, such as BGP-4 (presented in Section 20.5), or static routes. External routes are passed transparently throughout the AS and kept separate from the OSPF link-state data. External routes can also be tagged by the advertising routes.

A packet to be sent to another area in the AS (inter-area routing) is first routed to an ABR in the source area (intra-area routing) and then routed via the backbone to the ABR that belongs to the destination area. Finally, it will be routed to the ultimate destination.

Route calculation introduces high complexity and, as an OSPF router stores all link states for all the areas, the overhead is high in a large internetwork. On the other hand, OSPF scales well and converges quickly. It also provides several appealing features, such as:

- Security, as all the exchanges between OSPF routers (e.g., LSAs') are authenticated, thus preventing intruders from manipulating routing information.
- Type of Service (TOS) support, as each link may feature different costs according to the traffic TOS requirements.
- Load balancing between multiple equal-cost paths.
- Triggered updates.
- Designated routers: on a LAN, if several routers may be connected, one will be elected as the *designated router* and another one as its backup. The designated router is responsible primarily for generating LSAs for the LAN to all other networks in the OSPF area.
- Explicit support for VLSM and the ability to have discontinuous subnets (i.e., made up of single networks or sets of networks featuring noncontiguous addressing). This feature is very useful in the Internet.
- Tagged external routes; thus, OSPF is capable of receiving routes from and sending routes to different ASs'.
- Route summarization: an area border router can aggregate two subnets belonging to the same area so that only one entry in the routing table of another router will be used to reach both subnets. This minimizes the size of topological database in the routers, thus significantly reducing protocol traffic.

Integrated IS–IS

The *IS–IS* [23] is a link-state protocol. It is an open standard and its name indicates that this protocol is used by routers to talk to each other. Developed for the OSI world, IS–IS was made "Integrated," so that

© 2005 by CRC Press LLC

it could route both OSI and IP protocols simultaneously. Similar to OSPF, Integrated IS–IS uses the SPF algorithm and is based on LSAs sent to all routers within a given area and hello packets to check the current state of a router. As it is a link-state protocol, it converges fast, but at the expense of high complexity. Integrated IS–IS supports VLSM, load sharing, and triggered updates. Still not widely deployed at present (it is confined to telco and government networks), Integrated IS–IS has a good potential for medium-to-large IP networks.

20.6 Exterior Gateway Protocols for IP Internetworks

EGPs are responsible for routing between ASs. Possible alternatives in the IP world are static routes, the EGP [24], and the Border Gateway Protocol (BGP) [25].

Static Routes

Static routes can be applied to both intra- and inter-AS routings. However, as they lend particularly appealing features to inter-AS routing, they are included in this subsection. Configuration of static routes is simple, and it is very easy to enforce policy (as no routes equals no access). With static routes, no routing protocol messages travel over the links between ASs. On the other hand, maintenance of static routes in large internetworks may be complex, as they do not scale. For this reason, many network designers adopt the Dynamic Host Configuration Protocol (DHCP) [26], which dynamically allocates a default gateway from a set of candidate gateways. Static routes also lack flexibility (as there is no way to choose a better path that could have been selected if dynamic routing protocols were used); thus, they are not suitable for changing environments. They do not respond to topological changes. To enforce fault tolerance in static routes, a secondary gateway is usually maintained, which could adopt the role of the primary one if the latter becomes unreachable or goes down.

EGP

The EGP [24] was the first EPG to be developed. It runs directly over IP and is a best-effort service. The routing information of EGP is similar to distance-vector protocols; but it does not use metrics. EGP has some design limitations, as it does not support routing loop detection and multiple paths. If more than one path to a destination exists, packets can easily get stuck in routing loops. Nowadays, it has been declared obsolete and has been replaced by the BGP.

BGP

The BGP version 4 (BGP-4), originally specified in RFC 1771 [25], is a very robust and scalable routing protocol, which is becoming *a de facto* standard for inter-AS routing on the current Internet. BGP-4 is an open standard. It somewhat resembles distance-vector protocols, as it is a distributed protocol where information exchange occurs only between directly connected routers. However, it is more appropriate to define BGP-4 as a path-vector protocol. This is because, as stated in [25], "the primary function of a BGP speaking system is to exchange network reachability information with other BGP systems." Network reachability information includes only the list of ASs' that need to be traversed in order to reach other networks. *Path information*, instead of *cost information*, is exchanged between neighboring BGP routers, and BGP-4 does not specify the rule to choose a path from among the advertised ones. Routing mechanism and routing policy are therefore separated. A policy is manually configured in order to allow a BGP router to rate possible routes to other ASs and choose the best path.

Two BGP routers first have to establish a TCP connection. After a negotiation phase, in which the two systems exchange some parameters (such as BGP version number, AS number, etc.), they become *BGP peers* and can start exchanging information. Initially, they exchange the full routing tables. Thereafter, only incremental updates are sent, when some change in the routing tables occurs. No periodic refresh of

© 2005 by CRC Press LLC

the entire routing table is needed; thus, a BGP speaker maintains the current version of the entire BGP routing tables of all of its peers for the duration of the connection. In order to maintain the connection, peers regularly exchange *keep-alive* messages. Notification messages are sent in response to errors or special conditions. In the event of error, a notification message is sent and the connection is closed.

Network reachability information is used to construct a graph of AS connectivity, from which routing loops may be pruned and policy decisions at the AS level may be enforced. Each BGP router maintains a routing table with all feasible paths to a given network.

As mentioned above, BGP does not propagate cost information, but path information, and does not specify which path should be selected from those that have been advertised, as this is a policy-dependent decision left to the network administrator. This is because, as was previously stated (in Section 20.3), when dealing with inter-ASs routing, policy is more important than performance.

However, when a BGP speaker receives several updates describing the best paths to the same destination, it should finally choose one of them. The selection criteria are based on rules that take *path attributes* into account. Once the decision has been made, the speaker places the best path in its routing table and then propagates the information to its neighbors. The path attributes generally used in the route selection process are [7,27,28]:

Weight: A Cisco-defined attribute that is local to a router and is not advertised to neighboring routers. If the router learns about more than one route to the same destination, the route with the highest weight will be preferred.

Local preference: Used to prefer an exit point from the local AS. It is propagated throughout the local AS. If there are multiple exit points from the AS, the local preference attribute is used to select the exit point for a specific route.

Multi-exit discriminator, *or metric attribute*: Used as a suggestion to an external AS regarding the preferred route into the AS that is advertising the metric.

Origin: Indicates how BGP learned about a particular route. The origin attribute can have one of three possible values: *IGP* (i.e., the route is interior to the originating AS), *EGP* (i.e., the route is learned via the Exterior Border Gateway Protocol (eBGP)), *Incomplete* (i.e., the origin of the route is unknown or learned in some other way — this occurs when a route is redistributed in BGP).

AS_path: When a route advertisement passes through an autonomous system, the AS number is added to the ordered list of AS numbers that the advertisement traversed.

Next hop: The IP address that is used to reach the advertising router.

Community: Provides a way of grouping communities, that is, destinations to which routing decisions can be applied. Predefined community attributes are *no-export* (which means that this route must not be advertised to EBGP peers), *no-advertise* (which means that this route must not be advertised to any peer), and *Internet* (which means that this route must not be advertised to the Internet community — all routers in the network belong to it).

Attributes are crucial to achieve scalability, define routing policies, and maintain a stable routing environment. Other BGP features include route filtering, that is, the ability of a BGP speaker to specify which routes to send and receive from any of its peers. Filtering may refer to inbound or outbound links and may be applied as permit or deny.

BGP-4 supports supernetting or Classless Interdomain Routing (CIDR) [29], which enables route aggregation, that is, the combination of several routes within a single-route advertisement. This minimizes the size of routing tables and protocol overhead.

BGP was originally designed to perform inter-AS routing; but it can also be used for intra-AS routing. BGP connections between ASs are called External BGPs (e-BGP), while those within an AS are called Internal BGPs (i-BGP).

Figure 20.5 shows a typical scenario for e-BGP, that is, a multi-homed AS connected to the Internet. All the networks X, Y, Z, 1, 2, and 3 are ASs. In particular, 1 and 3 are stub networks, 2 is a multi-homed stub network, while X, Y, and Z are backbone provider networks. A stub network is such that all traffic

© 2005 by CRC Press LLC

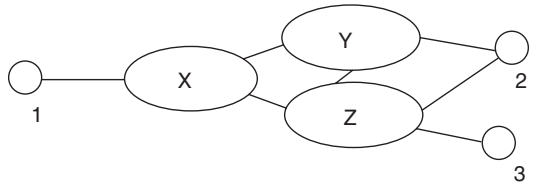

FIGURE 20.5 A scenario for BGP.

entering it should be destined to that network. A multi-homed AS is connected to multiple ASs (e.g., via two different service providers[4]), but does not allow transit traffic.

Stub network 2 will be prevented from forwarding traffic between Y and Z by a selective route advertisement mechanism. BGP routes will be advertised in such a way that network 2 will not advertise to its neighbors (Y and Z) any path to other destinations except itself. For instance, 2 will not advertise path 2 Z 3 to network Y; thus, the latter will not forward traffic to 3 via 2.

The i-BGP protocol can be used to distribute routing information to routers within the AS regarding destinations (networks) outside the AS. Running i-BGP offers several advantages, such as a consistent view of the AS to external neighbors, more control over information exchange within the AS, flexibility, and a slightly shorter convergence time than e-BGP (which is slow).

Table 20.3 (a) and (b) lists the various IGPs and EGPs discussed till now and compares them according to multiple design criteria. Table20.3 can be helpful to guide the designer's choice when dealing with routing protocols in the IP domain.

We have seen that various IGPs and EGPs exist in the IP domain, among them, proprietary protocols and open standards. In a composite, complex internetwork, they may coexist either for historical reasons or due to the presence of multiple vendor solutions. This coexistence may cause incompatibility problems due to both the different metrics adopted and peculiarities of the various protocols. Therefore, a way to overcome incompatibilities and form a holistic view of the network topology is needed, thus enabling interoperability. This is the case for *route redistribution*.

Route redistribution is the process that enables routing information from one protocol to be translated and used by a different one. A router can therefore be configured to run more than one routing protocol and redistribute route information between the two protocols. Redistribution is needed in two cases:

- at the AS boundary, as IGPs and EGPs do not match and
- within an AS, when multiple IGPs are used.

Redistribution has direction. That is, routing information can be redistributed symmetrically (mutual redistribution) or asymmetrically (hierarchical redistribution). Handling redistribution is not an easy task and it is difficult to define a general approach. Solutions are typically vendor-dependent, as the problems that can occur are strictly related to the details of the various protocols.

The following section presents a case study, that is, a global IP network for a large-scale mission-critical enterprise, and gives practical guidelines related to route redistribution in the considered scenario.

20.7 Case Study: A Global IP Network for a Large-scale Mission-Critical Enterprise

This section addresses IP routing technologies and design criteria to be adopted in designing a global IP network for a large-scale mission-critical enterprise. Mission-critical means that high availability (uptime 100%), uninterruptible service, and fault-tolerance (i.e., redundancy, fast, and reliable recovery) must be

[4]In this situation, multiple service providers are used to increase availability and to allow load sharing.

TABLE 20.3 (a) and (b) IP routing Protocol Comparison According to Multiple Design Criteria

Protocol		Technology	Type	Metrics	Scalability	VLSM support	Hop Count limit	Load Balance (equal paths)	Load balance (Unequal paths)	Standard	Convergence time	Routing Algorithm
	IGRP	Distance Vector	Classful	Band-width, delay, load, reliability, MTU	Medium	No	100 (up to 255)	Yes	Yes	No	Slow	Bellman-Ford
	RIPv1		Classful	Hop Court	Small	No	15	yes	No	Yes	Slow	Bellman-Ford
IGP	RIPv2		Clasless	Hop court	Small	yes	15	Yes	No	Yes	Slow	Bellman-Ford
	RIGRP	Advanced Distance Vector	Classless	Band-width, delay, load, reliability, MTU	Large	Yes	100 (up to 255)	Yes	Yes	No	Fast	Dual
	OSPF	Link State	Classless	Cost	Large	Yes	200	yes	No	Yes	Fast/Slow	Dijkstra
	IS-IS	Link State	Classless	Clost	Very large	Yes	1024	Yes	No	Yes	Fast/Slow	IS-IS
EGP	BGP-4	Path Vector	Classless	Cost, Hop, Policy	Large	Yes		No	No	Yes	Slow	

provided to guarantee business continuity. This scenario is related to a global-independent manufacturing company, which is a leader in developing and delivering semiconductor solutions across the spectrum of microelectronics applications. The company extends over three macro-regions — Europe, North America, and the Asia-Pacific region. The corporate headquarters are in Europe, with backup from the U.S. headquarters. The main servers are located in both headquarters.

To support the growing demand for data and streaming media, the company chose IP protocols as the basis for voice, video, and data convergence. That is, unlike past solutions, where different protocols were used to support voice and data traffic, respectively, nowadays, IP is the single technology used for all the different kinds of traffic present in the considered scenario.

The architecture of the global IP network system (the infrastructure) has been defined bearing in mind the need for the enterprise to have a supporting network frame capable of providing very high service levels in terms of the available transmission bandwidth, business continuity (for mission-critical environments), and, more generally, the quality of service that users are provided with.

Also, possible new needs that the enterprise may have, with respect to emerging technologies and applications and, above all, in terms of changes in traffic flows, that are anticipated and/or desirable, have been taken into account in the design phase.

The realization expects to implement a high-performance communication architecture at both the backbone and single-area (up to workgroup) level, with a fundamental aspect of redundancy at the single device and system architecture levels.

Infrastructure Requirements for a Large-scale IP Network

From a design viewpoint, analysis of the company network requires an approach oriented toward scalability and high-performance levels that will be adequate for a large number of users (servers and clients) spread over a vast geographical area.

The architecture of this global IP network should be able to provide a large-scale, high-available/reliable, *carrier-grade* infrastructure. The concept of large-scale availability and reliability means that the reachability of an IP packet is guaranteed by improving the reliability and performance of the routing and forwarding functions on the network. Carrier grade means that support of the global IP infrastructure is outsourced to large-scale networks provided by specialized carriers with mechanisms that guarantee Quality of Service (QoS), Service Level Agreement (SLA), redundancy links, etc. [30].

To increase the size of the IP network, it is necessary to improve the switching capacity of the routers and reduce both the time required to search for an IP address in a router and the traffic involved in IP routing between the various routers. In addition, a sophisticated quality monitoring and control mechanism is essential for a real-time infrastructure supporting a "best-effort" approach toward the data and services to be exchanged.

A basic issue in designing this infrastructure is identifying the IP routing technology to support a real multi-service network providing convergence with respect to data, applications, and services.

IP Routing Technologies: Backbone level (Company-wide)

Figure 20.6 shows a scheme of the network infrastructure devised for the large-scale company considered in this case study. It comprises three geographically distributed macro-regions (Europe, America, Asia), each equipped with an ABR gateway and belonging to the same backbone, that is, Area 0. The common layer 2 is Frame Relay [31]. The Company backbone consists of a large set of hosts, routers, and networks under the same administration, which has consistent and complete information about all destinations.

The company infrastructure is an AS Confederation (according to the *divide and conquer* strategy, a large AS is split into sub-ASs), composed of Area 0 (Backbone) and Areas 1,2,..,*n*, where each subarea is a Site of the Company. Sub-AS may use multiple IGPs and metrics, but appear as single AS to other ASs. Internet connections occur only through ASBR routers (Internet is a special kind of AS, which is named "Core AS").

© 2005 by CRC Press LLC

The traffic types throughout the Backbone are divided into:

- *Local,* that is, traffic originating or terminating at each AS and
- *Transit,* that is, nonlocal traffic.

Figure 20.6 also shows a Partner Gateway link toward a partner's extranet and mobileusers' application using Internet Core as the common infrastructure.

The scheme in Figure 20.6 shows the use of dynamic routing protocols that exchange routing information through neighboring routers. The Company Corporate decision is to have an IP infrastructure in which routing policies are transparent to users spread over a wide geographical area with respect to the servers (e.g., mobile users). In general, it will use EIGRP and RIP in a site AS and OSPF as dynamic routing between the various sites of the regions.

The choice of OSPF as the intra-Company and inter-Area Border routing protocol is based on the following considerations:

- Cost of the transmission bandwidth and consequently limited throughput capacity.
- Congestion and delay.
- High network latency.
- Large number of addressable subnetworks.
- Multivendor environments.

OSPF is highly suitable for this context as it converges fast with a low workload as compared with the amount of data transmitted per time unit. It is also standard and therefore does not require homogeneous environments (unlike EIGRP, which requires CISCO in each of the areas indicated).

In addition, OSPF provides fast, efficient addressing of a number of subnetworks as it uses the concept of route summarization (which cannot be implemented in RIPv1).

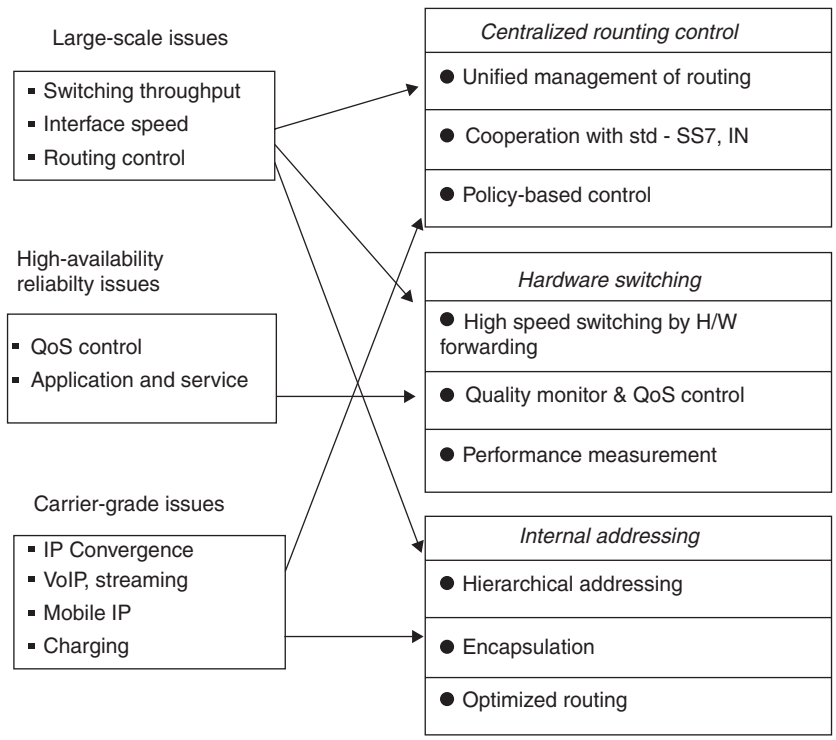

FIGURE 20.6 Large-scale Company IP infrastructure.

© 2005 by CRC Press LLC

Because OSPF supports VLSM, it can be really developed into a true hierarchical addressing scheme. This hierarchical addressing results in very efficient summarization of routes throughout the network. Discontinuous subnets (i.e., composed of single networks or sets of networks featuring noncontiguous addressing) are also supported by OSPF because subnet masks are part of the link-state database [32].

Internet access is only possible through ASBR gateways, by means of a BGP routing, by which the routing tables toward the intranet will be redistributed (see the section on Redistribution of routing tables). Like OSPF and EIGRP, BGP exchanges variations in topology with neighbors (incremental update) in relation to the associated metrics (BGP AS number, path attributes, etc.). A substantial difference lies in the fact that although the ASBR routers of the single ISPs adopt a dual homing mechanism (i.e., redundant links), BGP does not implement load-balancing between the two links, because it always chooses a single path (i.e., the best route) to route data.

Routing Technologies in an AS Domain (Company Site)

Let us consider a single Company Site, such as a campus network model representing a Manufacturing Site, where we distinguish between three large macro-levels related to different application domains that have been identified as Manufacturing, CAD, and Business (Figure 20.7).

We also define three levels of access to the single domain network (Figure 20.8):

- Access layer, hosting only clients (PCs, printers, workstations, etc.).
- Distribution layer, hosting servers connected through an optical fiber connection and implementing the intra-domain routing engine and layer 3 switching (CISCO switch layer 3 [33]).
- Backbone level, which represents the high-throughput core of the infrastructure implementing inter-domain routing.

Access devices have the task of concentrating traffic coming from end users into Ethernet 10/100 technology and then sending it toward the backbone level, which has the task of distributing the traffic toward other networks, both logical VLANs (Virtual LANs) and physical ones, inside and/or outside the campus itself.

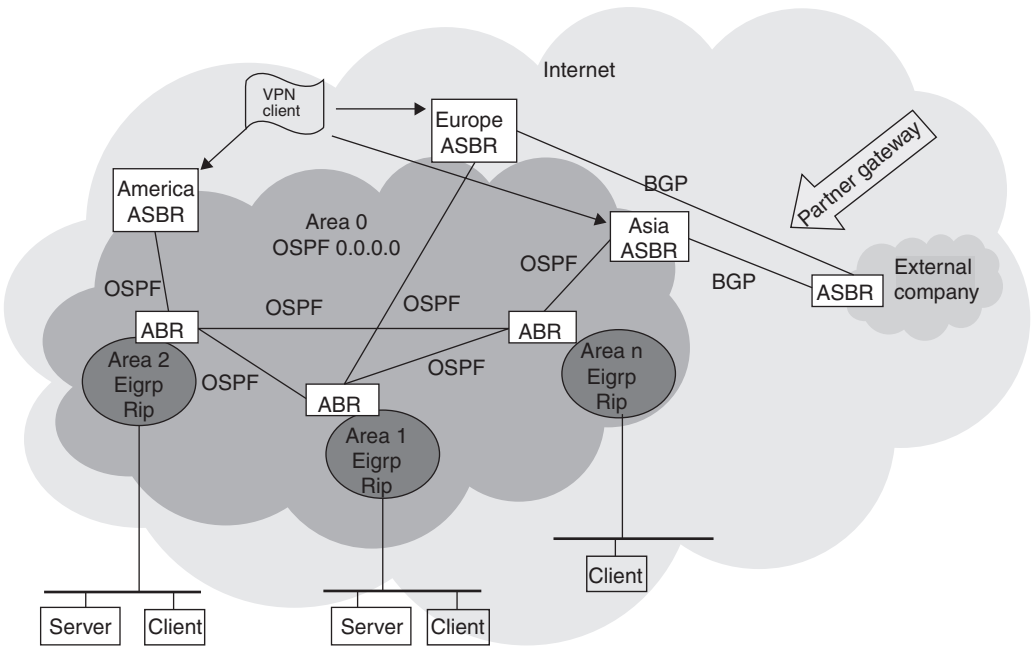

FIGURE 20.7 Large-scale Company IP Infrastructure.

© 2005 by CRC Press LLC

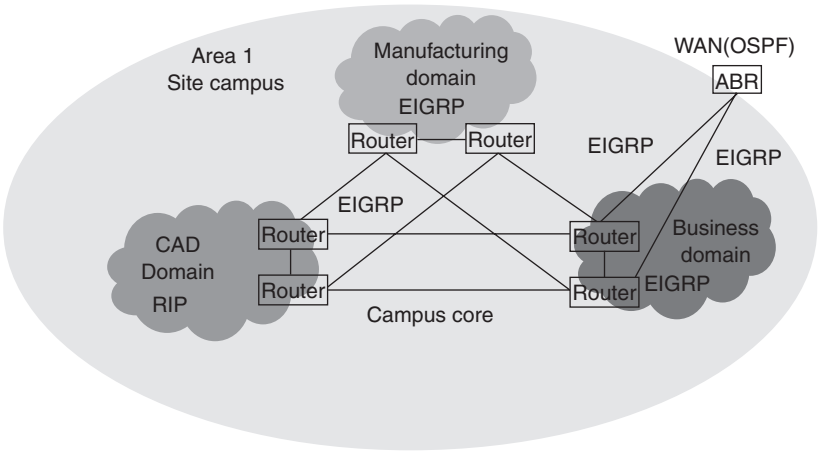

FIGURE 20.8 Company Site IP Infrastructure.

Access devices are planned to be connected in dual homing (with a double LAN connection to two different networks), through an optical fiber connection, a high-throughput (1000 Mbps) Layer 3 Switching device making up the backbone level of the network frame structure. In addition, to ensure maximum continuity of service required for mission-critical environments, they are designed to be completely redundant in power supply and matrix switching.

Both Access level devices and those of the Distribution/Backbone level are endowed with functions allowing completely automatic and simultaneous management of both load sharing on available links and backup functions, with the consequent use of the only link left available in the event of a fault in the other link.

The Distribution/Backbone nodes inside the campus are interconnected by multiple high-throughput links. Together, the nodes will achieve a throughput of more than 4 million packets per second (pps) on the two interconnected devices, which will reduce to two million pps in the event of a complete fault in one of the two devices, without, however, jeopardizing the normal functioning of the network. They have the task of gathering the traffic generated by all the switches present at the access level, concentrating the servers located in the server farm and connecting the campus LAN with the routers needed to guarantee access to a wide area network service, thus allowing interconnection with other sites and/or other organizations. So a high level of performance is available to enable a large amount of data traffic to transit through the campus network (Figure 20.9).

The Backbone devices are therefore capable of forwarding the traffic generated at both level 2 and level 3 (according to needs), using common transmitting/routing protocols. Multi-protocol routing is also allowed by the routers.

The Backbone nodes are required to be completely redundant at the level of both the HW components and the SW functions and at the network architecture level.

Choice of Routing Protocols

In a hybrid environment like a manufacturing site, in terms of the applications and services used, the choice of one routing protocol rather than another may have a considerable impact on performance and efficiency. Thus, the choice of one information routing mechanism rather than another is significant.

In a CAD environment, where the main elements on the network are hosts whose traffic is mostly confined to the environment itself (80% internal traffic and 20% external traffic), it is possible to choose RIP: even if updating due to link faults is not timely, this will not affect normal activity. In some cases of satellite sites, even static routes are used. In environments like Manufacturing and/or Office Automation, on the other hand, where the traffic proportions are 20/80 (20% internal traffic and 80% external traffic) and where convergence times and performance levels have a significant impact on network performance, it is necessary to choose OSPF or, if the hardware architecture allows it, EIGRP.

© 2005 by CRC Press LLC

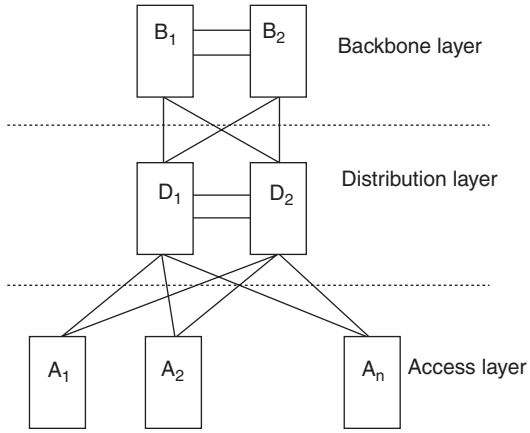

FIGURE 20.9 Manufacturing Domain: Three-level LAN access Infrastructure.

It should, however, be pointed out that choices at the site level are usually homogeneous. If we assume Cisco to be the standard, EIGRP is applicable.

In any case, these three domains can be interconnected via OSPF rather than EIGRP, given the redundancy between the links and the traffic load balancing.

Another difference affecting the choice of one protocol rather than another is the possibility of subdividing networks by using VLSM. In our context, with the exception of the CAD environment, the subdivision into subnets improved the management of addressing and the subdivision of the broadcast domains according to the working environments.

Another decisive factor in choosing a routing protocol is convergence time. This is at the basis of the concept of high availability, which is of great significance in an area like manufacturing, where mission-critical applications require fault tolerance and redundancy. The introduction of QoS policies has to integrate routing policies to support fast convergence of the network topology following a fault or a Spanning Tree event, considering that the convergence time is mainly affected by the update mechanism (hold-down timers, like in the case of DV protocol — RIP), size of topology table, route calculation algorithm, and media type.

In our example, there is also a need to use multiple routing protocols. There are several reasons for this:

- Existing UNIX servers using RIP.
- Multivendor interoperability, as some department may not want to upgrade its non-Cisco routers.
- Groups do not want to work and play nicely with others, etc.

In these cases (as well as in IGP–BGP interaction), *route redistribution* is needed.

Route Redistribution — Implementation Considerations

Redistribution is performed by boundary routers connecting different ASs to exchange and advertise routing information received from one AS to another AS.

Within each AS, the internal routers have complete knowledge of their network. The router interconnecting ASs is the ASBR. The ASBR must have each single routing process as active.

Redistribution is powerful, but increases the complexity of IP routing; key features that may cause complexity are:

- Routing feedback: similar to the routing loop that occurs in distance vector protocols.
- Incompatible routing information (e.g., RIP uses hops and OSPF uses costs): path selection using the redistributed route information may not be optimal.
- Inconsistent convergence time: different routings converge at different rates.

© 2005 by CRC Press LLC

A common global approach to implementing redistribution is how the routers select the best path when more than one IP routing is running. Cisco, for example, uses two parameters:

- Administrative distance, which addresses the trustworthiness of a routing protocol (as seen in Section 20.1).
- Routing metrics, a value representing the path between a local and a remote router.

Once a reliable protocol for a specific area and for each specific destination has been identified, the routing tables are filled with the single routes. This happens for each protocol. The router only distributes the routes from one protocol to another if both have been configured with the respective metrics. Some protocols, for example, IGRP and EIGRP (Cisco proprietary), do this automatically; but this is not the case between RIP and OSPF. It should also be pointed out that only protocols belonging to the same stack can be redistributed (e.g., TCP/IP): if the metrics are configured, RIP and OSPF can redistribute, for example, because they both support TCP/IP.

A significant implementation issue is identification of the core and edge between protocols. In our campus example, EIGRP is the core.

Edges are both the router toward the WAN, which redistributes using OSPF and the routers toward the CAD domain, which redistribute using RIP.

Redistribution: EIGRP vs. RIP

This is the case of the router that in Figure 20.7 connects two networks belonging to CAD and Business domain: the first one uses RIP and the second one uses Enhanced IGRP, respectively. RIP converges slower than EIGRP; thus, if a link goes down, the EIGRP network will learn of it before the RIP network.

The goal of this router is to advertise RIP routes in the Enhanced IGRP network and to advertise Enhanced IGRP routes in the RIP network, while preventing the occurrence of route feedback, (i.e., the router must be configured so that Enhanced IGRP does not send routes learned from RIP back into the RIP network and so that RIP does not send routes learned from Enhanced IGRP back into the Enhanced IGRP network). The redistributed EIGRP router configuration command specifies that routing information derived from Enhanced IGRP be advertised in RIP routing updates. The default-metric router configuration command causes RIP to use the same metric value for all routes obtained from Enhanced IGRP. A default metric helps to solve the problem of redistributing routes that have incompatible metrics. Whenever metrics do not convert, using a default metric provides a reasonable substitute and enables the redistribution to proceed.

Redistribution: IGP vs. BGP

Depending on the mechanism used to propagate BGP information in a given AS, special care must be taken to censure consistency between BGP and IGP. There may, in fact, be time windows between the instant at which a border gateway (A) receives new routing information, originating from another border gateway (B) in the same AS, and the instant at which the IGP in the AS is able to route the routing traffic to BGP (B). During this window, "black holes" may be created. To minimize this problem, BGP (A) should not announce a path to an external network X to all adjacent BGPs in other ASs until all the internal BGPs in the AS are ready to route the traffic destined toward X through the correct border gateway (B). The best choice is OSPF vs. BGP rather than EIGRP vs. BGP, due to the better stability of OSPF at Area 0. EIGRP, in fact, transmits any variation (when it occurs) from every single host across the network due to the lack of areas' definition at the protocol level. It may severely impact the performance. In case of EIGRP at the backbone level, it is mandatory to distribute the only summary toward the BGP. Table 20.4 summarizes qualitative assessments to be taken into account while redistributing from/to AS (IGPs') vs. i-BGP and e-BGP.

© 2005 by CRC Press LLC

TABLE 20.4 IGP and EGP Redistribution

IGP vs. EGP		EGP vs. IGP	
Interior	Exterior	Interior	Exterior
Automatic neighbour discovery	Specifically configured peers	Carries ISP infrastructure addresses only	Carries customer prefixes
Generally trust your IGP routers	Connecting with outside networks	ISPs aim to keep	Carries Internet
Prefixes go to all IGP routers	Set administrative boundries	The IGP small for efficiency and	Prefixes
Binds routers in one AS together	Binds AS's together	scalability	EGPs are independent of ISP network topology

General Guidelines

In the following, useful guidelines to be taken into account in the routing design phase are listed:

- Decisions based on facts, that is, on knowledge of the data flow mechanisms in the company.
- No overlapping of routing protocols in the same domain, if it is Manufacturing or Business. The CAD domain may implement RIP and EIGRP at the same time.
- Redistribution in a single direction (preferable): this avoids loops and convergence problems due to different convergence times. This can be achieved by configuring a default route.
- Redistribution in two directions: if this is necessary, techniques to reduce the risk of loops must be applied, for example, routing table filters (i.e., limits on the path a packet can take), or modifications to the values the metric can take, etc. This prevents changes in routing tables imported from an AS from being reinserted into the same AS as if they were new routing tables. This point is of strategic importance in our example, where the geographical development of the company (WAN) uses lines whose cost is proportional to bit/s transmitted. In this way, one can avoid constant circulation of information regarding routing table alignment, which generates useless and expensive traffic.

21.1 Introduction

A wide variety of upcoming Internet applications like audio/video conferencing, multiplayer games, database replication, etc. require group communication. Group communication denotes the communication between more than two end systems. The realization of group communication with multiple point-to-point communication channels is possible but extremely inefficient. Especially, the communication within large and widely distributed groups would lead to overload in network components and end systems. IP multicast provides an efficient way to distribute data to multiple receivers. The basic principle is that the sender sends only one packet, which is then replicated only at junction points on the way to the receivers. With this, it is possible to support applications that rely on group communication without wasting resources in the network and end systems.

21.2 Addressing Principles

Different applications require different kinds of group communication. The following types of group communication can be distinguished (Figure 21.1):

In *one-to-many* communication, a single sender sends data to multiple receivers. One-to-many communication is required, for instance, for audio/video distribution (e.g., TV, radio, remote lectures), file distribution, and caching applications and any kind of distribution or publishing of information to a group of receivers (headlines, network time, stock prices).

In *many-to-many* communication, multiple senders send data to multiple receivers. Many-to-many communication is needed, for instance, for interactive applications like multimedia conferencing, for the synchronization of distributed data bases, for parallel processing, file sharing, interactive simulations, and multi-player games.

In *many-to-one* communication, multiple senders send data to one receiver. This is useful, for instance, for data collection applications (like accounting), for the discovery of resources and for auction and polling applications.

In order to realize the different types of group communication, the following basic addressing principles exist in the Internet:

© 2005 by CRC Press LLC

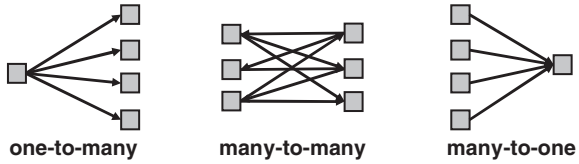

FIGURE 21.1 Group communication types.

Unicast addresses address one specific receiver. They are used to establish the communication between two endpoints. Most current Internet applications rely on unicast connections.

Broadcast addresses address all reachable stations, for instance, all systems on a local subnet. Broadcast is natively supported in some LAN technologies (e.g., Ethernet). Some protocols use this broadcast functionality to push information to all connected stations.

Multicast addresses address a group of receivers. Multicast is also natively supported in some LAN technologies (e.g., Ethernet). Multicast can be seen as the most generic addressing principle because unicasting can be realized by multicasting to a group with only one member and broadcasting can be realized by multicasting to a group with all stations as members.

Anycast addresses address one station out of a group. In anycast, the first suitable station answers the request. This is a special addressing principle, which is useful, for instance, to find the nearest station that offers a specific service.

21.3 IP Multicast

It is possible to send the same data to a group of receivers using unicast or broadcast. With unicast, the sender can simply send a duplicate of the IP packet to each receiver. This method is very inefficient, especially if the group is large. The sender has to send multiple copies of the same IP packet. Furthermore, equal copies of the same packet travel over the same network links. This leads to unnecessary load on the sender in terms of the network connections (Figure 21.2).

One can also address a group by broadcasting. The IP packet would simply be sent to all reachable receivers. Receivers not interested in the packet just need to discard the packet. This method also leads to unnecessary load on the network and on the receivers who are not members of the group.

IP multicast provides a method that prevents unnecessary resource consumption in the network and in end systems. The sender sends only one IP packet. The packet is then replicated only at the junctions on the way to the receivers. Packet replication takes place in the routers that are the junction points of the distribution tree. This method significantly reduces the required resources in the network and at end stations (Figure 21.2).

IP Multicast communication is unidirectional and runs over UDP, which means there is no flow control available. IP multicast allows a *dynamic membership* [RFC1112], that is, hosts may join and leave groups at any time. Furthermore, there is no restriction on the *location of members* and on the *number of members* in a group. A host can be a member in *multiple groups* simultaneously. A host does not need to be a member of a group to send IP packets to it.

A. IP Multicast Addresses

The address range 224.0.0.0 up to 239.255.255.255 is reserved for IP multicast addresses. Multicast addresses are called *class D addresses*. They consist of the pattern "1110" for the high-order four bits that identify the address as a class D address and the multicast group ID that specifies the group. The Ethernet also provides multicast addresses at the MAC layer. For mapping IP multicast addresses to Ethernet multicast addresses, the last 23 bits of the IP multicast addresses are mapped to the last 23 bits of the Ethernet address (Figure 21.3). Since this mapping is not unambiguous, multiple IP multicast addresses can map to the same Ethernet address. This does not really cause a problem because it is very unlikely that two IP

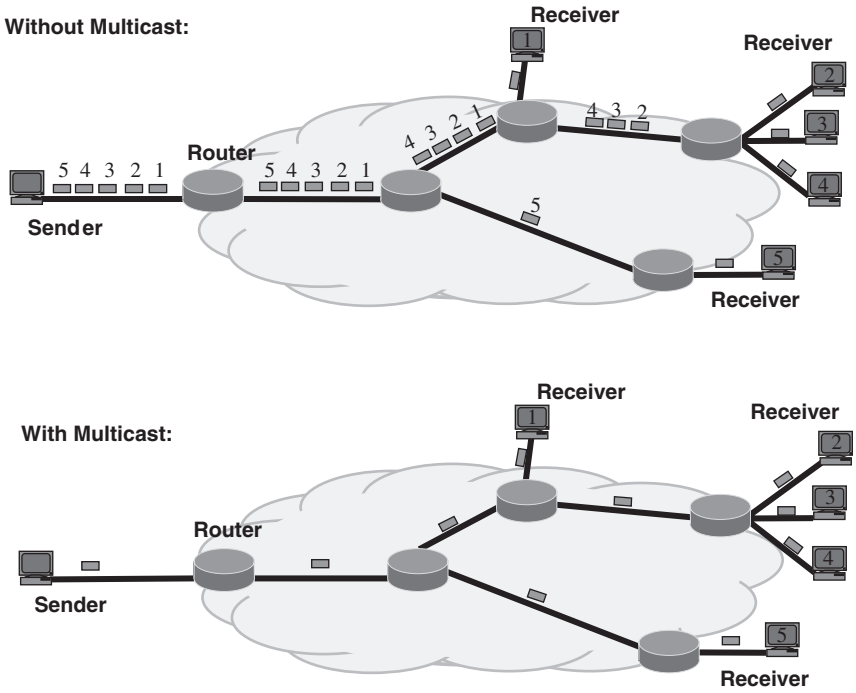

FIGURE 21.2 Group communication with and without IP multicast.

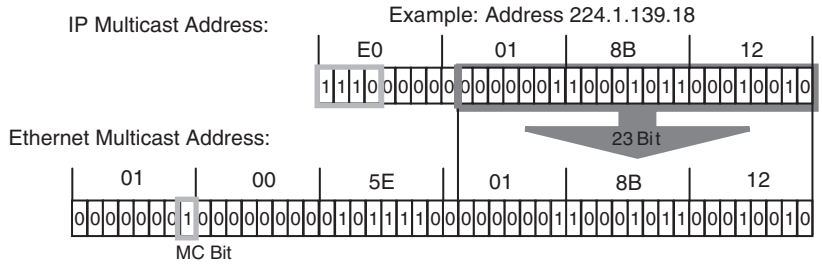

FIGURE 21.3 Mapping of IP multicast address to Ethernet address.

multicast addresses that map to the same Ethernet address are active at the same time in the same network. Furthermore, if a receiver really received a packet that is not intended for it, the IP layer would recognize that no application is listening to the IP multicast address, and may simply discard the packet.

In unicast communication, the distribution of a packet is terminated if it has reached the receiver. For multicast, the scope of the packet is at first undefined. Without any kind of additional *scope control,* multicast packets would be distributed everywhere. A solution to limit the scope is to set the Time To Live (TTL) value in the multicast packet to a specific value and configure thresholds at multicast routers. Routers then discard multicast packets with a TTL value below the threshold. With this, the distribution of packets can be controlled.

B. IP Multicast Protocol Overview

In order to send an IP packet to a multicast group, the sender only needs to specify a multicast address in the destination field. If an end system wants to receive packets that are sent to a specific multicast group,

© 2005 by CRC Press LLC

it has to join the group first. If the sender and receiver belong to the same physical network and the network provides a broadcast functionality, the receiver just needs to instruct its network interface to receive the multicast packets.

In networks that do not provide broadcast functions, additional mechanisms are required to ensure that all interested end systems receive the packet. In ATM networks, for instance, a Multicast Address Resolution Server (MARS) is required to map multicast addresses to the ATM addresses that belong to the group. With this information, a point-to-multipoint connection can be established to the multicast receivers in the ATM network.

If the sender and receiver belong to different networks, the receiver needs to inform the router in its network that he is interested in listening to a multicast group. This is done by the *Internet Group Management Protocol (IGMP)*. In IGMPv1 end systems send membership reports to inform the associated router about their wish to join a group. The routers initiate the forwarding of multicast packets [RFC1112]. Routers can also send queries to find out whether there are group members in the network they serve. Newer IGMP versions, IGMPv2 [RFC2236] and IGMPv3 [RFC3376], allow group- and sender-specific queries and membership reports.

Multicast routers exchange information about which multicast packets have to be forwarded to which networks. The establishment of a multicast distribution tree is done by multicast routing protocols. The *Distance Vector Multicast Routing Protocol (DVMRP)* [RFC1075] was the first multicast routing protocol and was already used in the early times of the *Multicast Backbone (MBone)*. It is based on the *Reverse Path Forwarding (RPF)* principle. That means it first assumes that all nodes have members and distributes the data by flooding the network. The nodes with no members are then removed (pruning). It is also possible to explicitly add nodes with new members (grafting). Due to the flooding, it produces a high amount of unnecessary load, especially for sparse multicast groups (few receivers distributed over a wide region). Furthermore, it requires the establishment and maintenance of additional unicast routing tables as helper functions for the establishment of the distribution tree.

The *Protocol Independent Multicast (PIM)* [RFC2117] is a newer improved multicast routing protocol. It operates in two modes: *PIM-dense mode (PIM-DM)* and *PIM-sparse mode (PIM-SM)*. The dense mode is very similar to DVMRP. But in contrast to DVMRP it does not need to maintain additional unicast routing tables. Instead, it uses already existing unicast routing tables at the router (protocol independent). PIM-SM is specialized for sparse groups. Instead of flooding the network, it first assumes that no router has multicast members. Then, the distribution tree is established by explicitly adding nodes with members to the distribution tree. Routers with group members join the tree via some known selected routers (*rendezvous points*).

The sender and receiver may belong to networks with different administrative responsibilities. Different autonomous systems may deploy different multicast routing protocols. Furthermore, certain internal routing information is not relevant for other autonomous systems. Therefore, specific routing protocols for routing between autonomous systems and interoperation among multiple independent multicast routing domains were developed [RFC2715]. The Border *Gateway Multicast Routing Protocol (BGMP)* provides such functions and allows the establishment of a distribution tree over multiple autonomous systems.

Not all routers in the Internet have IP multicast functions enabled. Therefore, it is necessary to tunnel through areas where only unicast forwarding is available. This is done by encapsulating multicast packets in a unicast packet. An IP unicast header is added to the packet at the entry point of the tunnel and removed by the router at the tunnel exit.

21.4 Reliable Multicast

IP multicast is an unreliable protocol, which means that the correct reception of all data at the receivers is not guaranteed. Since many applications (e.g., database replication, file transfer, etc.) require reliable transport, the development of concepts for reliable multicast has become a very active research area (Figure 21.4). One problem with addressing this issue is that the concrete requirements for the different types of applications are

© 2005 by CRC Press LLC

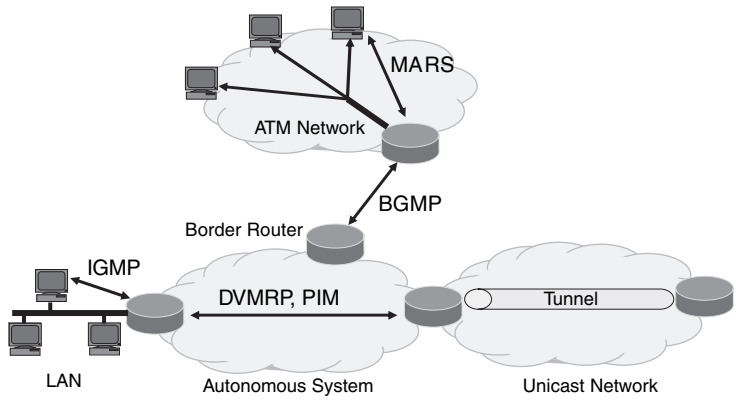

FIGURE 21.4 IP multicast protocol overview.

quite diverse. It seems impossible to find a single solution that serves the needs of all applications. Therefore, a wide variety of methods and protocols have been proposed to support the various application demands.

Within the Internet Engineering Task Force [IETF], an attempt is made to derive a common set of building blocks for reliable multicast support from these approaches. In order to reduce the design space, the Reliable Multicast Transport group (RMT) concentrates on the widely needed but complex problem of bulk data transfer to large groups. [RFC2357] describes primary requirements that need to be met to allow a widespread deployment of a reliable MC protocol in the Internet. *Congestion control* is important to ensure a fair sharing of network resources between applications. *Scalability* is required to allow operation with large groups. Furthermore, *security* issues have to be addressed to deploy reliable multicast in the Internet.

Secondary requirements that allow support for specific applications are summarized in [RFC2887]. Different applications may require different *degrees of reliability*. For applications that require *total reliability,* the loss of one single piece of data renders the whole set of transmitted data useless (e.g., file transfer), whereas applications that require only *semi-reliability* would just experience a quality reduction if data are missing (e.g., audio transmission). Furthermore, it is important to know whether the sender needs some kind of *delivery confirmation* or whether a correct *ordering* or *time-bounded delivery* is required.

Some applications require to *constrain the differences* between receivers, for example, to provide similar delays for the reception of data for all receivers (e.g., stock price distribution, multiplayer gaming). Furthermore, the properties of the network(s) for which the protocol is designed have to be considered. Requirements for a deployment in the Internet differ from requirements in intranets. It is important to know whether a *return path* is available or not (e.g., like in satellite communication). Additionally, there may already be some reliable multicast *support functions* in network that can be utilized.

Packet losses indicate congestion. Furthermore, they need to be defeated to accomplish a good throughput. Therefore, it is essential for reliable multicast protocols to measure packet losses and invoke an appropriate reaction if losses occur. The following basic methods for reliable multicast can be distinguished [RFC2887]:

ACK-based mechanisms are based on positive acknowledgement (ACK) of received data packets. The simplest realization would be that each receiver sends an ACK for every received data packet. This only works for very small groups because the amount of ACKs that arrives at the sender increases with the number of receivers and leads to an *ACK implosion* at the sender. Therefore, this approach is not suitable for most applications. An improvement that allows operation with slightly larger groups can be achieved by sending multiple ACKs in one data packet. To prevent implosion, *ring-based* approaches organize receivers in a ring where an ACK token is passed around (e.g., [WhMK94]). Nevertheless, establishment and maintenance of the ring can be difficult. More robust approaches that are also easier to configure are *tree-based* solutions that arrange receivers in trees. ACKs are only sent to parent nodes. Parent nodes

© 2005 by CRC Press LLC

aggregate the ACKs from their child nodes and send this aggregated ACK to their own parent. The aggregation schemes can operate in different ways. It is possible to send an ACK only if all child nodes have confirmed the data reception or alternatively to send an ACK with a list of all children that have acknowledged the reception. A further possibility is to send an ACK with a list of all children that have not confirmed the reception. Trees can also be used to organize retransmissions in a way that lost data are retransmitted by receivers themselves to their child nodes. Nevertheless, the establishment of the tree can be difficult and limit scalability. A tree-based approach is, for instance, used in the *Reliable Multicast Transport Protocol (RMTP)* [RMTP, LiPa96, PaSL97].

NACK-based mechanisms are based on negative acknowledgement (NACK) of missing data packets. Advantages are, for instance, that senders do not need to be aware of the amount of receivers. Furthermore, receivers are responsible for reliability and senders do not need to maintain state for all receivers. This simplifies fault tolerance and unburdens the sender. One NACK is sufficient to inform the sender that a packet is missing by at least one receiver. Therefore, *NACK suppression* mechanisms are used to reduce the number of NACKs. The disadvantages of NACK-based mechanisms are that senders do not know which receivers miss data and that they have no indication at what point of time all receivers have successfully received the data (i.e., when the transmission buffer can be freed). NACK-based protocols mainly differ in the suppression method they use. Examples are the *Scalable Reliable Multicast (SRM)* [SRM, FlJM95] and the *Multicast Dissemination Protocol (MDP)* [MDP, MaAd99].

Redundancy-based methods are based on the sending of redundant information, so that information can be recovered if not all packets are received. The most common method is the *Forward Error Correction (FEC)* [LiCo83]. FEC methods can be grouped in *proactive* methods where the sender directly adds redundancy to the data packets and *reactive* methods where the sender uses feedback from receivers (ACKs' or NACKs') to determine the amount of redundancy that should be added. It is also possible to combine both methods in a way that a certain amount of redundancy is sent proactively; but then the amount is adapted to receiver feedback. FEC-based methods reduce the amount of repair traffic. But due to the processing time needed for adding the redundancy, the end-to-end latency can be increased. This is not a problem for bulk data transfer, but is problematic for interactive applications. A further method is *layered FEC* where the data including redundancy are spread over multiple multicast groups (layers). By joining different amounts of layers, receivers can control the amount of redundancy they receive. With this, it is possible to achieve different reception qualities and data rates for participants of the same application. The method requires no feedback from receivers. It is especially useful in heterogeneous environments where receivers join with different access capabilities or for distinguishing quality levels for commercial data distribution. Furthermore, it provides optimal support if the coding scheme for the application data itself already has a layered structure (layered coding).

It is also possible for reliable multicast protocols to utilize *router assistance* if available. With this constrained NACKs and retransmissions and other network functions can be supported. An example is the *Pragmatic General Multicast (PGM)* [RFC3208]. Furthermore, some *hybrid* approaches exist that are based on a combination of the described methods. A hybrid approach is used, for example, in *RMTP-II* [WhTa00].

21.5 Application Layer Multicast

IP multicast standards have existed for quite some time and router vendors already support IP multicast. Nevertheless, many network operators do not deploy IP multicast. Reasons are, for instance, that native IP multicast does not provide support for error and congestion control. Furthermore, the network management becomes more complex. An additional reason is that there are still no useful accounting methods that appropriately reflect the resource sharing approach that is realized in IP multicast.

In order to support applications that require group communication in networks without native IP multicast support, methods were developed where only end systems handle all multicast functions like group management, multicast routing, and packet duplication. These methods are called *application layer multicast*. Application layer multicast moves the multicast functionality to higher layers and with this unburdens

© 2005 by CRC Press LLC

the network from complexity. Since no changes to existing networks are required, application layer multicast pushes the deployment of applications that rely on group communication. Nevertheless, the major advantage of native IP multicast is the resource-sharing concept that prevents sending multiple copies of the same packet over the same paths. Such avoidance of redundant traffic can only be achieved by deploying multicast functions in the network and it is not possible to that extent in application layer multicast [ChRZ00]. Therefore, application layer multicast is more suitable for small groups and interactive applications (audio/video conferencing, multi-player games, etc.) than for the distribution of data from one source to a large number of receivers (e.g., Internet TV).

The provisioning of application layer multicast requires the establishment of an *overlay structure* that consists of unicast paths between end systems. In most cases, a *control topology* is used, which forms a mesh of (unicast) communication channels between members of the group. It is used to exchange control information, like periodic messages to update group membership information. The data are forwarded via the *data topology*. Usually, a tree structure is used for distributing the data. There already exist a variety of application layer multicast protocols. [BaBh03] classifies the protocols according to the sequence of the construction of the control and data topology.

In *mesh-first* approaches, members first establish the control topology. Based on the control topology, a source-specific tree at each member can be established, for example, by using the Reverse Path Forwarding method. An example for a mesh-first approach is the *Narada* protocol [ChRZ00]. Here, designated hosts have the role of the rendezvous points. They maintain the membership information about the group. A host that wants to join a group obtains this information from the rendezvous point and then tries to connect to the mesh by contacting neighbor nodes. Information about the new member is distributed to other members. The data topology is established according to the reverse path forwarding method by using unicast connections between the members. The Narada protocol generates a high control load, because all members of the group have to obtain and retain information about the other members of the group. Therefore, Narada is mainly suitable for small groups. A further mesh-based approach is *Scattercast* [Chaw00], which uses network agents to form the overlay network. Here, small groups of clients are built that connect to the agents. A protocol called *Gossamer* is used to build the client groups.

In *tree-first* approaches, the data delivery tree is established first. Each member is responsible for finding an appropriate parent node to connect to the tree. Again, rendezvous points are used to maintain and provide group membership information. If an end system does not find an appropriate parent, it can become the root of the tree. After establishment of the tree, members periodically try to find better connection points. In some cases, this may lead to a partitioning of the tree. Examples of tree-first approaches are *Your Own Internet Distribution [YOID]* [Fran00] and the *Host Multicast Tree Protocol (HMTP)* [ZhJZ02]. In Yoid additional connections are established with other members that are not direct neighbors on the tree. These connections are used to recover from tree partitions. In HMTP, no explicit control mesh is established but members gather information about some other tree members. This also supports recovery from tree partitions.

Implicit approaches define the data delivery paths implicitly in the control topology, which means that the protocols cover the forwarding of data and control messages. Examples are *NICE* [NICE] ("NICE is the Internet Cooperative Environment") and *Content Addressable Network Multicast (CAN-Multicast)* [RaHK01].

In NICE, members are assigned to different layers of a hierarchical topology. This topology builds the basis for data and control topology. Members within a layer are grouped into clusters. Cluster members periodically exchange control information. The data forwarding is realized by applying specific forwarding rules within the topology.

CAN-Multicast is based on the content addressable network concept proposed in [RaFH01]. A CAN provides an efficient way to map file names to file locations. Such indexing mechanisms are, for instance, required for peer-to-peer file sharing systems. The efficient mapping is achieved by organizing the CAN members in a coordinate space where each member owns a zone. This architecture is used to store key-value pairs. Keys are mapped to points in the coordinate space by a hash function. A key-value pair is then stored at the node

© 2005 by CRC Press LLC

that owns the zone to which the hash value belongs. With this, other members can easily locate the data by simply calculating the hash value for the key. In CAN-Multicast, this is used to establish the overlay control topology. For the data distribution messages are simply flooded over the CAN. If all CAN members do want to participate in multicast, mini CANs are established that contain only the multicast members.

21.6 Future Aspects

A. IP Multicast in IPv6

IP version 6 was developed as the successor of the currently used IP version 4. Reasons for developing a new IP standard were, for instance, the limited amount of IPv4 addresses and the inefficient use of the address space, which sooner or later leads to an address shortage. The number of needed addresses increases not just due to the immense increase of computers that are connected to the Internet. Also, the assignment of IP addresses to other devices like mobile phones, personal digital assistants (PDAs), or even household appliances has the effect that one day the number of available addresses will be exhausted. IPv6 addresses consist of 128 bits. Using this, many more addresses can be expressed than by the 32-bit long IPv4 addresses.

IP multicast functions were directly integrated into the IPv6 standard. In order to reduce network load, IPv6 uses multicast for the provisioning of some functions that in IPv4 are realized with broadcast. [RFC2373] describes the IPv6 address format, which is used to express unicast, multicast, and anycast addresses. The first 8 bits of an IPv6 multicast address are set to 1 to identify the address as multicast address. This is followed by a 4-bit field for flags and another 4-bit field for the scope of the address. The remaining bits identify the group ID. The scope field allows an explicit scope control without the need to set specific TTL values. For nonpermanent addresses, the group ID is only valid within the scope. IGMP functions are integrated into the Internet Control Message Protocol for IPv6 (ICMPv6) [RFC2463].

B. Multicast Security

Security concepts for unicast cannot simply be applied to multicast communication. Already the establishment of security associations between multiple participants is much more complex than for a communication with only two participants. In general, three properties of group communication can be identified, which lead to many difficulties for the provisioning of security functions. Due to the *higher number of participants,* security associations have to be established between all members. This severely complicates the distribution and refreshment of cryptographic keys. The *dynamics of groups* leads to the demand for a dynamic establishment of security associations. Furthermore, the *anonymity of receivers* allows arbitrary end systems to join multicast groups without notifying the sender. The main security requirements for multicast communication are the management of *group membership* and *access control*, the *confidentiality* of sent data, and the *authentication* of senders and data. Restricted group membership and access control can be achieved by an authentication of potential group members and a secure distribution and refreshment of keys. Confidentiality of transmitted data can be achieved by encryption.

22.1 Introduction

The flexible architecture of the Internet and the decline in bandwidth prices have made it possible to use the Internet for various multimedia applications such as telephony and conferencing.

However, transmitting data packets into the network without regard to the actual available resources can easily result in overload situations and data losses. To avoid such a situation, some mechanisms are required to control the amount of data packets entering the network.

In the literature, there have been generally two approaches for traffic management in a network: admission control combined with Quality of Service QoS signaling protocols, on the one hand, and congestion control schemes that adapt the transmission and reception behavior of the end systems in accordance with the available resources in the network on the other.

In Section 22.2 a general survey of congestion control mechanisms as well as some evaluation criteria of congestion control schemes are given. Section 22.3 describes briefly different proposals for QoS control architectures that provide for tighter control on the number of admitted flows to the network and the amount of network resources received by each flow. In Section 22.4, a short overview of the advantages and disadvantages of congestion control schemes compared to QoS architectures is given.

© 2005 by CRC Press LLC

22.2 Congestion Control in the Internet

As the Internet does not provide for any mechanisms for regulating the transmission behavior of sending end systems, a single misbehaving end system sending data at a rate higher than the available bandwidth might lead to severe unfairness problems in the best case and to network congestion collapse in the worst [13].

The unfairness problems arise from the existing architecture of the network elements in the Internet. Currently, most of the network nodes, commonly known as routers, in the Internet employ tail discard queuing systems, mainly due to their simplicity. With such an approach, an end system sending a data stream at a high rate competing with an end system sending at a lower rate will have the same loss probability as the low-rate sender. Hence, the high-rate stream actually receives a larger share of the available bandwidth than the low-rate stream even though it actually caused the congestion [13]. This scenario is even worse for the situation of TCP connections sharing the same bottleneck with UDP flows. In response to the loss of packets, TCP connections reduce their transmission rate. However, without any rate reduction on behalf of the noncongestion-controlled UDP traffic sharing the same bottleneck with the TCP traffic, the congestion situation would prevail and the TCP connections would starve and receive a much smaller bandwidth share than the nonresponsive flows [13].

Severe and consistent congestion states might also lead to congestion collapse. Such a situation occurs when the network is utilized to a very high degree but with only a small amount of useful data reaching the receivers. Congestion collapse in the Internet was first reported by Nagle [22] and was largely due to TCP connections unnecessarily retransmitting data packets that were either in transit or have already arrived at the receivers. This form of collapse has since been avoided by different improvements in the TCP congestion avoidance mechanisms [16].

Other forms of congestion collapse arise when the network transmits fragments of packets that will be discarded at the receiving end systems because they cannot be reassembled into a valid packet. Such a situation might occur from the mismatch between the link level transmission layer and higher transmission layers. For example, when carrying large IP packets over an ATM network, dropping an ATM cell might lead to discarding of the entire IP packet at the receiver. Such a situation might be avoided by mechanisms aimed at providing lower layers with knowledge about the fragmentation of data in higher layers.

The congestion collapse form that we are interested in arises when network resources are wasted by transporting packets through the network only to be dropped before reaching the receiving end system. This situation arises when the sender is transmitting data at a rate higher than that of some bottleneck on the path toward the receiver. Such a situation can be avoided by adjusting the transmission rate of the sender in accordance with the available network resources.

The issue of congestion control in data networks has received considerable attention in the literature. Citing only a fraction of the proposed work is, however, far too voluminous. Therefore, we first give a brief overview of classification possibilities of congestion control schemes and only present some examples for those classes.

- *Control loop*: Depending on whether or not the sender needs to collect information about the network path connecting it to the receiver in order to adjust its transmission behavior, we can distinguish two control possibilities:
  - *Open-loop adaptation*: The sender adjusts the shape of the data to be transmitted in accordance to prior knowledge or estimation of the available resources. For example, when transmitting live video with a variable bit rate over a constant rate link, the sender can adjust the quality or frame rate of the video stream to be suitable for transmission over the available network capacity. This is often realized by using a leaky bucket [21] for enforcing a specific transmission rate. By monitoring the buffer length of the leaky bucket, the application can determine the appropriate quality factor to send the data with. Additionally, instead of altering the transmission behavior, the sender might in a different scenario adapt the priority of its data packets in accordance to their content and the available resources. in [28], Sanneck presents an approach for

© 2005 by CRC Press LLC

improving the quality of audio communication over the Internet. In addition to the audio data, the sender includes information that can be used for the concealment of lost packets. The amount of additional information needed for reconstructing the original content is adapted to the importance of the sent audio data.

- *Closed-loop adaptation*: With open-loop adaptation, the sender can only adjust its behavior based on prior knowledge of its own resources or of the static amount of network resources available to it. Here, the aim is to maintain or improve the quality of the communication in accordance with an amount of fixed resources. To actually avoid network congestion, the sender needs information about the path connecting it to the receiver and back. Such a closed-loop adaptation is a more general case where the sender adjusts its transmission behavior not only based on the locally available resources but also based on feedback information from the receivers or the network. This approach has the major advantage of avoiding network congestion or overwhelming the receiving end-system with data it cannot use.

- *Transmission mode*: Depending on the number of participants in a communication scenario, different issues need to be considered when designing congestion control schemes.
  - *Unicast*: For the case of point-to-point communication, tight control can be realized. Similar to the case of TCP, the receiver of a multimedia flow can send frequent feedback messages to the sender without overloading the sender. This would then allow for fast reactions to changes in the network state.
  - *Multicast*: Multicast communication describes, in general, multi-point to multi-point communication sessions. Having a large number of receivers sending frequent feedback messages to the sender can easily result in overloading the sender or might cause congestion on the link connecting the sender to the network. Hence, for the case of multicast, scalability issues play a crucial role in the design of congestion control schemes. Additionally, due to the heterogeneity of the Internet links and receivers, congestion control schemes need to be carefully designed to achieve a high performance in a variety of situations.
- *Architecture*: Depending on the systems involved in the congestion control, scheme different modes can be distinguished:
  - *End-to-end*: In this case, only the end systems, that is, the senders and receivers, are involved in collecting information about the congestion state in the network and adapting the number of packets entering the network.
  - *Network-supported*: In addition to the end systems, network routers could participate in collecting state information as well as manipulating the amount of data transported in the network.

Note that these classes should only be considered as conceptual ones, which aid us in discussing different features of congestion control schemes. Actually, congestion control schemes usually belong to overlapping classes. Network-supported schemes can, for example, be either open-loop or closed-loop and be used for unicast as well as multicast communication. In this study, we will restrict the scope of investigated congestion control schemes to closed-loop schemes for unicast communication. While we will be mainly concentrating on the end-to-end communication scenario, we will also be briefly looking at network-supported approaches. We first give some criteria for evaluating the efficiency of congestion control schemes. Next, different approaches and schemes for realizing congestion control schemes for unicast are described. A short survey of network-assisted congestion control schemes is then presented.

Evaluation Criteria for Congestion Control Mechanisms

By deploying congestion control mechanisms in the context of multimedia communication, we aim at improving the network performance compared to the case when no control is deployed, thereby increasing the user's satisfaction. In this section, we will describe some of the evaluation criteria for the efficiency of the control.

© 2005 by CRC Press LLC

Network Congestion State

The primary goal of congestion control schemes is to achieve a high network utilization level and at the same time reduce the packet losses at the network level. In estimating the loss performance of a scheme, one should consider the losses as seen at the networking layer and not only at the application layer. Using forward error correction (FEC) mechanisms [9] for reconstructing lost data packets might lead to loss-free data transmission as measured by the application. However, in this case, network resources are wasted transporting redundant data. Hence, while FEC mechanisms improve the quality of single streams, by using congestion avoidance mechanisms, one aims at improving the overall performance of the network and thus all streams traversing the network.

Scalability

Based on the multicast architecture of the Internet, a sender can transmit a media stream to a nearly unlimited number of receivers in an effective way. The performance of an efficient congestion control scheme should therefore not degrade substantially with the increased number of participants in a multicast session. Additionally, the complexity of the schemes used should still be acceptable.

Convergence

Convergence is generally measured by the speed or time with which a system approaches some stable state from any starting state. Efficient adaptation algorithms need to have a short convergence period and lead to a stable state.

Fairness in the Context of Congestion Control for Multimedia Communication

When confronted with the case of connections or users competing for some shared resources such as network bandwidth, we need to consider the aspect of fair resource distribution. However, the term fairness only has a subjective meaning, which differs depending on the situation. Thus, a system can be considered fair if the competing instances receive a share that conforms to some pre-established fairness definition.

In the context of multimedia communication, there have been two major definitions of the values of a fair share a connection can receive: max–min fairness and TCP-friendly bandwidth distribution. Which definition to use depends generally on the control scenario and the information available for the adaptation process.

The Max–Min fairness: The max–min fairness criteria are usually applied when the adaptation involves the distribution of available resources for a known number of instances, for example, bandwidth for a number of streams or processing power for a number of processes.

Taking the example of bandwidth distribution among competing streams, whereas here a stream indicates the flow of data packets from one sender to one or more receivers, the fair share (F_i) of a flow i is minimally

$$F_i = \frac{B}{n} \tag{1}$$

where B is the bandwidth of a network node and n is the number of flows traversing this node. (F_i) can maximally reach

$$F_i = \frac{B - \sum B_{cong}}{n - \sum n_{cong}} \tag{2}$$

where B_{cong} is the bandwidth of the flows bottlenecked elsewhere and n_{cong} is the number of flows bottlenecked elsewhere. A bottlenecked flow indicates that the fair share a flow can receive at some other link is smaller than its minimum fair share at this link. A flow's fair bandwidth share is then set to the minimum fair share calculated at all traversed hops.

© 2005 by CRC Press LLC

This definition can be further extended as follows:

Reservation proportional shares: With each user reserving — or paying for — a guaranteed share (S_i) of some resource R, each user (i) gets a fair share proportional to its S_i. For n flows, the fair share F_i can be calculated as follows:

$$F_i = R * \frac{S_i}{\sum_i^n S_i}$$

Reservation plus equal shares: With each user reserving — or paying for — a guaranteed share S_i of some resource R, each user (i) gets its reserved S_i plus an equal share of the available resources. For n flows, the fair share F_i can be calculated as follows:

$$F_i = S_i + \frac{R - \sum_i^n S_i}{n}$$

Weighted shares: Here, the resource (R) is allocated for each connection proportionally to a pre-determined weight W_i — for example, priority level. For n flows, the fair share F_i can be calculated as follows:

$$F_i = \frac{R * W_i}{\sum_i^n W_i}$$

Note, however, that applying these enhanced definitions requires a mechanism for establishing reservations or setting the allocation weights. As such mechanisms are currently not available in the Internet, these definitions are inappropriate for control mechanisms realized only at the end systems.

TCP-Friendly adaptation: Often, it is the case that the adaptation process is based on an estimation of the performance of a system and the adaptation instance heuristically adjusts its behavior in accordance with the estimated performance without exact knowledge of the available resources or number of other competing instances. Adapting the transmission behavior of a video stream based on the measured loss and delay values in the network provides such an example. In this case, applying the max–min fairness criterium is rather difficult. Instead, we need to consider the effects of using an adaptation scheme on the shares received by other adaptive traffic. As around 95% of the traffic carried over the Internet is TCP traffic [12], there has been a current consensus in various works [13] that adaptation mechanisms and congestion control approaches should be TCP-friendly. TCP-friendliness indicates here that if a TCP and an adaptive flow with similar transmission behavior traverse the same path and thus compete at the same bottleneck, round-trip delays, and face the same loss values, both flows should receive similar bandwidth shares. Due to the different natures of TCP and multimedia traffic, it is expected that a TCP-friendly multimedia flow would acquire the same bandwidth share as a TCP connection only averaged over time intervals of several seconds or even only over the entire lifetime of the flow and not at every time point.

The requirements for fulfilling both the max–min fairness criteria and TCP-friendliness are, however, rather contradictory. With the max–min fairness definition, the resource distribution depends only on the number of flows sharing a bottleneck. Various simulative [32] as well as analytical studies have shown that the bandwidth a TCP connection can utilize depends not only on the number of connections traversing a shared link but also on the round-trip delays and the number of traversed congested hops. That is, connections having large round-trip delays or traversing a larger number of congested hops receive a smaller bandwidth share than a connection with a smaller round-trip delay or less congested hops in its path.

User Satisfaction

Users' satisfaction is in general difficult to measure and quantify. There have already been some proposals for assessing the QoS of multimedia contents using rating schemes as was proposed by the ITU [15], for example.

However, in evaluating the performance of an adaptation scheme, users' satisfaction is just one evaluation criterion out of many. Aspects of network performance or scalability of the scheme are just

© 2005 by CRC Press LLC

as important. Due to the complexity of the measurement mechanisms, one could refer to a simple measurement of the loss ratio of the data presented to the user. Studies on the transmission of MPEG video streams over the Internet have shown that losses are a major source of QoS degradation and that losses as low as 3% might render about 30% of a video stream unusable. Hence, an effective adaptation scheme should aim at minimizing the loss ratio observed at the users' end systems.

End-to-End Unicast Congestion Control Schemes

Basically, congestion control schemes for unicast communication can be divided into two major categories of algorithms: window- and rate-based mechanisms. In rate-based adaptation, a limit is placed on the rate at which the source can send packets. In window-based flow control, at any time there is a limit to the number of packets a sender can transmit before having to wait for an acknowledgment from the receiver; but there are no constraints on the rate at which packets can be sent.

The adaptation decision itself can be based on either explicit or implicit indication about the available resources. Explicit information can be as detailed as the actual bandwidth share a sender should be using to avoid network congestion or simply a single bit indicating the congestion state of the network. Explicit indications are created by the network and are either forwarded downstream on the flow's path toward the destination or sent directly back to the senders. With the forward error congestion notification (FECN), the sender transmits special messages that collect information from all traversed routers along the path to the receiver, which echoes them back to the sender. This approach provides the destination with a complete overall view of the congestion state along the flow's path; however, it introduces additional delay as the information needs to traverse all the path up to the destination before being sent back to the sender. FECN also minimizes the needed number of congestion messages compared to the backward error congestion notification (BECN). With BECN each intermediate router creates and sends congestion notification to the source end system when congestion is observed. This can be achieved by creating special messages to be sent to the end systems or by including the congestion notification in the messages that are sent from the receiver to the sender.

On the contrary, the network congestion state might also be implicitly estimated using loss and delay indications measured at the receiving end systems and carried in feedback messages sent by the receivers. In addition to losses and round-trip delays, the end systems might use the delay variations of the received packets as an indication of the buffer lengths in the network and hence as an estimation of the network load.

With the lack of mechanisms for collecting and distributing explicit information about the network congestion state in the Internet, most of the control schemes found in the literature refer to heuristic approaches for adjusting the transmission rate or window, see window-based Adaptation and Rate-based Adaptation sections. This heuristic approach is usually based on some variation of an increase/decrease mechanism (ID). With ID schemes, the bandwidth share of a flow is gradually increased by some amount during underload situations and reduced during overload situations. A popular version of ID schemes is the additive increase and multiple decrease (AIMD) mechanism. With this approach, the sender can increase its resource share by an additive amount during underload periods and reduces it by a multiplicative factor during overload periods. The choice of AIMD can be briefly justified as follows. If the network is operating below the optimal point designated by high utilization and low losses, all users go up equally. If the network is congested, the multiplicative decrease makes users with higher resource shares go down faster than those with smaller shares, making the allocation more fair. In [11], Chiu and Jain show that this approach leads to a stable adaptation behavior and an equal bandwidth distribution.

Window-Based Adaptation

There have been several proposals for adaptation schemes that, similar to the TCP adaptation mechanisms, are based on the so-called sliding window approach.

With the sliding window approach, a window represents the number of packets the sender can transmit before having to wait for an acknowledgment packet from the receiver. In case of losses, TCP reduces the window size by half and starts increasing it again using the slow start and congestion avoidance

© 2005 by CRC Press LLC

mechanisms [16]. In addition to these schemes, there have been various other proposals for adapting the window size to the network congestion state. To mention a few out of many:

Slow start and search (*Tri-S*): The Tri-S scheme [36] uses the changes in throughput as an indication of congestion. The algorithm computes the normalized throughput gradient and compares it to some thresholds to keep the connection at the optimal operating point.

Dual-Window: With this algorithm [37] the sender maintains two windows, one for congestion control and one for flow control. The flow window adapts the transmission rate of the sender in accordance with the available buffers at the receiver and the congestion window adapts the transmission behavior in accordance with the network congestion state.

Delay-based adaptation: In [17], Jain presents an approach for congestion control based on estimating the round trip delay. The sender estimates the round-trip delay as the time passed between sending a packet and receiving an acknowledgment for it. The window size is then adjusted based on the variations in the measured round-trip delay.

Rate-Based Adaptation

With window-based adaptation schemes, the transmission rate of the sender is only controlled indirectly by adjusting the transmission window size. On the contrary, rate-based adaptation schemes control the rate of the sender directly. To mention just a few out of many schemes proposed in this area:

Scalable feedback adaptation: In [5], Bolot et al. present an approach for scalable control of multicast media streams. The senders probe the receivers to solicit feedback information about the losses observed at the receiving end systems. Based on the collected information, the sender either additively increases its transmission rate or decreases it multiplicatively.

Backward congestion notification: In [19], Kanakia et al. present an approach for adapting the transmission of real-time video. The adaptation algorithm uses feedback information sent by the routers about the available buffers to determine the appropriate transmission rate.

RAP: In [27], Rejai et al. present a congestion control scheme called rate adaptation protocol (RAP). Just as with TCP, sent packets are acknowledged by the receivers with losses indicated either by gaps in the sequence numbers of the acknowledged packets or timeouts. Using the acknowledgment packets, the sender can estimate the round-trip delay. If no losses are detected, the sender can periodically increase its transmission rate additively as a function of the estimated round trip delay. After detecting a loss the rate is reduced by half in a similar manner to TCP.

TFRCP: Based on an analytical model of TCP, see Padhye et al. [24], Floyd et al. [14] present a scheme in which the sender estimates the round-trip delay and losses based on the receiver's acknowledgments. In case of losses, the sender restricts its transmission rate to the equivalent TCP rate calculated using the analytical model; otherwise, the transmission rate is increased.

LDA+: LDA+, see [33], is an additive increase and multiplicative decrease algorithm with the addition and reduction values determined dynamically based on the current network situation and the bandwidth share that a flow is already utilizing. During loss situations LDA+ estimates a flow's bandwidth share to be minimally the bandwidth share determined with the theoretical TCP model; see [24]. For the case of no losses, the flow's share can be increased by a value that does not exceed the increase of the bandwidth share of a TCP connection with the same round-trip delay and packet size.

Network-Based Adaptation

Besides various proposals for increasing the fault-tolerance of networks [23] and adapting the transmission of routing information in accordance with network congestion, various studies have investigated network-based mechanisms for adapting multimedia streams in accordance with the network congestion state. Placing the adaptation entities in the network has the clear advantage of solving the congestion problem at the point at which it occurs. However, such an approach requires a network capable of actively reshaping the transferred data, which adds a considerable load on the network nodes and increases the complexity and costs of building and operating such networks.

© 2005 by CRC Press LLC

The proposals for network-based adaptation schemes range form simple buffer management approaches to complicated QoS architectures. To describe just a few examples:

Available Bit Rate (ABR): The ABR service [31] was specified as an ATM service for applications mainly handling data transfer and having the ability to reduce their sending rate if the network requires them to do so. Likewise, such applications may wish to increase their sending rate if there is an extra bandwidth available within the network. Applications using the ABR service can expect the following quality of service commitments from the network:

1. The available bandwidth is fairly distributed among all active ABR connections.
2. A minimum cell rate that is agreed upon during the connection establishment phase.
3. Only a preset fraction of the sent data can be dropped as long as the sending behavior of the application conforms to the negotiated values.

With the ABR service, a source sends a so-called resource management (RM) cell every–sent data cells. These cells indicate the current cell rate (CCR) and the desired one of the senders. The destination end system turns the RM cells around and sends them back to the source. The intermediate switches determine the fair bandwidth shares that the ABR connections should use in order to avoid congestion based on the traffic situation in the network. These values are then written in the backward RM cells in the explicit rate (ER) field. The source should then increase or decrease its rate in accordance with the ER noted in the RM cells. Additionally, the network switches could also just indicate their congestion situation by a single bit indicating an over- or underload situation.

Early congestion notification (ECN): TCP relies primarily on detecting loss events for activating its congestion avoidance mechanisms. That is, a TCP sender only reacts to the congestion situation when it is already too late and packets have been lost. Floyd et al. [26] present an approach in which the network nodes indicate their congestion situation by setting a congestion bit in the TCP packets. As a guideline for the sender's reaction to the congestion bits, Floyd et al. propose the following:

1. TCP's response to ECN should be similar over longer time scales to its response to dropped packets or timeouts.
2. Over smaller time scales, TCP's response to ECN can be less conservative than its response to lost packets.
3. TCP should react to ECN at most once per round-trip time.
4. The response to ECN does not trigger the sending or retransmitting of any data packets.

With ECN, TCP senders can reduce their transmission windows before packets get dropped and thereby avoid the long recovery periods caused by data losses.

Explicit windows: For a better integration of TCP and ATM in [18] Kalampokas et al. propose to adjust the window information carried in the TCP acknowledgment packets based on the available bandwidth share calculated by the network nodes. This approach removes the need for the additive increase and multiplicative decrease used by TCP for setting the transmission window size and, hence, leads to a better overall performance.

PLoP: The predictive loss pattern queue management scheme [29] proposes a mechanism for reducing loss burstiness of audio streams and thus allowing for more efficient usage of forward error correction approaches.

Video gateway: In an effort to reduce the bandwidth of a stream to better suit the capacities of a receiver, in [2] Amir et al. propose using gateways for transcoding high bandwidth video streams into low bandwidth ones. These gateways can be placed at points connecting high- and low-capacity links or where congestion is very likely to happen.

Active networks: Active networks [35] also present a realization possibility of network-based adaptation. With such an approach, a network node can reshape a data stream based on information and procedures provided by an entity with knowledge about the data stream.

Throttling: Another approach is to enhance the routers to identify flows that use more bandwidth than allowed by a theoretical model of TCP and then throttle these flows.

22.3 Quality of Service Control for Multimedia Communication

The packet switching architecture of the Internet provides a flexible infrastructure for the interconnection of networks with different architectures. However, it provides only for a best effort service with little control over the packet delay and loss processes at the network nodes. This best-effort service makes it impossible to provide guarantees for a minimum bandwidth or a maximum delay.

One approach for providing an improved QoS control in the Internet is to augment the current best-effort service to include new services that provide performance guarantees desired by the applications and users. In this section, we briefly describe a few of the most current proposals for such enhanced services.

The Integrated Services Model (IntServ)

The integrated services framework [7] provides the ability for applications to choose among multiple, controlled levels of delivery service for their data packets. To support this capability, two things are required:

1. The individual network elements such as the subnets and IP routers along the path traversed by an application's data packets must support mechanisms to control the QoS delivered to those packets. These mechanisms can be roughly divided into three parts:

   Call admission control: This instance checks if the requested reservation level can be supported by the router.
   Classification: In order to determine the appropriate service to provide for a data packet belonging to some flow, this packet first needs to be classified based on the previously made reservation for this flow and is then inserted into the appropriate scheduling level.
   Scheduling: This instance determines when to forward a data packet based on the reservation made for it.

2. A way to communicate the application's requirements to the network elements along the path and to convey QoS management information between the network elements and the application must be provided.

The integrated services model supports three service types:

Guaranteed load: Maximum delay and bandwidth requested by the application are guaranteed [30].
Controlled load: Only a minimum bandwidth is guaranteed. Traffic sent above this minimal rate is treated as best-effort traffic [38].
Best effort: Data packets are sent without any guarantees.

With the resource reservation protocol (RSVP) [6], Braden et al. have proposed a QoS signaling protocol, in which the sender informs the receivers about the traffic shape of the data flow. In reaction to this, the receivers send reservation requests indicating the amount of required resources to support the flow.

Each network node traversed by the control messages maintains information about the requested resources for each flow. Reservation requests by different receivers for the same data flow are merged together at the network nodes. For each flow that has made a reservation, the network nodes periodically send control messages to their neighboring nodes to indicate the state of this flow. As all the nodes need to maintain state information for each flow and send and receive control messages to and from neighboring nodes to detect the state of each flow, RSVP incurs a significant processing overhead on the network nodes. In addition, various problems resulting from issues like merging of reservations and reservation updates need to be considered with RSVP.

Pang and Schulzrinne propose a sender-based reservation scheme called YESSIR [25] in which the sender issues the reservation request. Each traversed router processes the reservation request, decides to accept or reject it, and establishes some state information for the signaling flow in case of acceptance. After receiving a reservation message from the sender, the receivers issue acknowledgment packets indicating the result of the reservation. After establishing a reservation, the sender periodically transmits control messages to refresh its state at the network nodes. This approach reduces the complexity of RSVP as

© 2005 by CRC Press LLC

it does not require the routers to exchange per-flow refresh messages. However, it still requires per-flow state information at the routers.

The Differentiated Services Model (DiffServ)

The need for maintaining per-flow states, periodically refreshing this information as well as the overhead of per-packet classification and processing results in scaling problems for the IntServ model and RSVP when handling a large number of flows. The differentiated services (DiffServ) model [3] was designed to avoid this problem by using service-level agreements (SLA) between the network providers and the users. These SLAs describe the QoS level that the aggregated traffic of a user can expect from the provider. Traffic sent in conformance with the established SLA is marked as belonging to a specific QoS level. At the core routers data packets are serviced differently based on their marked QoS level. As all packets with the same marks are treated equally, the core routers need only to maintain information describing the resources allocated for the supported QoS levels.

As the SLAs are used for traffic aggregates, there is no need for per-flow states. Additionally, with the DiffServ model, only the edge routers need to police incoming traffic and adopt admission control procedures.

Broadly speaking, any traffic management or bandwidth control mechanism that treats different users differently, ranging from simple weighted fair queuing (WFQ) [10] to RSVP and per-session traffic scheduling counts as a DiffServ solution. However, in common Internet usage the term "DiffServ" is beginning to mean any relatively simple, lightweight mechanism that does not depend entirely on per-flow resource reservations.

While such an approach avoids the scalability problems of the integrated services model, it is rather rigid. SLAs are currently mainly thought to be established in a static manner or to be changed only infrequently on the order of days or weeks. Hence, the DiffServ model does not allow the user to increase or decrease the amount of its reserved resources in accordance with its traffic requirements. In addition to the static nature of the SLAs specifying a QoS level for an aggregate of flows can result in unfair distribution of resources among the flows belonging to the same aggregate due to the aggressiveness of some flows, differences in round-trip delays, and the paths taken. Further, the core routers are expected to be dimensioned large enough in a manner as to provide the user with the agreed upon QoS level on any path taken by the user at any time in accordance with the SLA. As the exact path taken by a user's traffic is not known in advance, the network needs to be highly overprovisioned to account for all possible cases. This is even more pronounced for the case of multicast as the user's traffic might take different paths in the providers network and hence sufficient resources need to be available on all paths simultaneously. To allow for dynamical establishment and changes of the resources provided for a user, currently there are different proposals that aim at introducing lightweight signaling protocols as well as different efforts for aggregating state information to reduce the load on the network routers.

QoS Architectures

In addition to the above models, various studies describe complete architectures for reserving network resources and controlling the QoS of the network traffic. While these architectures offer a good basis for the QoS research and first experiences, they are too complicated and could, thus, not gain any significance in the Internet.

While these approaches differ in their scope and complexity, they all have common requirements:

The networking infrastructure needs to be substantially enhanced in order to realize the improved services. This involves improving the network routers by introducing more complicated buffer management schemes than simple FIFO for enforcing the requested QoS levels, admission control mechanisms to effectively utilize the network resources, as well as defining signaling mechanisms for establishing the required QoS by the users.

Provide incentives to encourage applications to request the proper service class for their requirements. In the absence of such incentives, applications could request the highest quality level no matter what their

© 2005 by CRC Press LLC

requirements are. One way of providing incentives is via pricing the communication service based on the requested QoS.

In order for the users and applications to benefit from the upgraded networking infrastructure, the applications need to be able to specify their requirements and support the appropriate signaling protocols for doing so.

22.4 Adaptation vs. Reservation

While reservation-based schemes guarantee the required QoS level, deploying such mechanisms leads to a substantial increase in the complexity of the network due to the necessary enhancements of the routers and the introduction of billing mechanisms [4]. Additionally, due to the admission control, the user satisfaction of the network service might be reduced due to the possibility of blocking a service request during overload periods.

On the contrary, end-to-end congestion control schemes require no or only minimal enhancements to the network and rely, mainly, on enhanced end systems. Such adaptive mechanisms aim at improving the quality by adjusting the amount of traffic in the network and hence reducing losses on the one hand and increasing utilization on the other, which is particularly beneficial for multimedia communication. Thus, at the expense of slight degradation in user satisfaction, it is possible to adjust the amount of network resources consumed by a media stream in accordance with the network congestion state. Additionally, it is usually the case that due to the loss of content or the need to use a considerable overhead for forward error correction a low bandwidth video stream, for example, with no or only low losses can have a higher perceived quality than a high bandwidth yet lossy stream. Further, as the adaptive applications are better suited to take advantage of dynamical changes in the network resource availability during a session, which is particularly beneficial during long-lived sessions typical for multimedia communications, higher network utilization levels can be reached. Such a behavior can be achieved by reservation-based schemes only by renegotiating the reservation, which further increases the complexity of these schemes.

In an analytical study, in [8] Breslau et al. show that by overprovisioning the capacity of a network, a best-effort network can provide the same quality levels as a reservation-based network. Thus, for providing a network supporting a high QoS, there is a clear trade-off between the costs of introducing reservation-based schemes and the thereby required network enhancements, billing, and admission control mechanisms on the one hand and the costs of additional network resources required for a best-effort network in order to provide the same QoS level. For both cases, the costs are considerably decreased when deploying adaptive applications. For the reservation case, the applications require a smaller amount of network resources and less stringent control mechanisms. For the best-effort case, users' satisfaction with the QoS can still be high even with a smaller amount of resources, thus allowing for less overprovisioning of the resources.

Whether the future high-quality networks will be based on strict QoS control mechanisms or simply be overprovisioned will be a question of costs. In any case, efficient adaptation mechanisms will be required to reduce the overall costs.

As a combination between the two approaches, one might consider integrating adaptation schemes with a reservation scheme such as YESSIR [25] or RSVP. Through this integration, the receiver can reserve a minimal QoS using YESSIR and try to achieve a better QoS level through utilizing free network resources using adaptation. Alternatively, an approach similar to the scalable resource reservation protocol (SRP) [1] can be integrated with adaptation. That is, the sender keeps informing the network about its desired transmission rate and the routers indicate the actual reserved capacity. Additionally, the senders can still try to use a higher transmission rate using an adaptation scheme.

Another important issue to consider is the aspect of flow protection, that is, protecting adaptive flows from unresponsive ones that do not reduce their transmission rate during congestion states and might thus lead to the starvation of adaptive traffic. Without protection schemes at the routers, a greedy connection can cause the adaptive flows to face losses and thus reduce their bandwidth share. Lakshman et al. [34] present an intelligent buffer management approach that supports the isolation of responsive from unresponsive flows in a simple way.

© 2005 by CRC Press LLC

22.5 Summary

In this article, we have taken a broad look at different congestion and QoS control mechanisms. While both issues have been subject to a great deal of attention in the literature and research, little has found its way to the Internet as we know it today. Data applications such as FTP and WWW use TCP for congestion control. However, applications based on UDP such as voice over IP (VoIP) and some streaming applications still do not deploy any congestion control schemes. The IETF is currently working on proposing another transport protocol more appropriate to multimedia applications, see [20], which will allow the usage of different congestion control schemes. The success of this protocol is, however, still to be seen. With regard to QoS, the only approach used currently for improving the QoS in a network is to overprovision it, that is, to deploy more bandwidth than is expected to be used. This stems mainly from the notion that QoS architectures are considered to be too complicated to introduce and require a considerable change in the infrastructure of the networks as well as in their management, the required billing structures, and inter-domain relations. However, with the introduction of next-generation networks, there is an increased interest in providing QoS based on tighter control by the providers. The exact development in this area is therefore still to be seen.

23.1 Introduction

Advances in mobile communication technologies such as wireless network standards IEEE 802.Ha/b/g or Bluetooth, and the high availability of portable computing devices like personal digital assistants (PDAs) or notebooks require additional network protocol support for roaming and ubiquitous computing in the Internet. Using IP, which usually means IP version 4 (IPv4 [Pos81]) unless stated otherwise, seamless roaming of mobile devices is only possible up to the physical and link layer (referring to the seven-layer notion of the OSI Reference Model [DZ83]).

23.2 Mobility on the Network Layer

Network layer mobility in the Internet mainly suffers from the IP addressing and routing strategy. When addressing hosts or, more general, network interfaces, the topological structure of the network is explicitly used. An IP address is built up by a prefix referring to the network of the host, followed by a host address. Based on a dynamically changing and best-effort strategy, IP datagrams are routed to the network stated by the receiver host's IP address.

As a consequence, in case a mobile host moves from one network to another, the network prefix of its IP address has to be changed. This change implicates reconfigurations of address parameters in Internet services and applications. However, changing numerous Internet services does not scale and is not desirable from a network protocol design point of view. Figure 23.1 shows a scenario of a PDA with IP address 192.160.32.80 roaming from its home network with a network number or prefix 192.160.32 to a network using 160.80.40 as the network number. The owner of the PDA demands network management by the foreign network (160.80.40) and the redirection of IP packets from the home network (192.160.32) to its mobile device while being reachable using the existing IP addressing and routing scheme.

The Internet Engineering Task Force (IETF) proposed a model [Per96a], which does not require any IP adaptations to support mobile hosts. Thus, the redirection of IP packets requires a managing *home*

© 2005 by CRC Press LLC

agent at the home network. It acts as a proxy fetching IP packets addressed to the mobile host and rerouting them to the foreign network currently visited by the mobile host. In the foreign network, the mobile host borrows an IP address, the *care-of address*. This address can be an IP address assigned by a *foreign agent* (*foreign agent care-of address*, usually the IP address of the foreign agent [Tan03]), which receives the rerouted IP packets and delivers them to the mobile host. In case the mobile host should be addressed directly, a local IP address is acquired (*colocated care-of address*), which can be a long-term address or a temporary-address attached using the *Dynamic Host Configuration Protocol* (*DHCP* [Dro97]), Figure 23.2 visualizes the IETF mobility model [Per98]. Home and foreign agents may either be an extended router or a separate system in the managed network.

In such a scenario, several services are required. First, the mobile host demands mechanisms for discovering the *mobility agent*, either home or foreign agent (*agent discovery and advertisement*). To allow the home agent to address the mobile host in the foreign network, the mobile host has to make the care-of address known to the home agent (*registration*). Finally, routing and transferring datagrams to the roaming mobile host have to be provided by the home agent (*tunneling*).

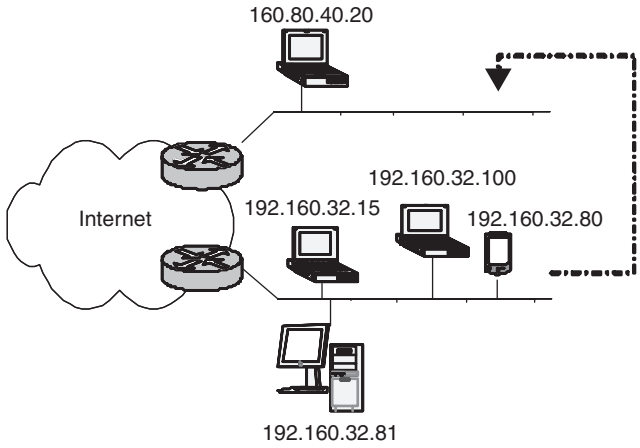

FIGURE 23.1 PDA roaming between different IP networks.

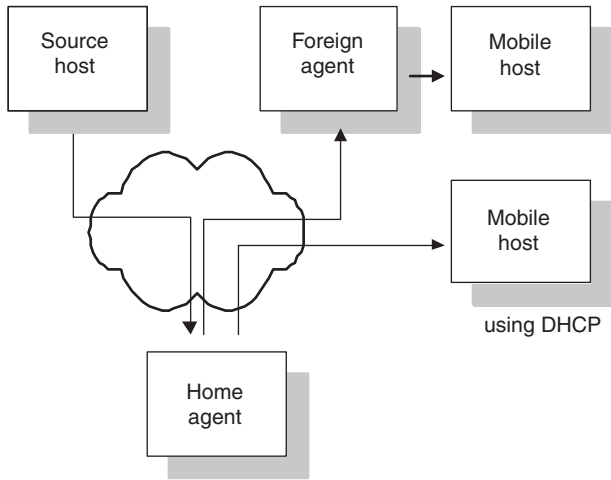

FIGURE 23.2 IETF Mobile IP model.

23.3 Agent Discovery and Advertisement

Whenever a mobile host connects to a network, it needs to find out whether it is linked to the home network. In such a case, it operates without Mobile IP support. In contrast, if a mobile host is connected to a foreign network, it requires a temporary care-of address related to the foreign network. The care-of address is either assigned by a link-layer protocol, or the *agent advertisement* and *agent solicitation* protocol is used.

Agent advertisement messages are sent periodically by mobility agents (home or foreign agents) using broadcasting or multicasting. Using the address information contained in this message, the mobile host is able to contact the mobility agent for further registraion actions. In case the mobile host does not receive an agent advertisement within a reasonable time, it sends an agent solicitation message to force the mobility agent to answer with an advertisement immediately. The interval between two successive solictation messages has to be iteratively extended using a binary exponential back-off mechanism to reduce message overhead. Both messages are extensions to *Internet Control Message Protocol* (*ICMP*) *router discovery messages* [Dee91], used by routers and links to make the routers known to the links. Each ICMP message is encapsulated in an IP packet. Thus, source and destination IP address can be found in the IP header.

To create an agent advertisement message, several ICMP router advertisement message fields are set to selected values and the messages is extended by mobility agent-related fileds. In detail, the IP field *destination address* is required to be either the multicast address for all-systems-on-this-link 224.0.0.1 or the limited-broadcast address 255.255.255.255 and the IP field, TTL (*time to life*) is set to 1, which means that the ICMP message is discarded by the first processing node (e.g., a router or a gateway).

Figure 23.3 describes the ICMP fields in a router advertisement message. As in any router advertisement message, *Type* is set to 9. The field *Code* indicates whether the mobility agent also handles common traffic acting as a router (Code value 0), or not (Code value 16). The *Checksum* is calculated as the 16-bit one's complement sum of the ICMP message and the field *Num addrs* refers to the number of router addresses advertised in this message. The *Addr entry size* field gives the number of 32-bit words for each router address and *Lifetime* controls the maximum number of seconds the advertisement is considered to be valid. Finally, *Router addresses* [*i*] (i=1 … Num addrs) represent possible router's IP addresses followed by a preference value (*Preference level* [*i*]).

Following the router advertisement fields, the agent advertisement extension indicates that the message is an agent advertisement sent by a mobility agent. Figure 23.4 [Per98] shows the fields of the extensions in detail.

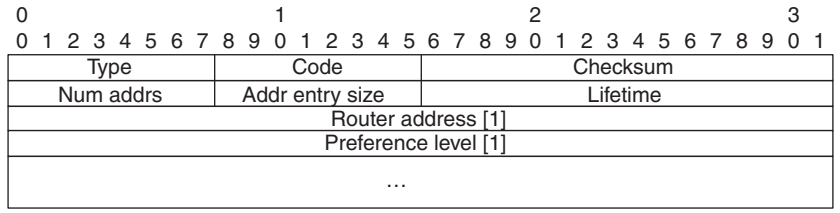

FIGURE 23.3 ICMP router advertisement message.

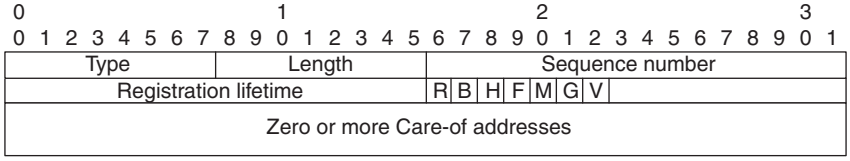

FIGURE 23.4 Mobility agent advertisement extension.

© 2005 by CRC Press LLC

The message *Type* is set to the constant value 16, which identifies the message as an agent advertisement; the *Length* field is calculated by 6+4*N*, with *N* being the number of care-of addresses listed at the end of the advertisement *Registration Lifetime* refers to the maximum lifetime value the agent is willing to accept in registration requests (65,535 is used on behalf of infinity). The bits following are used as flags. *R* indicates whether registration with the foreign agent is required. In case of enhancing the reliability of IP datagram redirection, a mobility agent may need to ensure a registration (even if the mobile host has used, e.g., DHCP for care-of address assignment). If the agent is too busy to accept any further registrations from mobile hosts, the flag *B* is set. The flag *H* is set, if the agent offers home agent services on the link, while *F* is set in case foreign agent services are offered. The flags *M* (*Minimal Encapsulation* [Per96b]) and *G* (*Generic Record Encapsulation, GRE* [HLFT94]) give information about the tunneling facilities supported by the agent, while *V* indicates that the agent supports van Jacobson header compression [Jac90].

23.4 Registration

Registration is the method used by mobile hosts to inform the home agent about their care-of addresses. The procedure causes a binding between a care-of address, the home agent, and potentially the foreign agent. Furthermore, it can be used to renew a binding or to deregister in case of returning to the home network. Several care-of addresses may be used simultaneously by one mobile host. After registration, each one is only valid during a *registration lifetime.* Some optional registration steps are the discovery of the home agent in case the mobile host cannot provide information about the home agent's IP address, the selection of tunneling protocols, and the request for van Jacobson header compression.

Registration can either be done via the foreign agent or directly between the mobile host and the home agent. In case the mobile host uses a foreign agent care-of address, it is compulsory to register via the foreign agent. Direct registration is used whenever the mobile host uses a colocated care-of address or it is registering at the home network. Figure 23.5 shows the basic registration message flow where the care-of address is equal to the IP address of the foreign agent (160.80.40.8). Thus, the foreign agent acts as a mediator in the example network structure.

Mobile IP registration uses the *User Datagram Protocol* (*UDP* [Pos80]) on the transport layer. This unreliable protocol without retransmission and ordering facilities is sufficient because retransmission is done via the Mobile IP protocol itself. Besides, an unreliable transport protocol avoids overhead caused by upcoming retransmissions and thus supports wireless links with varying network quality of service far better.

The format of a Mobile IP registration message is a sequence of IP header fields, UDP header fields, the Mobile IP message header, and extensions. The IP fields mainly give information about the source and the destination address, while the UDP fields consist of a destination port with fixed value 434 dedicated to Mobile IP registration and a variable source port.

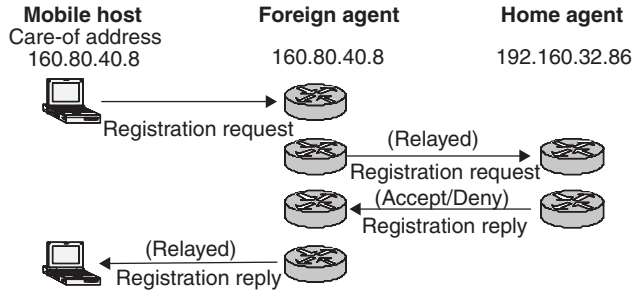

FIGURE 23.5 Mobile IP registration.

© 2005 by CRC Press LLC

Figure 23.6 shows a picture of the Mobile IP fields, starting with a *Type* with fixed value 1 and followed by a sequence of flags. In case the mobile host requests retaining its prior mobility bindings, the *S* flag is set. Setting the *B* flag requests the redirection of any broadcast message received at the home network. The *D* flag is set in case the mobile host itself decapsulates datagrams transferred to the colocated care-of address. The flags *M* or *G* are set, in case Minimal Encapsulation or GRE is provided. *V* is used to enable/disable van Jacobson header compression. After an unused reserved area (*rsv*), the field *Lifetime* states the seconds remaining until the registration is considered to have expired. The following addresses refer to the original IP address of the mobile host (*Home address*), the IP address of the home agent (*Home agent*), and to the datagram tunneling endpoint (*Care-of address*). The *Identification* number is generated by the mobile host and is used for comparing the request with the agent's reply, and for security reasons.

Returning to the home network, the registration request message can be used to deregister all care-of addresses at the home agent by setting the care-of address to the mobile host's home address and setting the lifetime to 0.

To answer the request, a registration reply is sent back from the mobility agent. The most interesting field in the registration reply is an 8-bit *Code* referring to the success of the request [Per98]. In case of acceptance, the Code values 0 or 1 are used (value 1 is used, if simultaneous mobility bindings are not supported). Otherwise, the code indicates the reason for denial, for example, value 66 is used for insufficient resources at the foreign agent, while value 131 is used for a failed mobile host authentication [Per98].

23.5 Tunneling and Route Optimization

To be able to redirect IP datagrams from the home network to the care-of address of the mobile agent, the home agent works as a proxy. First, the home agent fetches all IP datagrams addressed to the mobile host. In the second step, the home agent forwards the datagrams to the registered care-of address.

Since IP addresses are neither used nor understood by the underlying data link layer hardware, a protocol for matching network and data link layer addresses is needed. The *Address Resolution Protocol* (*ARP* [Plu82]) uses broadcast messages to send an IP address to all data link addresses on the network. The host identified by the IP address recognizes its own IP address in the data link broadcast and responds to the sender. Thus, the link between data link address and IP address is found. For a mobile host, ARP is slightly changed. Whenever a mobile host registers at the home agent, the home agent performs *gratuitous ARP* [Ste94] to update ARP cache information of other nodes (routers) in the home network, replacing the home address of the mobile node with its own IP address. Furthermore, the home agent performs *proxy ARP,* that is, sends ARP replies on behalf of the mobile node [Pos84].

After the original datagram has been fetched by the home agent, it is encapsulated into another IP datagram using the care-of address as the new destination address. The encapsulated datagram is received by the owner of the care-of address and is decapsulated. In case a colocated care-of address is used, the decapsulated packet has reached its final destination. Otherwise, if a foreign agent care-of address is used, usually the foreign agent itself is addressed and transfers the decapsulated packet to the mobile host.

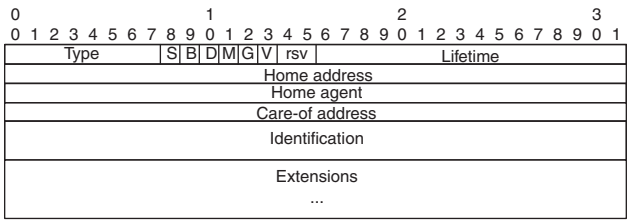

FIGURE 23.6 Request for registration: Mobile IP fields.

© 2005 by CRC Press LLC

Using the tunnel metaphor, the home agent and the care-of address owner are the tunnel endpoints. For encapsulation, *IP-in-IP Encapsulation* [Per96c], Minimal Encapsulation, or GRE may be used.

IP-in-IP Encapsulation is used in case no other encapsulation strategy is agreed on. Basically, an outer IP header and some optional additional headers like an authentication header are added. Thus, the original datagram is interpreted as the payload of the new datagram. The original header (now the inner header) is not changed, except the time to life field, which is decremented by 1. Figure 23.7 shows the tunneling in general using IP-in-IP Encapsulation in case of using a foreign agent care-of address.

In case of nonfragmented datagrams, Minimal Encapsulation may be used to save space. A Minimal Encapsulation header is built based on the original destination and the original source address, if this address is available. The outer IP header is built using the original IP header while replacing the source and destination addresses by the tunnel endpoints' IP addresses. Furthermore, the protocol type number is set to the value 55 (for the Minimal Encapsulation protocol).

The most generic encapsulation method is presented by GRE, which fits to a variety of protocols apart from IP. The GRE packet structure consists of a delivery header, where the source and destination addresses (i.e., the endpoints of the tunnel) are included, a GRE header, which can be used for authentication and routing information and the payload [Per98].

The concept of sending IP datagrams to the home agent and tunneling these packets to the care-of address is by its nature inefficient. One topic of route optimization concentrates on overcoming this triangle by using *binding caches* for mobile hosts' care-of addresses at (source) hosts. In case a home agent receives a datagram for a mobile host connected to a remote network, it may send a *binding update* message to the source host, which establishes a direct tunnel to the care-of address as shown in Figure 23.8 via steps 1 and 2. On the other hand, in case a foreign agent receives a datagram for a mobile host that has already left its visited network, it may send a *binding warning* message to the source of the tunnel (e.g., the home agent) to indicate out-of-date cache information [Per98].

In contrast, for example, the handover strategy used in *GSM* networks [MP92], where a handover between a visited *Mobile Switching Center* (*MSC*) and its successor is specified, the foreign agent is not informed of a new registration of a roaming mobile host (i.e., registration at another network). To make the foreign agents aware of the roaming history, an additional *foreign agent smooth handoff* strategy [Per98] is introduced using an *agent notification extension* in the mobile host's registration request message containing the IP address of the old foreign agent.

Figure 23.8 shows the main messages and actions while performing smooth agent handoff from steps 3 to 6. It is assumed that the mobile host roams between two networks and therefore changes its supporting foreign agent from Foreign agent 1 to Foreign agent 2 (step 3). Step 4 represents the registration procedure, where the IP address of the old foreign agent (Foreign agent 1, 160.80.40.8) is contained in the registration request message. After relaying the request to the home agent (step 5), Foreign agent 2 informs Foreign agent 1 about the new care-of address of the mobile host (step 6). This strategy allows

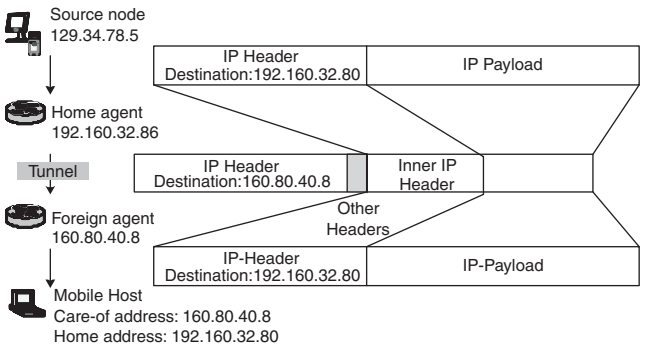

FIGURE 23.7 Tunneling using IP-in-IP Encapsulation.

© 2005 by CRC Press LLC

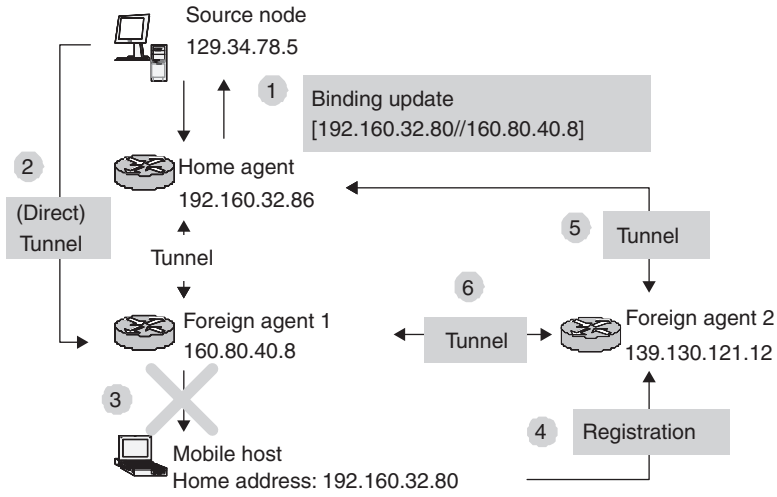

FIGURE 23.8 Route optimization.

the old foreign agent to release any resources assigned to the mobile host accurately and to redirect datagrams still tunneled to the old care-of address.

In case a foreign agent receives a datagram addressed to an unknown mobile host, the foreign agent tunnels the datagram back to the home agent using a *special tunnel* [Per98]. (A mobile host is supposed to be unknown, in case it is neither listed in the visitor list, nor in the binding cache).

23.6 Security Issues

Route optimization uses binding relationships between mobile hosts and several foreign agents. Thus, it facilitates the intrusion of imposters. To secure these relationships, authentication is needed.

During the registration procedure, a *registration key* is used between the anonymous foreign agent and the mobile host [Per98]. In case the mobile host and the foreign host share a security association or the mobile host transmits its public key, the foreign agent can calculate the registration key and send it directly to the mobile host. Otherwise, if security associations both between the mobile host and the home agent, and between the home agent and the foreign agent exist, the home agent calculates the key and transmits it to both partners. The home agent is also used for publishing the registration key in case it knows the public key of the foreign agent. Besides, the registration request/reply messages have to contain a mandatory authentication extension to establish a trusted relationship between the home agent and the mobile host. Although an arbitrary authentication method is possible, at least the *Keyed MD5* (*MD5 Message-Digest Algorithm* [Riv92]) has to be supported, which allows authentication and integrity checking. To avoid replaying of registration messages, the identification field is used for either placing timestamps or nonces to assure the freshness and originality of the registration message.

23.7 DHCP and IPv6 Issues

DHCP [Dro97] is a mechanism to assign IP addresses dynamically. In case of Mobile IP, the care-of address may be assigned using DHCP services. As a consequence, the mobile host plays the role of the foreign agent itself. Disadvantages can be seen when trying route optimization or agent smooth handoff. If there is no foreign agent in the network (in general), it will not be possible to redirect out-of-date datagrams. Furthermore, the mobile host itself must support decapsulation procedures.

Using *IPv6* (*Internet Protocol version 6* [DH98]), several Mobile IP tasks have to be redesigned because they are much better supported than in IPv4. If it is possible to enable the mobile host to take over all

© 2005 by CRC Press LLC

functions of the foreign agent, the need for a supporting agent in the foreign network is eliminated [Per98]. IPv6 supports automatic address configuration, allowing the mobile host to configure its globally routable care-of address without agent solicitation and agent advertisement. Enhanced security options (i.e., encryption and authentication fields in the IPv6 header) render the Mobile IP authentication procedure obsolete. Furthermore, a *neighbor discovery* [NNS98] method may substitute ARP (and therefore proxy ARP and gratuitous ARP). Using this new discovery method, the corresponding nodes are informed about the care-of address by the mobile host itself. The concept of the home agent is still needed with IPv6 to redirect datagrams arriving at the home network using IP6-in-IP6 Encapsulation.

23.8 Summary

To provide mobility support on network level for the Internet, Mobile IP may be used to support and complement IP services. The basic concept uses the model of a home agent, which encapsulates and redirects IPv4 datagrams from a mobile host's home network to the mobile host in the foreign network currently visited (tunneling). To be able to address the mobile host in the foreign network, the mobile host uses a temporarily assigned care-of address, which is usually the IP address of a foreign agent or a colocated care-of address assigned via DHCP. To provide secure and efficient services, route optimization, registration, and authentication techniques, like the MD5, are used. Using the next-generation IP protocol IPv6, some concepts will be changed. Thus, a foreign agent is not necessary any more and enhanced security options may be used.

24.1 Introduction

The growing importance of mobile communication deserves support for host mobility in IP-based cellular and wireless networks. Originally, IP networks were designed under the assumption that hosts are stationary. This assumption implies that the IP address does not change and a host is reachable from other hosts by this very address. Data are carried by means of IP packets that contain source and destination addresses. Internet routers inspect the destination address contained in an IP packet. They make a forwarding decision based on the network part of the IP destination address and forward packets to the determined next hop. Consequently, this addressing scheme puts restrictions on the address usage. In particular, an IP address can only be used within the network of its definition. If a mobile host moves to a new network, the old IP address becomes topologically incorrect. Therefore, a new — topologically correct — IP address must be assigned to a mobile host. Such an address assignment allows using standard IP routing; its disadvantage is that existing sessions are interrupted as a session is associated with the old, now invalid IP address. This dichotomy — an IP address represents both host identification and location — is the fundamental problem of mobile IP-based cellular and wireless networks and needs to be overcome by mobility concepts. The requirements for a mobility solution are as follows: (I) Short break in communication during a handover, in particular, for real-time applications. (II) Small protocol overhead, including signaling load, indirect routing, data encapsulation, as well as storage and processing capabilities. (III) Scalability

© 2005 by CRC Press LLC

with the number of mobile hosts. (IV) Functional requirements, such as support of heterogeneous end systems and access networks, ease of deployment, as well as location privacy and anonymity.

The mobility concept currently considered to be the most likely candidate for short-term deployment is Mobile IP [RFC3220]. Mobile IP uses additional agents to separate the host identification from the current location and ensures that arbitrary hosts can communicate with a mobile host in an uninterrupted way even while the host moves around. Despite this achievement, Mobile IP has been criticized for its performance problems and for not matching all possible requirements for a mobility concept. Some of these performance problems result from technological developments: higher bandwidth demands necessitate higher frequency bands with a smaller coverage area, resulting in smaller cells with more frequent handovers, thus causing performance degradation. Some requirements are application-dependent: applications might need seamless handover or no packet loss during handover or certain tradeoffs between loss and jitter.

In the following sections, HMIP, the MosquitoNet Mobile IP extensions, RAT, HAWAII, CIP, multicast-based mobility, MPA, ICEBERG, and extended SIP mobility are considered as mobility schemes that attempt to modify, replace, or augment the basic Mobile IP. At first, basic Mobile IP is briefly explained stressing the drawbacks that have triggered the proposal of new schemes for host mobility. Then, the other approaches can be divided into four main categories: (I) extensions of basic Mobile IP preserving the principle of indirect routing and address translation by means of tunneling, (II) host-based routing, (III) multicast-based mobility, and (IV) application-layer proxies (each assigned a separate section). In order to work out the basic assumptions behind the schemes, the motivation to develop a new approach, the required mobility infrastructure, as well as the addressing and routing concept are emphasized.

24.2 Basic Mobile IP and its Weaknesses

With Mobile IP, a mobile host owns an IP home address and in addition gets assigned a temporary care-of-address (CoA) in a visited network. A correspondent host addresses the mobile host via its IP home address. Mobile IP adds two new instances to the network infrastructure: A home agent (HA) and a foreign agent (FA) are executed in IP routers. Routing is performed indirectly using address translation by means of tunneling: a correspondent host directs packets to the mobile host's home network. The HA intercepts and tunnels the packets to the CoA of the mobile host. Tunneling a packet means its encapsulation and forwarding the encapsulated IP packet using the common IP mechanisms. The FA de-capsulates the packets and forwards them via local mechanisms to the mobile host. For the reverse direction from the mobile host to the correspondent host, the mobile host is allowed to send packets directly. This is referred to as triangular routing.

In Mobile IP, the agents periodically send advertisements on the wireless links in order to advertise the offered service and to provide a means for handover detection by the mobile hosts. When the mobile detects that it has moved to a new visited IP network/subnetwork (e.g., it misses a new advertisement from the old FA and receives an advertisement from the new FA) and has obtained a new temporary IP address, it registers its new IP CoA with the new FA. The FA in turn relays the registration to the HA that binds the new CoA to the mobile host's IP home address. Following packets arriving in the home network will be interpreted by the HA and tunneled to the mobile host's new CoA.

In general, the mobility support in IPv6 [PER96] is based on the same main principles as Mobile IP for IP version 4. But in Mobile IPv6, a mobile host is able to create its own CoA using its link-local address and automatic address configuration (combine advertised subnet prefix with own hardware address). Mobile IPv6 introduces two new optional IPv6 header extensions: a Binding Update and a Binding Acknowledgment. These extensions of the header are handled only by the final destination. The mobile host can directly send a Binding Update in the same packets carrying effective traffic to its correspondent host. The correspondent host can then learn and cache the new mobile host's CoA and directly forward data packets to the mobile host without traversing the mobile host's home network.

Mobile IP has a number of problems. Triangular routing causes the first problem: it adds delay to the traffic toward the mobile host. Measurements have shown that Mobile IP increases the delay by 45% in

© 2005 by CRC Press LLC

a campus network [ZHA01]. For two-way real-time communication, this delay is — frequently experienced — not acceptable. Second, encapsulation adds an overhead of about 20 bytes (IP-in-IP encapsulation [RFC2003]) to each packet potentially resulting in segmentation of IP packets. In comparison to the packet size of typical real-time applications, such as audio, the overhead is remarkable. For example, the voice codec G.723.1 [HER00] has a data rate of 5.3 kb/s with a frame size of 20 bytes. With a protocol overhead for IPv4 (20 bytes), UDP (8 bytes), and RTP (12 bytes), a packet has a length of 60 bytes. Due to the encapsulation the total packet length increases by 33%. Third, triangular routing poses a problem due to ingress filtering. Ingress filtering is a common security mechanism in IP routers. The mechanism checks for topologically incorrect IP addresses. In Mobile IPv4, the mobile host uses its home address as the source address to send an IP packet directly to the correspondent host. When a router, such as the access router of the current IP network, examines this packet, the router detects that the packet seems to originate from outside the network. Therefore, these packets will be discarded. A solution is to use reverse tunneling that again increases the overhead. Fourth, Mobile IP may cause high handover latency. In Mobile IP, a mobile host sends a binding update to the home agent. When the home agent receives the binding update, the home agent starts tunneling IP packets to the new foreign agent. While signaling messages are transported to the home agent and back, the mobile host is not connected to the network. When the delay between the mobile host and the home agent is large, the service interruption is unacceptable. Moreover, during the handover process, packets destined for the mobile host will be misdirected to the old foreign agent. These packets get lost. The main reason for this performance problem is that in Mobile IP the point for rerouting is located in the home network that might be distant from the current location of the mobile host. Fifth, in Mobile IP, the mobile host sends a binding update to the HA each time the mobile host re-registers for refreshing the binding update in the network. When the current location of the mobile host is distant from the HA, the aggregate signaling traffic traverses many routers in the network and poses a considerable load.

Some of the weaknesses are solved in Mobile IPv6. Nevertheless, in view of the high number of installed systems using IPv4 and the unclear evolution of networks from IPv4 to IPv6, a mobility solution for IPv4 is needed. Moreover, some of the problems — such as the performance problems with handover — still exist in IPv6.

24.3 Extensions of Basic Mobile IP

Hierarchical Mobile IP and MosquitoNet extensions modify the basic Mobile IP. RAT simplifies basic Mobile IP and attempts to replace it. However, all of these proposals are based on indirect addressing and address translation.

Hierarchical Mobile IP (HMIP)

The Mobile IP extension of hierarchical foreign agents [FOR99] addresses a drawback of Mobile IP: if the distance between the FA and the HA is large, the signaling delay for the registration may be long, which then results in long service disruption and high packet losses. Therefore, the FA functionality is distributed to several routers. These FAs can be configured in a tree-like structure. The highest foreign agent (HFA) is the root of the hierarchy; the lowest foreign agent (LFA) is close to the mobile host. Intermediate FAs are on the path between the HFAs and the LFAs. The intermediate FA that belongs to the old and the new path at a handover event is called the switching FA. The classification of the FAs is only conceptual. The hierarchy may collapse down to a single FA, as in the original Mobile IP approach.

The LFAs send announcements including their own address and the address of the next higher level. When a mobile host first arrives at a visited domain, it sends a registration request to the LFA that creates an unacknowledged binding update and forwards the registration request upward to the next higher FA. This initial registration request creates an address binding in every FA on the path, and finally in the HA.

When a handover occurs, the mobile host generates a registration request that is forwarded by the LFA (Figure 24.1, the text beside the boxes indicates the routing entries for the mobile host before and after the handover, respectively). At some point, the switching FA receives the request and detects that a

© 2005 by CRC Press LLC

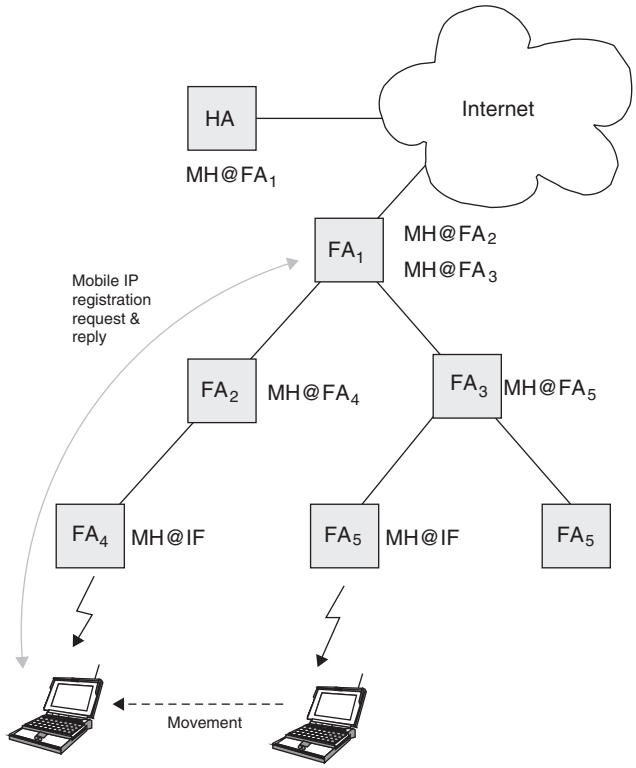

FIGURE 24.1 Handover process in hierarchical Mobile IP.

binding for the mobile host already exists but is coming from a different FA at a lower hierarchical level. This is interpreted as a local handover. The switching FA replies to the mobile host with a registration reply message.

MosquitoNet Extensions of Mobile IP

Other extensions have been proposed by the MosquitoNet group in [ZHA01]. These extensions address some of the problems of Mobile IP, namely the protocol overhead and the growing application of ingress filtering in border routers that prevents the usage of triangular routing in Mobile IP. Instead of modifying the basic Mobile IP principles, the MosquitoNet extensions allow a mobile host to use transparent mobility utilizing the Mobile IP infrastructure or not using it. In the latter case, the mobile host accesses the Internet directly using a temporary IP address in the visited network incorporating the Mobile IP infrastructure. Moreover, the mobile host can decide whether to use triangular routing or bidirectional routing. Mobile IP route optimization (triangular routing) fails when router ingress filtering is used: packets are dropped when they do not carry a topologically correct IP source address. Therefore, a mobile may use the more robust bidirectional tunneling, although it implies an additional overhead.

In the context of this approach, the support of multiple interfaces in a mobile host is essential. Each interface carries a temporary IP address. A flow can be bound to a specific interface. This is done with the help of a socket option. For data transmission, the route lookup has been modified, so that only routes with that specific interface are considered. For reception of data, a flow-to-interface binding (a flow is characterized by IP addresses and port number) is sent to the Mobile IP home agent that forwards datagrams to the appropriate CoA. The handover is similar to Mobile IP, but extends the protocol by an update of the flow-to-interface binding in the Mobile IP home agent. The extension is mainly intended for vertical handover of mobile hosts with multiple network interfaces.

© 2005 by CRC Press LLC

The basic Mobile IP approach is extended by the following functionalities:

A Mobile IP specific routing table extends the regular IP routing table. The Mobile IP-specific routing table contains the information as to whether to use transparent mobility or indirect routing, as well as triangular or bidirectional tunneling on a per-socket basis.

The Mobile IP home agent can manage multiple CoAs for a single mobile host simultaneously and bind a flow to a certain interface.

The protocol supporting registration between the mobile hosts and the home agent is extended.

These functionalities facilitate the flexible usage of Mobile IP in order to cause the protocol overhead only if it is necessary and to obviate the problem with ingress filtering.

Reverse Address Translation (RAT)

The RAT approach [SIN99] is motivated by the limited deployment of Mobile IP. It is intended to simplify mobility support in order to narrow the gap between the lack of applications, which require mobility support, and the poor deployment of Mobile IP. The RAT approach can be considered as a tradeoff: on the one hand, it dispenses with the requirement to maintain TCP connections. On the other, overhead is decreased and most of the traffic can be routed directly. Moreover, the inventors of RAT argue that implementation of Mobile IP functionality is operating system dependent (e.g., registration, tunneling, etc.), whereas RAT aims at a solution that is independent of the operating system.

In the RAT approach, the mobile host owns an IP home address and acquires a temporary IP address in the foreign network. The RAT approach adds new entities to the home network: a registration server and a RAT device. The network infrastructure remains unchanged. In particular, there are no mobility-specific entities required in the foreign network. The RAT approach applies Network Address Translation (NAT) [SRI01]. NAT is an Internet paradigm for extending the IP address space in IP version 4, and also supports the security when used in firewalls.

When a correspondent host sends a packet to the mobile host, it directs the packet to the home address of the mobile host. In the home network, the RAT device intercepts the packet and performs a network address translation. It replaces the destination address with the mobile host's temporary address and the source address with the address of the RAT device. Then, the packet is sent directly to the mobile host without tunneling. In the reverse direction, the mobile host sends a packet to the RAT device, which in turn performs the address translation and sends it to the correspondent host. This scheme is referred to as *reverse address translation (RAT)*. One of the main advantages of this approach is that the indirect routing is deployed for correspondent host initiated sessions only. When the mobile host initiates the session, it will use its temporary address (which is topologically correct) and communicate with the correspondent host directly. The authors argue that the mobile host initiates most of the sessions, and thus no indirect routing via the home network is required. This results in shorter routes and does not increase the packet length by encapsulation, without maintaining mobile host-initiated sessions during handover.

24.4 Host-Based Routing

With host-based routing, an IP address is considered as a unique host identifier without interpreting the network part as a location identifier. The network nodes route IP packets according to tables or caches indexed by host identifiers. The entries in the routing tables/caches are created by means of mobility-related signaling. HAWAII and Cellular IP supplement basic Mobile IP instead of replacing it.

Handoff Aware Wireless Internet Infrastructure (HAWAII)

HAWAII [RAM99] was proposed since Mobile IP results in high control overhead and high latency for local mobility. Also, HAWAII eases the usage of resource reservation protocols (such as RSVP) in a mobile environment, where a mobile host acquiring a new CoA on each handover would trigger the establishment of a new resource reservation.

© 2005 by CRC Press LLC

HAWAII defines a domain as a division of the wireless access network under the administrative control of a single authority. The domain consists of routers and access points. All of them are mobility-enabled by supporting HAWAII-specific signaling in order to optimize routing and forwarding. The router interconnecting the HAWAII domain and the Internet core network is called *foreign domain root router*. Each access point has Mobile IP foreign agent functionality (without decapsulation).

In the HAWAII approach, we distinguish between two types of mobility: *intra-domain* handover and *inter-domain* handover. For both cases different mechanisms are defined. The first case is supported by HAWAII and the second case is supported by Mobile IP. Both cases will be explained below.

In the HAWAII approach, a mobile host has a home domain (similar to the home network in Mobile IP) and a temporary unicast IP address. The home domain may support the HAWAII protocol. When the mobile host is in a foreign HAWAII domain the temporary IP address is assigned once to the mobile host and does not change as long as the mobile host stays in the domain. No address translation mechanism is required, and the Mobile IP home agent is not notified of the mobile host's movement. Instead, connectivity is maintained by using dynamically established paths in the foreign HAWAII domain based on host entries in the routing table of selected routers. Thus, a HAWAII-enabled access network does not rely on IP routing in the sense of routing based on the network's portion of the IP address.

For global mobility support, HAWAII reverts to traditional Mobile IP mechanisms. At first, the case is considered where the mobile host is within the HAWAII home domain. In this case, the mobile host carries a unicast (quasipermanent) IP address. When the mobile host powers up, it sends a Mobile IP registration message to the present access point. The access point then propagates a HAWAII path setup message to the domain root router using a configured default route. Each router in the path between the mobile host and the domain root router adds a forwarding entry for the mobile host. Finally, the domain root router acknowledges to the access point. The access point in turn sends the Mobile IP registration to the mobile host. Packets for the mobile host are sent to the domain root router based on the subnet's portion of the mobile host's IP address. The packets are routed within the domain using the host-based forwarding entries. It is important to note that the entries are in a soft state being kept alive by periodic hop-by-hop messages.

When the mobile host moves within the HAWAII domain (Figure 24.2), the mobile host registers with the new access point by sending a Mobile IP registration request. The new access point then sends a HAWAII path setup update message to the old access point. The old access point performs a routing table lookup for the new access point and adds a forwarding entry for the mobile host's IP address. Then, the message is sent to the upstream router. This router performs similar operations. If the router receiving this message is the crossover router,[1] then this router adds a forwarding entry to the new access point and packets for the mobile host are sent to the new access point. The path via the old access point will time out. This scheme is called *forwarding path setup* scheme since the HAWAII path setup update message is sent from the new to the old access point, and the old access point forwards packets to the new access point only for a limited time. This scheme is optimized for networks where the mobile host listens/transmits to only one access point simultaneously. An alternative scheme is the *nonforwarding* scheme, which is optimized for networks where the mobile host is able to listen/transmit to two or more access points simultaneously. In this path setup scheme, the path setup update message travels from the new access point to the old access point via the cross-over router. Thus, packets are not forwarded from the old access point.

In order to interact with Mobile IP, the mobile host is assigned a co-located CoA from its HAWAII foreign domain. A correspondent host directs the packets to the mobile host's home address. The Mobile IP home agent intercepts the packets and tunnels them to the HAWAII foreign domain root router with the network portion of the outer IP address. This foreign domain root router and the following routers forward the packets according to its host-based routing entries.

The HAWAII approach differentiates between active and idle users as well as appropriate states for the mobile host. For an active user, the network knows the mobile host's current access point, and for an idle

[1] This router has a route to the old and the new access point via the same interface.

© 2005 by CRC Press LLC

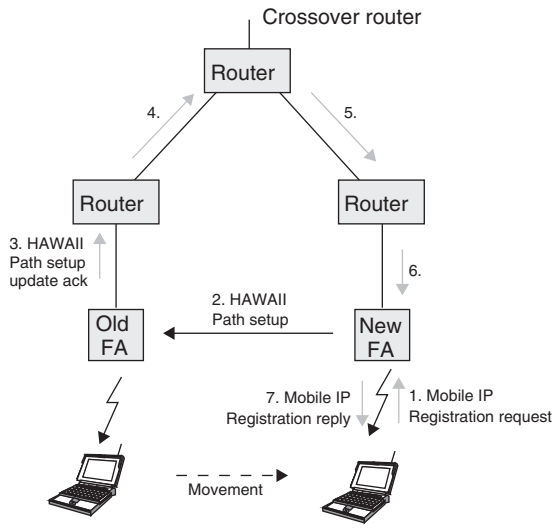

FIGURE 24.2 Forwarding path setup scheme in HAWAII.

user the network only knows the access point approximately, such as a set of access points. When packets for an idle mobile host arrive, the network pages the mobile to determine the mobile's current access point.

Cellular IP (CIP)

Cellular IP [VAL98] envisions a networking environment with ubiquitous computers where highly mobile hosts often migrate during active data transfers and the users expect minimal disturbance to ongoing sessions. The authors argue that Mobile IP is not an optimal solution, because it is optimized for macro-level mobility and relatively slowly moving hosts. Moreover, it is stressed that Mobile IP does not scale for a large number of mobile hosts, since every handover between Mobile IP FAs generates a binding update irrespective of the fact as to whether the mobile host is idle or active.

The Cellular IP approach proposes a hierarchical mobility management that separates global from local mobility. For global mobility, Mobile IP is applied to support handover across the Internet backbone. To support local mobility within the Cellular IP access network, regular IP routing is replaced with routing of packets hop-by-hop via lookup in specific tables (referred to as caches). The entries in the tables have a limited lifetime and time out (soft-state).

In a Cellular IP network, a mobile host is assigned a unique identifier that is used to route packets. It is not required that a mobile host has an IP CoA. For simplicity reasons, the unique identifier is an IP address (e.g., home address) that makes inter-working with Mobile IP easier. However, this is not really required, since within the Cellular IP access network no IP routing is performed.

For mobility support, Cellular IP adds a gateway router (GW) and Cellular IP (CIP) nodes to the network infrastructure. A gateway router interconnects the Internet backbone and the Cellular IP access network. The Cellular IP nodes are located in the Cellular IP access network and can be considered as access points working at the network level. They execute the Cellular IP protocol. It is not required that they be equipped with a wireless interface (if not, they act as a regular network node).

The global mobility support in Cellular IP is provided by basic Mobile IP. The Gateway router is colocated with a Mobile IP FA. The mobile host registers the gateway's IP address with its Mobile IP HA. Packets from a correspondent host are first routed to the Mobile IP HA and then tunneled to the gateway. The gateway detunnels packets and forwards them toward the access points. As long as the host is interconnected to the same access network, local mobility is concealed from the agent in the gateway router.

© 2005 by CRC Press LLC

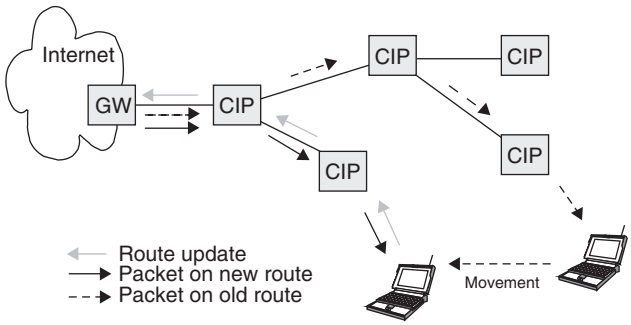

FIGURE 24.3 Hard handover process in Cellular IP.

The local mobility support works as follows (Figure 24.3): inside the Cellular IP access network, nodes are provided with a paging cache and a routing cache. Both contain mappings between mobile host identifiers and node ports (output port similar to a router port) on a soft-state basis. Paging caches are available in a few nodes. A paging cache is updated by data originating from the mobile host (data packets or specific signaling packets). The paging cache is used to locate a mobile host when there is no routing cache entry. In that case, the Gateway Router caches the IP data packets in order to send a paging packet to the mobile host across the Cellular IP nodes. The mobile host replies to that paging packet and creates routing cache entries in every node along the route. Now, the cached IP packets can be sent along this route without address translation and tunneling. Paging cache and routing cache entries are cleared by timers, with different timeout values: the routing cache timeout is on the order of several IP packets, whereas the paging cache timeout is set according to the handover frequency. Thus, an idle and active mobile host can be managed separately with different caches.

When a handover occurs, two cases have to be considered. In the first case, the mobile host generates a route update message when it enters the new cell in order to update the route caches in those nodes where the old and new routes diverge. After the route caches are updated, data packets are sent to the new location of the mobile host via the new route. For a limited time, the old and the new routing cache entry can exist in the routing cache and data packets are sent via the old and the new route. This is used for semisoft handover. In the second case, the routing cache entry in the Gateway was cleared, triggered by a timer, and a new paging packet is generated to locate the mobile host. The explicit search causes a small delay in sending packets; but it allows longer timeouts decreasing the amount of signaling packets.

24.5 Multicast-Based Mobility

The main idea of multicast-based mobility support is to utilize location-independent addressing and routing to support host mobility. In principle, each mobile host is assigned a multicast group address — a special-purpose address that does not contain a network part and, therefore, is independent of the location. The mobile host subscribes to the multicast group through its current access point to the network. Handover is performed by multicast operations, namely subscribe/un-subscribe to/from a multicast group. Data packets are distributed via a multicast tree with branches reaching the current locations of the mobile host on its movement. The branches of the multicast tree can grow and shrink, and hence, follow the mobile host's location. In particular, the branches can be simultaneously set up to multiple locations, including the current as well as the expected locations of the mobile host.

In comparison to the classical solution for IP mobility support, Mobile IP, a multicast approach has the following advantages:

Re-routing for handover is done in a router where the paths to the old and from the new access point diverge (and not in a software agent in the mobile host's home network as in the Mobile IP approach).

© 2005 by CRC Press LLC

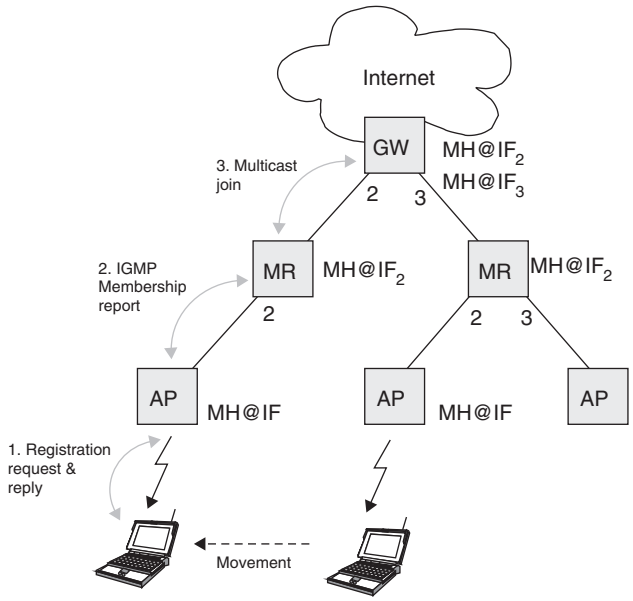

FIGURE 24.4 Handover process in multicast-based mobility support.

A handover-specific signaling and infrastructure is in principle not required; instead, multicast is reused for mobility purposes.

Multicast flexibly offers inherent mechanisms to minimize the service interruption caused by a handover between access points. It can be used to distribute IP packets to a group of access point that buffer the data. When a mobile host registers with one of the access points, data packets are already available and can immediately be forwarded to the mobile host.

Initially, it was proposed to use the classical any-source multicast (ASM) service model of the Internet (using IGMPv2 and DVMRP as multicast protocols) [MYS97]. It was proposed to put the multicast endpoint into the access point and to use an adapted signaling protocol on the wireless link [WU00]. [FES03] proposes to use alternative multicast service models other than ASM for mobility support.

A handover process for multicast-based mobility support with IGMPv2 [RFC2236] and PIM-SM [RFC2362] as multicast protocols is shown in Figure 24.4: a mobile host registers with the new access point (AP). The AP sends an IGMP unsolicited membership report to its designated multicast router (MR). The MR sends a PIM join message, which is forwarded up to the MR already having members of the mobile host's multicast group (rerouting node). In the example in Figure 24.4, the rerouting node is the gateway. The gateway starts forwarding packets on its interface 2, whereas the routing entry for the branch rooted at the gateway's interface 3 will time out.

24.6 Application-Layer Proxies

With application-layer approaches, the support for host mobility is independent of the underlying network-layer components. In particular, these approaches aim at mobility support between different types of access networks (e.g., GSM, WLAN) that are interconnected by the global Internet.

Mobile People Architecture (MPA)

The main goal of the Mobile People Architecture [MAN99] is to maintain a person-to-person reachability while preserving the mobile user's privacy. In the Mobile People Architecture, a *Personal Online ID* identifies

© 2005 by CRC Press LLC

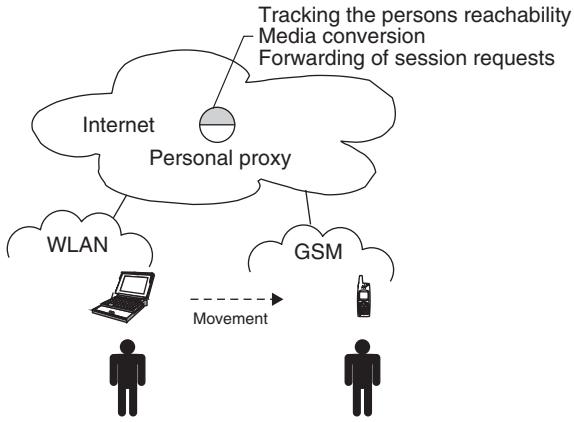

FIGURE 24.5 Mobile People Architecture (MPA).

a user. Additionally, a user is addressed by application-specific addresses (ASAs). Mobility is supported by mapping the Personal Online ID to ASAs.

In the Mobile People Architecture, a new entity is added to the network (Figure 24.5). This entity is called a *personal proxy* and acts as a *person-level router.* (The person level is added to the communication layer model on top of the application level.) The personal proxy tracks the user's current reachability, converts media, and forwards data to a specific end system. It is located in the mobile host's home network (if any), or is offered by a trusted third-party server.

When a user wishes to communicate with the mobile *person,* a call (call is regarded as a kind of session) is directed to the Personal Proxy, and then to the mobile person's preferred end system. When the reachability of the mobile person changes, the tracking agent updates the proxy state. The update can be done in a scheduled manner, manually or automatically.

It is assumed that local mobility is handled within the access network and hidden from the Personal Proxy. The case where a user changes the end system can be regarded as vertical handover. Then, the user updates the Personal Proxy (manually or automatically) and new calls will be directed to the user's new ASA. The case where a user changes the ASA while receiving service is not being considered.

ICEBERG

The motivation of the Internet CorE BEyond thiRd Generation (ICEBERG) [WAN00] is the current diversity of access networks, end systems, and services, in particular, traditional telephony services and data services. Therefore, ICEBERG aims at supporting personal mobility in the sense of seamless access to services independent of the access network and end system. It is intended to give the control of the communication to the callee, and not to the caller. In ICEBERG, a user can be uniquely identified (by means of a *unique-id*). Additionally, the user is associated with one or several *service-ids* (e.g., phone number, email address, and IP address). To achieve mobility, the unique-id is mapped to the service-id.

The ICEBERG network architecture consists of the Internet Core and several different access networks (e.g., GSM, PSTN, WLAN). At the interface between the core network, and an access network, an ICEBERG access point (IAP) transforms services (media converter). Additionally, ICEBERG adds service agents to the core network: preference registries, personal activity tracker (PAT), and extended naming services. The preference registry stores user preference profiles that can be modified by user interaction or by the PAT, which gives inputs about location information.

When a correspondent user wishes to call the mobile user, the call is routed to the IAP. In the access point, a name service lookup is performed, the preference registry of the called user is located, and the preferred end system is determined. After that, the call is established via the correspondent interface. The IAP can perform a service conversion (e.g., fax to jpeg).

© 2005 by CRC Press LLC

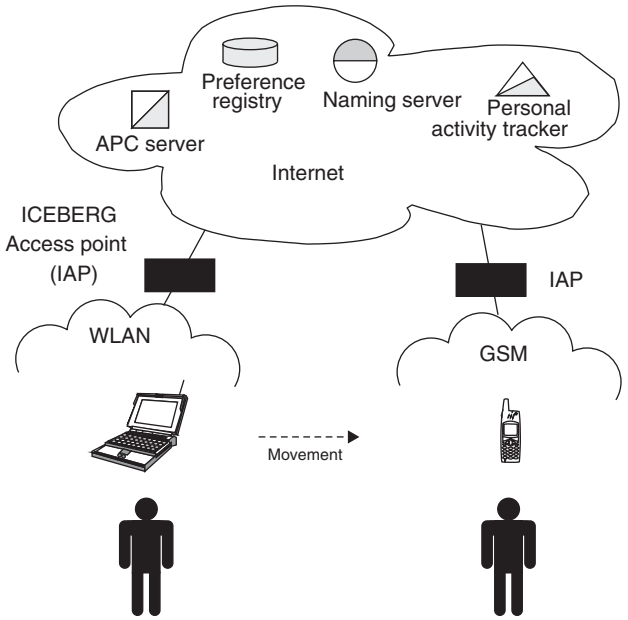

FIGURE 24.6 ICEBERG network architecture.

The ICEBERG approach focuses on user mobility between several access networks (Figure 24.6). It is implicitly assumed that host mobility is transparently supported in the access networks by technology-specific handover schemes (e.g., for GSM, IEEE 802.11).

Extended SIP Mobility

Extended SIP Mobility [WED99] is a mobility approach that utilizes the application-level signaling capabilities of the SIP protocol [RFC2543]. The motivation of the extended SIP mobility can be found in drawbacks of the Mobile IPv4 approach. The authors argue that for real-time traffic over IP, which is mostly RTP [RFC1889] over UDP traffic, there is a need for fast handover, low latency, and high bandwidth utilization. Mobile IPv4 suffers from indirect communication, which increases the delay and causes an overhead due to tunneling, thus decreasing bandwidth utilization.

The extended SIP mobility approach introduces mobility awareness at a layer higher than the network layer. SIP already supports user mobility, and the approach is meant to extend SIP as an application-layer signaling protocol in order to support end-system mobility. The main assumption behind the extended SIP mobility approach is that a mobile user is identified by a unique address (e.g., user@realm). This unique address is mapped to the current IP address of the mobile user's end system. No explicit home IP address is required. SIP introduces a SIP agent on the user's side, and a SIP server (SIP redirect server or proxy server) and location server to the network infrastructure.

User mobility is supported by means of the original SIP protocol: when a user wishes to initiate a session, an invitation is directed to the SIP server, which in turn queries the location server for the current IP address of the mobile user's end system. The SIP server sends the invitation to the called user. The invitation contains the IP address of the callee. If the mobile user moves, the location server is updated, and new sessions will be set up to the new IP address.

Host mobility with this scheme is mainly understood as an increased roaming frequency and as a change of an IP address during an ongoing session. Assuming that a session is already established, the mobile registers the new temporary address with the location server and the mobile reinvites the correspondent host with the same session identifier and the new temporary address (in the contact field of the SIP message). The session can be continued, although the IP address has changed.

© 2005 by CRC Press LLC

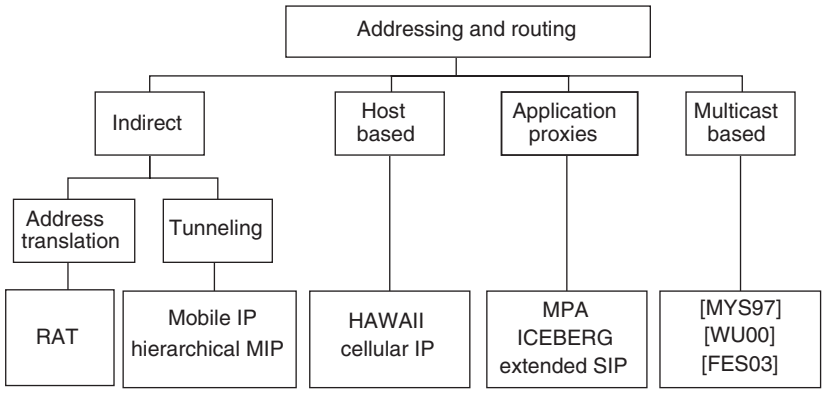

FIGURE 24.7 Classification of IP mobility approaches.

It is important to note that SIP does not support TCP, but UDP traffic only. Therefore, extended SIP mobility supports UDP traffic only. For TCP traffic, it is proposed to use Mobile IP. In fact, both approaches can coexist: for TCP traffic, Mobile IP is applied and for UDP traffic the extended SIP mobility approach is applied. For the simultaneous usage of network interfaces, the MosquitoNet approach of a mobile routing table [ZHA01] is adopted.

24.7 Summary

The basic Mobile IP represents the classical approach to host mobility in IP-based cellular and wireless networks. Despite its achievements, its performance problems have triggered the development of alternative approaches. In particular, it has been recognized that a single solution that attempts to fit all requirements, like Mobile IP, results in high costs for mobility support. The differentiation between global and local mobility, between active and idle hosts, as well as between user and host mobility meet the requirements for host mobility in an economic way. The categorization of existing approaches is shown in Figure 24.7. It can be seen that hierarchical Mobile IP and RAT are based on the same or very similar principles as basic Mobile IP. Hierarchical Mobile IP achieves a shorter service interruption by propagating the handover signaling messages only to a crossover node at the expense of additional infrastructure (hierarchy of foreign agents). RAT simplifies the basic Mobile IP in order to accelerate the hesitant deployment of mobile IP services, but does not support full transparency to the upper protocol layers. Host-based routing facilitates the integration of location management and routing. While in Mobile IP, location management is handled by Mobile IP signaling operations, routing is executed as an overlay on the existing IP routing. With host-based routing, the routes can be updated simultaneously with the location information since the route entries are host specific. Host-based routing, however, replaces standard IP routing. Multicast-based mobility support utilizes the capability of multicast as it potentially exists in future IP networks. It offers great flexibility for handover mechanisms that realize a tradeoff between service interruption/packet losses and protocol overhead. While the former approaches deal with local mobility support within an access network and can work with basic Mobile IP[2] for global mobility, the application-layer proxies attempt to replace (or at least supplement) Mobile IP for global mobility.

25.1 Introduction

In the last decade, the Internet has undergone an exponential growth and currently, there are no signs for an end or attenuation of this trend. In fact, with the convergence of currently separated networks, like telephone, radio, and television, the Internet will even accelerate its growth.

The need for more predictable and quality-based services than today's best-effort delivery is obvious. The Internet evolved from a purely scientific network to an important part of today's business and society. More and more activities are performed on-line, extending the variety of applications in the network constantly. For example, more and more companies use the Internet as a platform to perform their business-to-business (B2B) and business-to-customer (B2C) relationships. However, this increasing importance of the Internet also places strong requirements on its availability and resilience, and even more on the quality of its service. Not just multimedia applications, which are mostly named to motivate the need for value-added services, force the development and deployment of Quality-of-Service (QoS). More and

© 2005 by CRC Press LLC

more business applications would benefit from certain assurances. Moreover, the non neglectable market of distributed online games with their special needs also make it attractive for Internet Service Providers (ISP) to think about a deployment of services better than the traditional best-effort delivery.

Based on the Internet Protocol (IP), the Internet is only able to provide a best-effort delivery of data packets. This is implied by its fundamental design principles to keep the network core simple and to move as much actions as possible into end-systems. This allows the network to be scalable and able to continue its exponential growth. Routers in the core only have to perform routing lookups and forward data packets accordingly to the next hop. If a router receives more packets than it is able to forward these will be delayed or even dropped, if the capacity of queues is exceeded. Each packet is treated equally. This is sufficient for typical Internet applications like eMail or World Wide Web. In case of congestion, packets must be dropped. However, when more than best-effort delivery is needed, special actions must be taken, as will be shown in the next section.

This chapter introduces the Differentiated Services (DiffServ) approach and focuses on how a scalable and flexible QoS support can be realized for the Internet. First, Section 25.2 introduces basic elements necessary for an efficient support of quality-based services, and Section 25.3 provides a short insight into the interesting history of QoS approaches for the Internet and why they failed. Section 25.4 presents the Differentiated Services approach describing the main design principles and the overall architecture. After that, Section 25.5 continues by describing the elements of quality-based services in the DiffServ approach. Finally, Section 25.6 gives an introduction on how DS-services can be managed during the introduction phase and how this could be done dynamically in the future. Section 25.7 closes the chapter with a brief summary of the Differentiated Services architecture.

25.2 Elements for Realizing Quality-of-Service

Before taking a closer look at the details of the DiffServ architecture and previous QoS approaches, the following section discusses substantial components of quality-based communication systems. An overview of all functional units necessary for an efficient realization of QoS in packet-based communication systems is given.

The realization of quality-based services is tightly coupled with the management and scheduling of resources. A communication service needs certain resources, for example, CPU time, buffer space in queues, or a portion of a link's bandwidth capacity. Therefore, all QoS-enabled communication systems must consist of special components, whereby their concrete characteristics can be different in each individual case. Nevertheless, the following basic components can be identified and either be arranged in the data path or the control plane (cf. Figure 25.1).

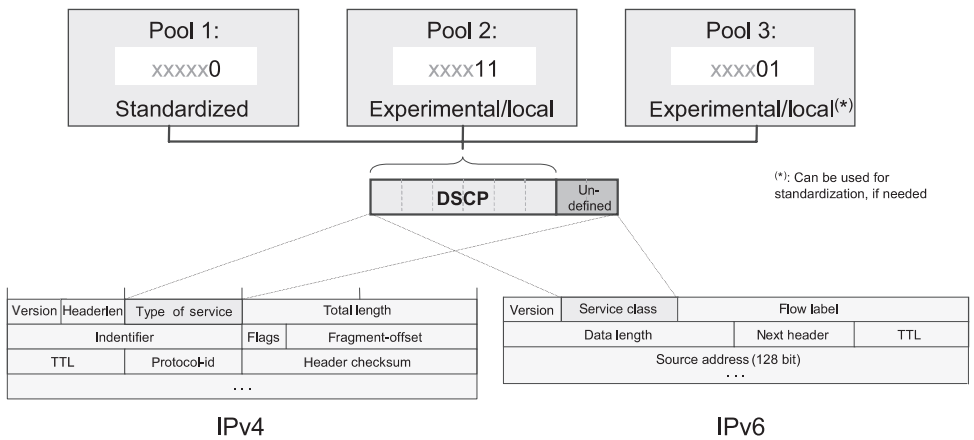

FIGURE 25.1 Elements for realizing Quality-of-Service.

© 2005 by CRC Press LLC

Data Path Components

The data path is defined by the path that data packets take in end-systems and routers, and by the components and mechanisms that deal with the treatment and forwarding of these packets. In the case of packet-based communication systems, the following components can generally be identified in the data path:

The *resource scheduling* is the main component in the data path. It carries out the final differentiation between data streams and thus realizes QoS. Generally, the resource scheduling consists of several components, which apportion the different resources (CPU cycles, buffer space, and bandwidth) to the respective packets, data flows, or aggregates. However, it is necessary that a reservation of the respective resources takes place before they are used. This is usually done via traffic profiles, which contain appropriate information about the exact treatment and the reserved resources of a data stream.

A *usage control* component monitors the data streams in QoS-enabled systems in order to supervise the compliance between resource usage and resource reservations. Therefore, incoming traffic is examined by traffic meters to check its conformity with the associated traffic profile. If necessary, misbehaving traffic can be treated according to the specification in the service-level agreement.

Control Plane

The control plane manages quality-based communication services and their resources. It does not perform any action on data packets.

A *resource manager* administers and assigns the resources mentioned above in a communication system. It has an exact overview of assigned and free resources and stores their assignment to certain data streams in traffic profiles.

The task of the *resource reservation* is the distribution of reservation requests between resource managers. This is usually accomplished over dedicated protocols. By separating resource reservation and resource management, several mechanisms or protocols for the resource reservation can be used simultaneously.

The *resources-based access control* decides on the acceptance of reservation requests. This decision can — next to resource availability — also be based on certain other rules, specified in policies, for example, political interests, agreements with other service providers, etc.

Accounting and billing components perform the task to log and prove concrete resource usage and tariff this to the service user.

The previously described elements are necessary both in data path and in control path to set up an efficient support for quality-based services in the Internet. The following description of failed approaches emphasizes this. Their failure was mostly implied by the lack of one of these elements.

25.3 Evolution of QoS in the Internet

The decision to create the IP as an unreliable and connectionless protocol was made at the beginning of the 1970s. The substantial goal — at that time certainly influenced by the military background of DARPA — was to develop a redundant network in which communication should remain possible, especially after the failure of some systems or links.

The fundamental problem with failing systems is the loss of state information, which normally has to be stored persistently. Therefore, the design decision was taken not to keep or manage status information in intermediate systems and to design all protocol mechanisms in a way that a system can configure itself again after a failure within a short time [14]. Thus, forwarding systems are scalable and can be prevented from carrying an exploding amount of state information. They have only to perform one main task, which is the fast forwarding of packets, and thus can be optimized thereupon.

However, a communication system cannot be designed completely without status information, because at certain points data on connections and their states must be stored. In order to avoid a heavy load on the components within the network, the Internet tries to store this necessary information in the involved end systems as often as possible. In case of a failing end system, only the connections of the failed

© 2005 by CRC Press LLC

system — which anyway is no longer operational after a loss — are concerned by the failure (*fate sharing*). This principle of moving the complexity to end systems and to keep the core as simple as possible, is often named as the "*Internet paradigm*" [14].

The following subsection presents a selection of former approaches to realize QoS support in the Internet. Each of them failed due to certain reasons, but mainly either the Internet paradigm was not considered or some of the important elements for QoS support (described in Section 25.2) were missing.

IP Type-of-Service

Since its beginning, the IP offered some support for a different treatment of data packets, which is the fundamental principle behind QoS. But as can be seen, much more is necessary to obtain real quality-based services.

The *Type-of-Service*-field in the IP header allowed to distinguish between different priorities (from 0 as the worst to 7 as the highest priority) and different preferences (low delay, high throughput, high reliability) for a packet [25]. However, there was no architectural framework that determined the concrete usage of the Type-of-Service-field and thus, no explanation of how QoS could be implemented with this approach across the whole Internet. Also, there was no real concept of how network resources should be assigned to ToS-priorities and -preferences and how their usage can be controlled and billed in the end. In practice, although some cases of usage exist, the ToS-field was ignored by applications as well as routers.

Stream Protocol

The Internet Stream Protocol ST (and later ST-II) [5] aimed to add a second network protocol next to IP to support real-time traffic in the Internet. ST was — in contrast to IP — a connection-oriented network protocol that allowed a reliable transport of data packets and, in conjunction with the Stream Control Message Protocol (SCMP), the negotiation of QoS-parameters for a connection.

Although ST-II has been standardized by the IETF, it failed to be deployed in the Internet due to various reasons. The main reason was obviously the establishment of a second network protocol next to IP, which contradicts the traditional hour-glass-model of the Internet with IP as the central protocol. The second reason for ST-II's failure was its connection-oriented nature, which was influenced by the telephone network idea of a connection as the main communication principle [11]. As outlined before, the character of connections requires state information in the network that needs to be maintained persistently and thus breaks with the principles of the Internet paradigm. Furthermore, the expected amount of connection and reservation states would lead to a similar scalability problem as in the case of the failure of the Integrated Services architecture, which is described in the next section.

Integrated Services Architecture

The Integrated Services (IntServ) approach [10] was the IETF's first attempt to develop a comprehensive support for quality-based communication services in the Internet. After the standardization of multicast and the initial experiences with the MBone, the necessity for a QoS-support in the Internet became apparent. Due to bandwidth bottlenecks and fluctuations within the utilization of the network, congestion and packet loss occurred increasingly. Particularly for multimedia applications developed at that time, the prevailing network conditions were insufficient for a satisfying communication.

The substantial goal during the development of the IntServ architecture was the support of multimedia applications by quality-based services without fundamental changes in the Internet architecture. The new services should especially offer support for group communication next to the traditional unicast. Audio and video applications, such as conferencing support were usually mentioned as the main examples. Quality-based services were deployed by a dedicated scheduling of individual data flows in each router. This enabled multiple applications to share one resource reservation, for example, in audio conferences where several participants share one reservation for an audio channel, which is only used by the actual speaker.

© 2005 by CRC Press LLC

In the IntServ architecture network, resources are explicitly assigned to a data flow in each router, for which dedicated reservation and access control mechanisms are needed. To distribute resource reservation requests, the Resource Reservation Protocol (RSVP) [9, 3] was developed. The final decision about accepting a reservation is taken by each router along the path. This implies that every router administers its resources locally and maintains a traffic profile explicitly for each quality-enhanced data stream.

Consequently, flow-specific data must be kept persistently within the core network, thus violating the Internet paradigm. The design decision proved to be problematic since the scalability of the IntServ-architecture cannot be ensured in a constantly growing Internet with an increasing number of data streams [3].

25.4 The DiffServ Approach

The previous examples showed that the realization of quality-based services in the Internet is a goal that has been targeted by numerous approaches so far, but has not been accomplished satisfyingly yet. Various problems led to the failure of the discussed architectures, above all the promising IntServ-approach, which is not suitable for an Internet-wide deployment due to its scalability problems [3]. Nevertheless, the realization of quality-based services in the Internet does not seem to be impossible and a new promising attempt was started, in which the experiences from the failed beginnings were considered

The DiffServ architecture [8] — often abbreviated as DiffServ or DS — was developed from 1998 to 2003 by the Internet Engineering Task Force (IETF). The main goal of the DS working group was to develop a scalable and flexible architecture for the realization of quality-based services in the Internet. According to the definition of scalability in [8], the DiffServ architecture will be scalable if and only if it still works efficiently in an environment with clearly larger characteristics. This means, for example, an environment with a larger number of users or a larger number of flows, even when these parameters grow by several orders of magnitude compared to the situation today.

Further design goals of the DiffServ architecture are considered more detailed in the following section.

Requirements and Goals of DS

The standard RFC 2475 explicitly points out the requirements on the DS architecture regarding the dynamic and unexpected growth of the Internet [8]. Also, it is expected that the number of Internet users, the available bandwidth, and the number of the flows will grow irresistibly, whereas a continuation of the exponential growth is not precluded. Likewise, the variety of applications using the Internet as infrastructure will increase. Consequently, an architecture for quality-based services has to take into account these expected developments and has to support them in an adequate and scalable manner — not only for the foreseeable future, but for a much longer timescale.

As a result, the following demands to the DS architecture have been defined in RFC 2475:

Scalability: As pointed out before, scalability is the main design principle of the DiffServ architecture. Using this, the problems of the IntServ architecture should be avoided, which maintains per flow state information in each router in contrast to the principles of the Internet paradigm [14, 24]. Current router architectures are not capable of performing such a fine-grained classification. Thus, the main design goal of DiffServ is the realization of quality-based services without the need to maintain per-flow-based state information in the core network.

Flexibility and extensibility: DiffServ should also offer many different services to end users, but it should not be the responsibility of the IETF to specify concrete services. Instead, the focus is on defining a basic architecture, on top of which individual services can be realized. The deployment of concrete QoS mechanisms and consequently concrete services is the responsibility of each ISP. This enables them to react faster and more flexibly to their customers' needs and to current market situations.

The IETF will only define basic mechanisms to realize quality-based services without keeping concrete services or certain applications in mind. The architecture should assure the interoperability between different ISPs but should also allow them to define mechanisms and services of their own choice. Concrete

© 2005 by CRC Press LLC

services will not be standardized but should evolve very quickly according to the needs of the market. Consequently, the realization of a *flexible* and *extendable* architecture is the second challenge of the DiffServ architecture next to scalability.

Next to these two main challenges, the DiffServ architecture should also fulfill the following demands — which partially result from the need for scalability, flexibility, and extensibility — but are explicitly mentioned in RFC 2475:

Compatibility to legacy applications: Legacy applications should be able to use a network running DiffServ without any need for modification. This implies that no changes on software or user interfaces are required in end systems for taking advantage of the new services.

Separation of traffic conditioning and quality-based forwarding: Mechanisms for traffic monitoring and conditioning should be separated — especially in the core of the network — from mechanisms realizing the differentiation of packets. This can significantly reduce the complexity of the overall architecture and improve scalability and flexibility.

Abdication of a perhop signaling: The DS architecture should not rely on a *hop-by-hop* signaling, as for example, the RSVP protocol in the IntServ architecture. Such a signaling method would finally reinduce the maintenance of states in the core network and thus lead to scalability problems.

The requirements can be summarized by the attributes *scalability*, *flexibility,* and *extensibility*. Based on these three building blocks, the IETF working group "*Differentiated Services*" developed the DiffServ architecture described next.

The Architecture of DiffServ

This section presents the major design principles of the DiffServ architecture. It will mainly be shown how the demands drawn up previously can be fulfilled. The choice of the services finally deployed by an ISP is not the responsibility of the IETF or the DiffServ architecture.

Carrying State Information Instead of its Maintenance

The main goal of the DiffServ architecture is to assure scalability, especially with having a continuously growing Internet in mind. The consideration of scalability in terms of QoS-support focuses mainly on the scalability of maintaining state information in the core network.

As indicated in Section 25.2, the realization of quality-based services in a packet-based network implies some kind of connection, which leads inevitably to maintenance of state information. Thus, it is necessary in a QoS architecture to have a so-called traffic profile for each flow using QoS, in which at least the following information is maintained:

Classification data for identifying a data flow and for assigning its appropriate traffic profile. Normally, for this mapping, a combination of several header fields is used, whereas the following five are the most common: IP source and destination addresses, TCP/UDP source and destination ports, and the protocol identifier in the IP header.

A specification of the *QoS parameters*, for example a specification of the service quality the data stream should experience. These parameters must be negotiated between the service user (customer) and the service provider (ISP) before service usage and should be codified in a Service Level Agreement (SLA).

Operational data arise only at the runtime of a service. Examples are runtime variables, such as the number of tokens in a token bucket meter, and also data about the usage, which can later be used for billing and accounting.

This information is necessary to support quality-based services in the Internet and must therefore be maintained. For example, in the IntServ architecture, this information was stored in each router, and thus led to scalability problems. However, the only way to avoid this problem seems to be by removing the traffic profiles from the inner part of the network, where the expected amount of information cannot be

© 2005 by CRC Press LLC

maintained in a scalable way. Consequently, the basis for the classification of individual data streams and their assignment to resources and service classes is missing.

The DiffServ architecture follows exactly this path. It removes the complexity from the core network and shifts it toward the less frequented edges — according to the Internet paradigm (cf. Section 25.3). The state information cannot be completely shifted into end systems since this would induce modifications to system interfaces and applications. Above all, ISPs would lose control over SLAs, since service users can arbitrarily modify them and assign themselves the best services.

For this reason, the traffic profiles are mainly stored in the first router of a communication path, which are typically located in less loaded access networks [3, 8]. The quantity of data streams arising in such low frequented access networks is quite small compared to the Internet's core and therefore the administration of state information can be accomplished efficiently. As will be addressed in Section 25.6, after a certain migration phase the administration of this data can be maintained in dedicated management units and the first nodes will only receive a copy of the data to perform usage control.

The crucial question now is: how can routers in the inner network decide which flows should experience a certain quality-based treatment without the necessary information? The answer to this question is the main design principle of DiffServ, which makes it a scalable and flexible architecture for quality-based services:

After the first router — which still maintains traffic profiles for each data stream — has classified a data packet and retrieved its associated traffic profile, a small tag identifying the service class will be written in the IP packet header. Consequently, each following router can easily determine the Per-Hop Behavior of a packet marked with this little tag called *Differentiated Services Codepoint* (DSCP). A detailed definition of a forwarding behavior will be given in Section 25.5.

To store the DiffServ codepoint in IP, the meaning of the Type-of-Service-field in the IPv4-header and of the Traffic-Class-field in the IPv6-header was changed in RFC 2474 as illustrated in Figure 25.2 [2]. The first six bits in this field store the DiffServ codepoint, which specifies the forwarding behavior (PHB)

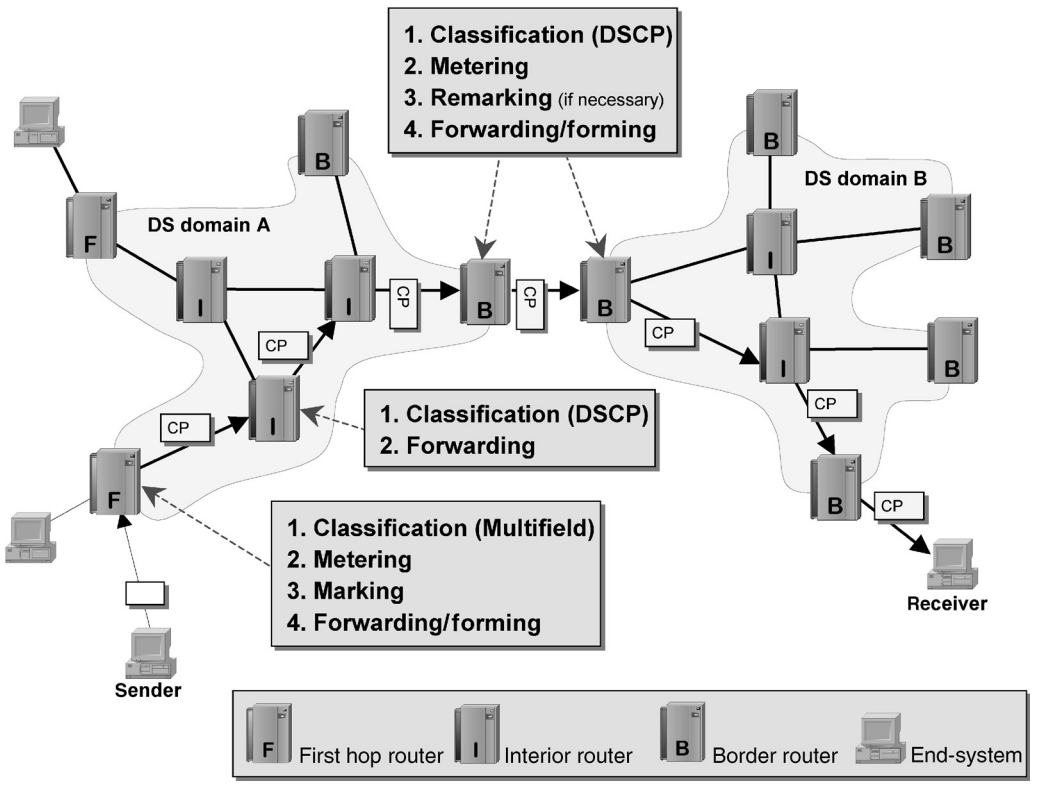

FIGURE 25.2 Format of IPv4 and IPv6 packet headers containing the DSCP-field defined in RFC 2474.

© 2005 by CRC Press LLC

of an IP packet. The DSCP can take values from 0 to 63, whereby only a maximum of 32 is currently released to be used in normal Internet traffic. The remaining 32 values are reserved for test purposes and a potential later standardization.

Consequently, the packet carries the necessary state information in itself; thus, this information does not have to be maintained by the routers, especially by those in the core network. The scalability of the architecture is assured, because no status information per data stream has to be stored anymore. But due to the limited information a DSCP can handle, some difficulties can arise:

Per-Hop Behavior: The DSCP cannot carry further information than the specification of the concrete forwarding behavior. Thus, sometimes special information about individual QoS characteristics can be missing, for example, the reserved bandwidth.

Aggregates instead of individual data flows: With the absence of classification and QoS parameters, it is no longer possible for an internal router to differentiate individual data streams with regard to their different QoS criteria. The only level of differentiation is the assigned Per-Hop Behavior, specified by a DSCP.

Therefore, the set of data streams with the same DSCP will be called an *(behavior) aggregate (BA)* in the following. In the core network, only aggregates can be differentiated. Individual data streams within an aggregate cannot be differentiated inside a DiffServ network due to the missing classification information.

Thus, the differentiation of data flows within the network bases on the DSCP stored in the IP header and all flows carrying the same codepoint will be treated as one aggregate. The isolation of individual data flows, as practiced in the Integrated Services architecture, is given up in favor of scalability.

This raised the question of whether a six bit long codepoint field, which specifies only the forwarding behavior, can be a real replacement for detailed information about individual data flows. This question was the topic of many discussions on the DS working group mailing list, for example, the discussion on aggregation in the Expedited Forwarding PHB and assumptions on their effects [13, 12].

DiffServ Domains

After the explanation of the fundamental design principles (avoidance of states in the network core and carrying service information through the DSCP), the following section presents the administrative structure and the components of a QoS-enabled Internet on the basis of DiffServ. Subsequently, the following section addresses the functional model of a DS-router.

DS domains form the organizational basis of a quality-based Internet. A DS domain consists of a coherent set of network nodes, which support DiffServ mechanisms (DS-enabled nodes) and mostly belong to the same administrative domain of one ISP (e.g., a routing domain or an autonomous system).

As described in [18], the Internet is a union of different autonomous networks (autonomous systems — AS) that are under the administration of many competing Internet Service Providers [16]. Therefore, considerable attention was given to the development of the DS architecture to consider these administrative domains of the Internet and to define mechanisms for a controlled transition of quality-supported data flows between these administrative domains.

According to RFC 2475, a DS domain forms a coherent part of the Internet consisting of several DS-capable nodes, which are all administered by one ISP. Usually, a DS domain will correspond exactly to one autonomous system. However, large autonomous systems can be subdivided into several DS domains.

As illustrated in Figures 25.3 and 25.4, different kinds of routers with different complexities and functions can be distinguished within a DS domain. Essentially, DiffServ nodes can be divided into two groups: *internal nodes* (Interior Router — IR) and *border nodes* (Border Router — BR). While the interior of a DS domain consists of internal nodes, border nodes are used at the edges of DiffServ domains in order to ensure a controlled transition to the next administrative domain. Depending on the direction of a data flow, border nodes can be distinguished either as Ingress Border Routers (IBR) or Egress Border Routers. Also, the first and the last border nodes of an end-to-end communication path receive special

© 2005 by CRC Press LLC

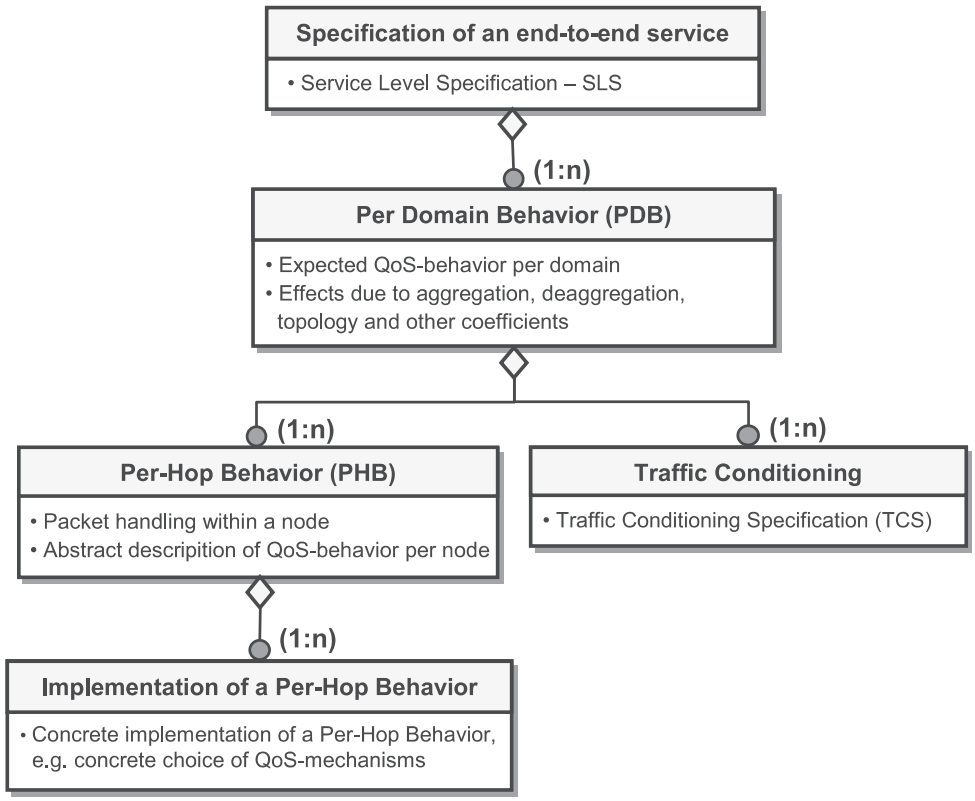

FIGURE 25.3 Components in a DiffServ domain.

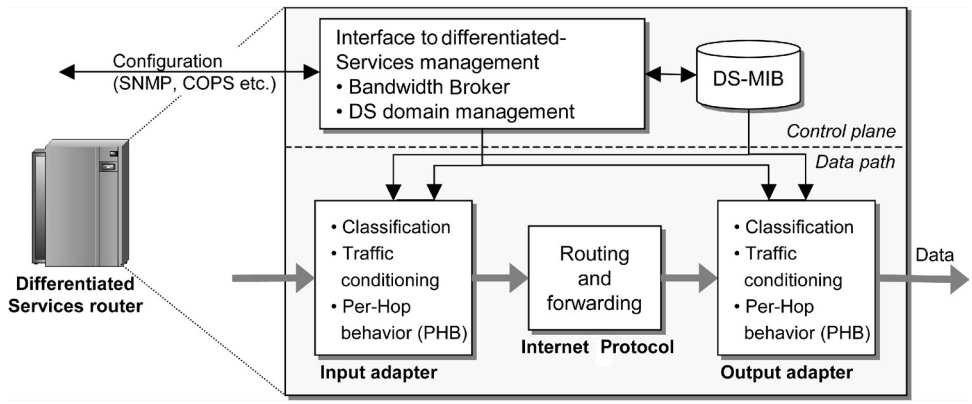

FIGURE 25.4 Hierarchical classification of different DiffServ-router types.

consideration as First Hop Router (FHR) and Last Hop Router (LHR) due to their special duties. It has to be noted that this partitioning is only a logical distinction according to the regarded direction of a data flow. These systems are not physically separated. Thus, for example, a FHR acts as a LHR, when the focus is on the reverse direction. This also emphasizes the unidirectional character of DiffServ.

In the following, the exact functions of the respective DS node types are described, whereby the succession of the explanation corresponds exactly to the path of a packet in a DiffServ-enabled Internet (cf. Figure 25.3):

© 2005 by CRC Press LLC

The first node (FHR) fulfills four substantial tasks. First, an incoming packet is classified, that is, assigned to one of the stored traffic profiles. This mapping is carried out with a multi-field classifier by comparing different packet header fields with the classification data in the traffic profiles. A multi-field classification is very complex, whereby the complexity increases linearly with the number of traffic profiles. For this reason, multi-field classification is accomplished in the DS architecture only in the first node. In such nodes, the number of data streams and thus the number of traffic profiles are expected to be noticeably smaller as compared to the core network.

After mapping to a traffic profile, a packet is examined for its conformity concerning the service class and the negotiated QoS characteristics stored in the traffic profile. In the negative case, appropriate QoS mechanisms can enforce the conformity, for example, by delaying, dropping, degrading the packets, etc. If no matching traffic profile can be found, the packet is assigned to the default traffic profile (Best Effort). In each case, a packet is marked with the determined DSCP, which specifies the forwarding mechanisms in the following nodes (principle of carrying the state information in the packet and not maintaining it in the network nodes).

Finally, the packet is forwarded using the appropriate DiffServ PHB as indicated by the DSCP, that is, the differentiation of the data streams finally takes place here, and thus the desired QoS is realized.

IR have only basic functionality, in order to be as scalable as possible. Arriving packets are also classified in the internal nodes, but only on the basis of the DSCP. Because this can only be up to 64 values, which are statically assigned to forwarding behaviors within a DiffServ domain, no scalability problem occurs here. Therefore, the codepoint-based classification is independent of the number of data streams and traffic profiles.

According to the classified DSCP, the packet is assigned to a PHB, performing the desired differentiated treatment of data streams. Compared to the FHR, the granularity is clearly smaller, because packets can only be differentiated according to their DSCP (aggregates). Individual data streams are nondistinguishable.

In the border node (BR) of a DiffServ domain, a further metering of the arriving packets is accomplished next to the PHB-based forwarding. However, no examination of individual data streams (also called *microflows*) takes place, but only a conformance check on the basis of aggregates is carried out, which consists of all packets with the same DSCP. Therefore, in border nodes, a codepoint classifier is used, where at least 64 traffic profiles have to be maintained for the classification. This way, DS BRs are also independent of the number of passing data streams and independent of the number of traffic profiles in FHRs, whereby scalability remains ensured.

The last node (LHR) in a communication is not explicitly mentioned in RFC 2475. However, there is no reason against its deployment and it becomes particularly necessary with the realization of a deterministic service with maximum end-to-end delay, for example, the Virtual Wire Per-Domain Behavior [20]. The complexity of the LHR, similar to its tasks, corresponds mostly to that of a FHR, and the same scalability considerations as for an FHR apply. Thus, it can also become necessary that the LHR has to differentiate individual data streams and therefore has to maintain traffic profiles for those data streams. The substantial need for a LHR exists particularly in the forming of individual data streams according to traffic patterns needed by an application in the receiving end system.

Thus, all DiffServ nodes, which are passed after the first node (and before the last node) along a way, differentiate only between aggregates with different PHBs. All packets with the same DSCP on a link belong to the same behavior aggregate, and experience the same forwarding behavior.

Functional Model of a DiffServ Node

Quality-based services are realized by a differentiated treatment of packets in routers and end systems. There are numerous algorithms and methods to change the forwarding behavior of a data stream. Since the IETF wanted to develop the DiffServ architecture as flexible as possible, no concrete mechanisms and thus no special services have been standardized. The actual realization of quality-based services is the responsibility of an ISP. Nevertheless, the IETF created a functional model of a DS node [6], allowing manufacturers and network providers to orient themselves on it (cf. Figure 25.5).

© 2005 by CRC Press LLC

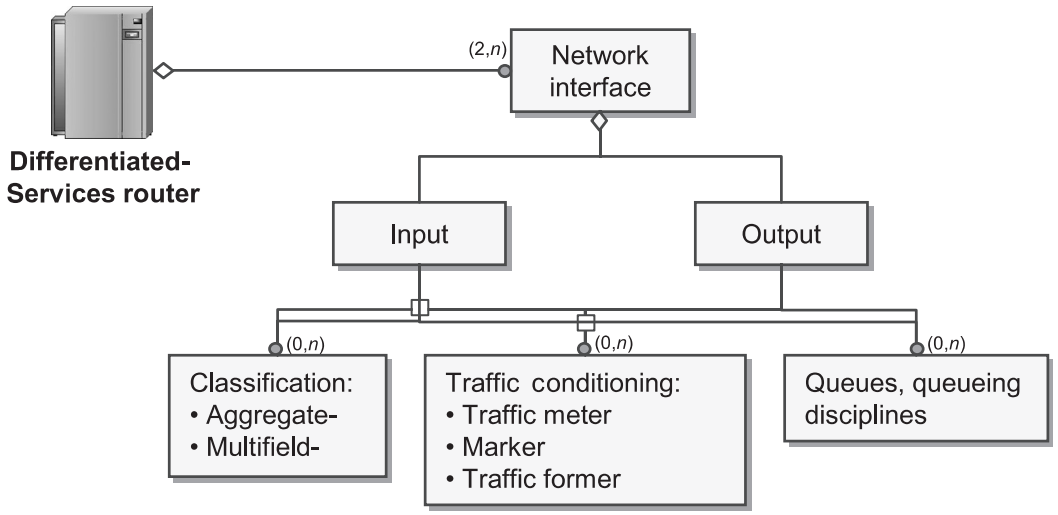

FIGURE 25.5 Components in a DiffServ node.

Thus, according to RFC 2475, the mechanisms used in a DS node can be divided into the following categories, which are illustrated in Figures 25.3 and 25.5:

Classification elements map packets to their appropriate traffic profiles and thus to their PHBs. Classifiers have no direct influence on packets. However, they decide what treatment a packet will experience in the further processing.

Elements for *traffic conditioning* change the actual characteristics of a data stream by performing operations on its packets. This operation does not always have to be active; consider for example, a dropper or a traffic shaper. It can also have an indirect impact, for example, a traffic meter influences the further treatment of a packet.

Queues and *dequeue disciplines* are traditional elements for performing a differentiated treatment on packets, for example, First-In-First-Out, Earliest-Deadline-First, etc.

The actually used algorithms and functions depend mainly on the position and on the kind of node considered. Internal nodes will usually use only DSCP classifiers and appropriate queueing mechanisms in the output interfaces for realizing a PHB. On the other hand, border nodes will have additional functionality, such as multi-field classifiers, metering elements and markers, and droppers or traffic formers.

The concrete implementation of a PHB is not standardized, so that an ISP can select the mechanisms for its implementation. Likewise, in RFC 2475, it is not described as to how these mechanisms have to be combined to form a concrete forwarding behavior (*Traffic Conditioning Block* — TCB), that is, which interfaces exist, which rules have to be considered, etc.

The next section takes a closer look at how in the DS architecture, quality-based services and their components can be described and specified, so that inter-operable end-to-end services can be deployed between different Internet Service Providers and their administrative domains.

25.5 Elements of DS Services

The goal of a QoS architecture for the Internet is the support of quality-based network services for applications. This implies that applications are the real user and therefore these services have to be provided from end system to end system over the entire network (*end-to-end*). Services for individual end-to-end data streams are realized by a differentiated treatment of their packets within the forwarding systems and by traffic-conditioning actions (cf. Figures 25.5 and 25.6). In the case of DS, an end-to-end service is

© 2005 by CRC Press LLC

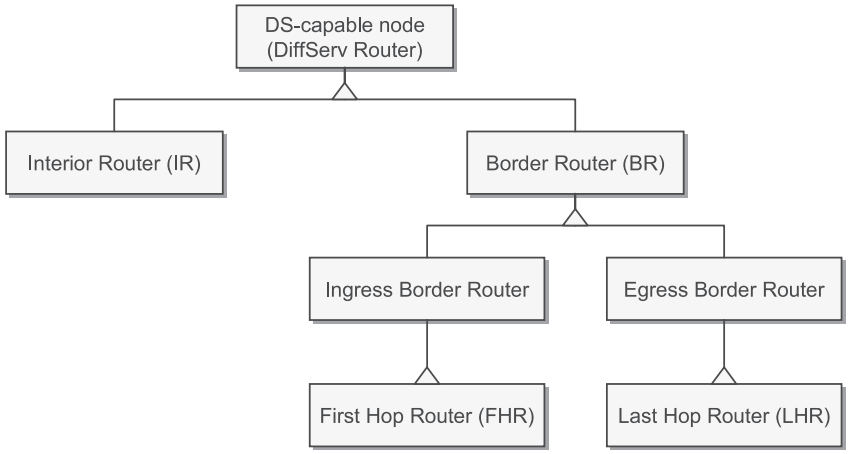

FIGURE 25.6 Classification of QoS mechanisms to be used in DiffServ-nodes according to RFC 2475.

realized gradually by a concatenation of several DS domains along the communication path between the involved end systems. In Section 25.4, it was already mentioned that the DS architecture only specifies a framework for QoS-support and imparts ISPs the greatest possible freedom for the realization of the respective QoS-elements and services. Thus, the question arises regarding how flexible but also how predictable can quality-based services be realized end-to-end over the administrative domains of different, independent, and competing ISPs?

To answer this question, the IETF defined several functional elements, which can be successively combined to deploy end-to-end-services in the DS architecture [8, 23]. The following sections will introduce these functional elements and explain how an end-to-end service can be combined from a set of Per-Domain Behaviors (PDB), which themselves consist of different Per-Hop Behaviors (PHB). The relationship among these functional elements is illustrated in Figure 25.7 using the Object Modelling Technique [26].

Per-Hop Behavior

A PHB represents the basic element for the realization of quality-based services within the DS architecture. It defines the forwarding behavior its packets will experience in a DS node. However, a PHB only defines the behavior as it is visible from the outside and no concrete QoS algorithms are specified. This means that a PHB describes only the basic characteristics that must be fulfilled by a concrete implementation, for example, an upper bound for the delay in the node or the avoidance of reordering within a data stream. Thus, a PHB does not prescribe an implementation, but specifies only the necessary behavior to realize the appropriate PHB to be classified as PHB-compliant [2].

A PHB mainly consists of the description of how the assigned aggregates should be treated differently. Thus, PHBs are usually implemented with certain queues and queueing strategies. However, it can be favorable not to regard several PHBs separately because sometimes packets of one data stream can be assigned to different aggregates. In such a case, the PHBs belonging together will be called a *PHB group* [2].

So far, the DS working group of the IETF has defined three PHBs, in order to conform to the earlier meaning of the Type-of-Service-field in the IP header and to standardize a certain set of PHBs to fulfill the basic demands. Based on these, PHBs PDB were defined, which can be used to realize the two traditional QoS-services for assuring a deterministic and statistic guarantee of a certain bandwidth. The following PHBs were defined so far:

- *Class Selector Compliant PHB Group* (RFC 2474, [2]).
- *Assured Forwarding PHB Group* (RFC 2597,[4]).
- *Expedited Forwarding PHB* (RFC 2598, [21]).

© 2005 by CRC Press LLC

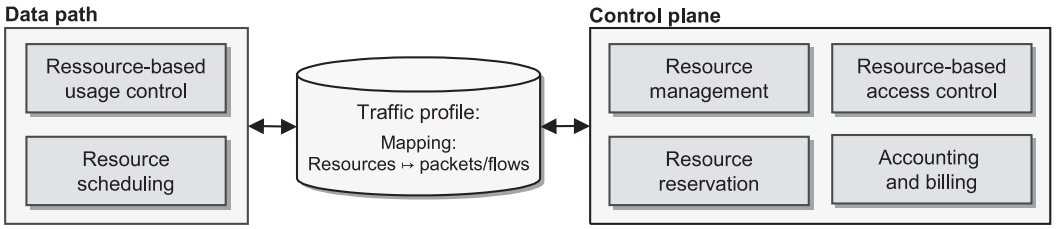

FIGURE 25.7 Relationship between functional elements of services in the DS architecture.

The Class Selector PHB group was defined to guarantee the compatibility with the ToS-field according to RFC 791. It consists of eight values that correspond to the eight relative priorities. The DSCP values were selected in such a way that none of the old ToS-attributes delay, throughput, and reliability were set. Furthermore, each DS-capable node must assign the Best Effort PHB to packets with DSCP 0, as well as packets of the two highest priorities (*network control* and *Internetwork control*) to a PHB that offers a better quality than Best Effort to protect routing traffic from non-DS-enabled systems against the remaining traffic.

Per-Domain Behavior

The differentiated treatment of packets forms the basis for the realization of quality-based communication services. However, as the overview of recent QoS approaches for the Internet in Section 25.3 showed, it requires much more features, like traffic control and traffic conditioning, to offer QoS support. Therefore, based on PHBs RFC 3086 defined the concept of PDB [23]. These describe the expected treatment of packets from edge nodes to edge nodes in a DS domain.

Next to a certain PHB, a PDB-definition also includes requirements for traffic conditioning at domain edges (cf. Figure 25.7). According to RFC 3086, these should be negotiated in a *Traffic Conditioning Agreement* (TCA). The resulting behavior of the PDB that an aggregate experiences when it enters and crosses a domain should be specified by quantifiable and measurable QoS parameters. The behavior will particularly be defined depending on the defining elements of a PDB, that is, dependent on the appropriate PHB and traffic conditioning mechanisms. However, more factors possibly influencing the service quality of an aggregate must be described, for example, the topology of the domain or the load of a node [23].

The description of the PDB can be made with QoS parameters and service classes, as for example, in the following two examples:

Example 1: *The packet loss rate should not be larger than 0.1%, when measured over an interval that is not greater than T.*

Example 2: *The delay can be specified as follows: 50% of the packets should take no longer than d ms, 30% of the packets no more than 2d ms, and 20% of the packets no longer than 3d ms.*

A further difference between a PDB specification and the definitions of a PHB lies in the explicit consideration of aggregation and de-aggregation effects and their impacts on the behavior of an aggregate within a DS domain. One main goal of a PDB definition is the assurance of quantifiable predictions of an aggregate's behavior within a domain. However, if these predictions can be affected by effects of merging or partitioning aggregates within the domain, then these effects should be described as quantifiably as possible. By repeated consideration of these implications for each hop in a domain, it should be possible to predict the domainwide behavior of an aggregate.

End-to-End Behavior

Since the average TCP connection traverses four to five autonomous systems, a quality-based service will reach over several DS domains (*end-to-end service*). The substantial components for an ISP for the realization of an end-to-end service will be PDBs (cf. Figure 25.7). The quality of an end-to-end service thus

© 2005 by CRC Press LLC

results from the combination of the PDBs on the resulting path from the sending to the receiving end system, presupposing that all these are DS-capable.

For describing a quality-based service, a *Service Level Specification* (SLS) between the service provider and the service user is negotiated. It covers the technical aspects of the service and is part of the Service Level Agreement (SLA), which additionally contains further legal arrangements, for example, noncompliance clauses, etc. The offered QoS behavior of an end-to-end service is described in the SLS. An important component of the SLS is the *Traffic Conditioning Specification* (TCS), in which traffic-conditioning mechanisms are specified.

The traffic profile in the TCS negotiated between the provider and the user specifies the maximum amount of services and QoS characteristics that the customer can use, for example, the allowable throughput, etc. For the case of violations of these agreements appropriate actions will be taken, which are likewise a part of the TCA. For example, if a sender exceeds the negotiated amount of traffic, the traffic conditioning elements become active and the nonconforming packets are treated accordingly (e.g., rejected, delayed, degraded, etc.).

Beyond this, the SLS contains some more general QoS characteristics that also describe — next to the quality-specific characteristics — operational and security characteristics of the end-to-end service [8]. Some examples are listed below:

- Availability and reliability of the service, with special consideration of the consequences a failure of the service would have, for example, when the traffic has to be bypassed on another path.
- Security, for example, encryption, authentication, etc.
- Special restrictions on certain routing paths, for example, due to operational or political reasons.
- Mechanisms for monitoring and verifying a service.
- Responsibilities as well as the consequences of a breach of contract and customer services.
- Accounting and billing.

A SLS usually differs from a PDB definition in terms of the amount of technical details and parameters. In an SLS, usually not all technical details of the concrete PDB implementation will be revealed to the customer. It is assumed that a service provider decides which service specific characteristics he directly offers to his customers in a contract. These characteristics can sometimes differ clearly from those specified in a PDB definition. QoS-specific attributes are often weakened or removed from contracts in order to avoid recourse payments in case of noncompliance.

Service providers can realize arbitrary services and thus are more flexible in reacting to new applications or market developments. It does not require lengthy standardization processes to deploy a new service. This can be realized in a simple manner, especially if an ISP first offers a new service exclusively in his administrative domains.

However, if the considered end systems are in DS domains that are administered by different providers, arrangements and agreements between the operators, along the communication path become necessary. However, the service user should not notice this fact because he requests a service from the service provider he is directly connected to. It is then the responsibility of his service provider to make the appropriate agreements with the next domain toward the customer's communication partner. This procedure continues gradually until the DS domain of the target system is finally reached. If the service can be provided in each concerned domain, an SLS between the customer and the first service provider will be made.

The implementation of the DS architecture in the Internet of tomorrow will proceed gradually. First, a service provider updates the nodes in his administrative domain with the mechanisms of the DiffServ data path, whereby traffic profiles are installed statically, for example, with SNMP. At this time, only services between directly connected DS domains of the same ISP will be possible.

In a further step, static agreements are made with neighboring domains, in order to be able to offer end-to-end services along several domains. If a customer needs QoS support, this still has to be negotiated between the customer and an authorized person of the ISP. Then, the negotiated traffic profile will be installed manually in the appropriate nodes at the right time. The service can be scheduled at certain times of a day or weekdays — nevertheless, the static character of the service administration remains rec-

© 2005 by CRC Press LLC

ognizable, because services cannot be initiated *ad hoc*. Re-negotiations, for example, for necessary adjustments, can be made periodically, in an interval of days, weeks, or months.

The following section surveys the management of services and nodes in DiffServ-enabled networks and presents some efforts for a dynamic establishment of services.

25.6 Management of DS-nodes and -Services

So far, the management of DS domains has not been regarded, that is, the configuration of DS nodes and traffic profiles, as well as the administration of resources, for example, the initiation and processing of reservations, access control, etc. These questions are currently under discussion, and standardization has begun within the IETF [19]. Actually, the DS architecture was developed in such a way that a dynamic management of resources and nodes is not necessary at all. The concept of separating the data path from the control path has already been applied successfully to the Internet routing and was therefore also selected for migration to a quality-based Internet.

The following section illustrates how DS domains will be managed in the beginning, that is, before a dedicated management architecture is introduced. Subsequently, a brief overview regarding promising efforts for a dynamic administration is given.

Static Management

In the DS architecture [8], it is assumed that a service user first contacts the service provider for negotiating an SLA [27]. This SLA should also specify technical parameters, which define the desired service more exactly, for example, which throughput with which kind of service class has to be guaranteed. Before the agreement is given to the traffic contract, the operator examines the validity of the desired QoS support and the availability of the necessary resources. At the beginning, access control and resource administration are performed manually.

If the endpoint of the communication does not lie within the same DS domain, the domain operator must contact the next neighboring domain operator toward the target in order to likewise negotiate a service agreement. This procedure continues until each domain along the whole communication path has reserved the appropriate resources for the desired quality-based service. Before the service is used, the QoS parameters (in terms of a traffic profile) are installed in the appropriate First Hop Router. All arriving packets in the FHR matching this traffic profile will then experience the desired QoS.

All of these mentioned procedures will be carried out manually via appropriate management interfaces in the DS nodes during the introduction phase of DS, for example, with SNMP. In [1], the appropriate administrative data structures — the DS Management Information Base (DS MIB) — have already been specified for this purpose.

However, a manual administration of DS domains is not acceptable for the future, particularly because of inevitably high delays during the installation of a service. In the long term, a static management of QoS services will handicap the acceptance of a quality-supporting Internet. The necessity for a dynamic reservation of resources and an appropriate management of DS domains has already been recognized by the IETF and is currently being discussed in the working group *Next Steps in Signaling* (*NSIS)* [19].

Next Steps in Signaling

The IETF working group NSIS [19] was formed in 2002 to develop a framework for signaling information about a data flow along its path in the network. This is the current effort of the IETF to develop a framework for dynamic reservation of resources, for example, for DS. But the scope of NSIS is not just limited to QoS reservations. It should also support many other applications that have to signal information, for example, in case of mobility.

© 2005 by CRC Press LLC

So far, the working group has just defined a basic framework for signaling protocols [17], which does not seem to be the final solution but clearly shows the direction of a future signaling approach. One main design decision in this framework was to decompose the overall signaling protocol suite into a generic (lower) layer, with separate upper layers for each specific signaling application. The framework also considers general interactions between signaling and other network-layer functions, for example, routing and mobility.

25.7 Summary

The architecture of DS clearly shows as to what has been learned from the experiences of previous QoS approaches and that the right conclusions were drawn for the support of quality-based services in the Internet. Now with the DS architecture, a promising solution can be found for this challenge. The primary goal consisted of developing a scalable QoS architecture that does not pose problems concerning the feasibility and manageability of services and their necessary administrative information, especially with regard to a further constantly growing Internet. With the principle of carrying the state information in the packets, the management of status information per data stream can be avoided in routers.

Despite the missing state information in the network, resources can still be assigned to the data streams by enforcing a strict access and usage control at network edges, especially at the access network. However, the level of accuracy that can be reached and which problems arise with the aggregated treatment of data streams (e.g., aggregation effects) are still the subject of ongoing research.

The DS architecture was developed consciously with the goals of *flexibility* and *extensibility*, that is, it should be possible to offer various services and to flexibly integrate new services. For this reason, no concrete QoS mechanisms are prescribed by the DS architecture to ISPs. DiffServ is only a framework that regulates the interoperability and the specification of quality-based services and their elements (Per-Hop and Per-Domain Behaviors). The concrete realization of the service elements is left to the respective ISP.

26.1 Introduction

This article describes the main features of Multiprotocol Label Switching (MPLS), a standard architecture proposed by the Internet Engineering Task Force that integrates label swapping forwarding with network-layer routing. The role of MPLS in overcoming limitations of overlay models, such as IP over Asynchronous Transfer Mode, and of conventional routing in IP networks, is discussed. The main concepts are introduced and the operation of MPLS is explained — classification of packets into Forward Equivalence Classes, label allocation and binding to routes, label distribution, setting up of Label Switched Paths, and route selection. Finally, support of traffic engineering and Quality of Service mechanisms in MPLS networks is analyzed.

26.2 MPLS — Rationale for a New Routing and Forwarding Architecture

The success of the Internet is mainly due to its flexible architecture, based on IP, the ubiquitous internetworking-layer protocol.

IP networks offer unparalleled scalability and flexibility for the deployment of value-added services and are becoming increasingly attractive for carrying services with hard and soft real-time constraints.

© 2005 by CRC Press LLC

This requires extending the traditional best-effort model, designed from the outset for elastic data traffic, with mechanisms that provide differentiated and predictable Quality of Service (QoS) to a wide variety of applications with different requirements [1]. The Internet Engineering Task Force (IETF) has already specified the Integrated Services (IntServ) [2] and the Differentiated Services (DiffServ) [3] models with these goals in mind.

Carriers' Requirements

With the increasing demand and explosive growth of the Internet, service providers require a dependable and controllable network infrastructure that can offer consistent performance. In many cases, the original router-based backbone networks evolved into a two-level structure composed up of a high-speed core network interconnecting edge devices (IP routers) that in turn interface with access networks and provide common services to users, such as security, accounting, Virtual Private Networks (VPNs), web hosting, etc.

Management of such networks requires powerful traffic engineering techniques, that is, the capability of mapping flows into the physical network topology and evenly distributing traffic over the network links, to achieve an efficient utilization of network resources, avoid congestion, and improve network performance.

Integration of IP and ATM

With the deployment of Asynchronous Transfer Mode (ATM) switches in many carriers' backbones, integrating IP and ATM appeared as a natural and attractive architectural choice to fulfill these goals, since it combined simple and robust routing techniques with a scalable, fast switching technology. Moreover, ATM includes provision for traffic management and differentiated transport services [4], which are essential in satisfying carriers' requirements.

However, this integration was not without problems. Initial solutions were based on overlay models, such as Classical IP over ATM (CLIP) [5], which are easy to deploy but have a number of serious shortcomings [6,7], especially in large networks where IP routers are interconnected by a full mesh of ATM connections, to avoid extra hops in the path across the backbone. In fact, in this architecture, two types of nodes (IP routers and ATM switches) run different signaling and routing protocols, on different address spaces, with the IP logical topology segregated from the ATM physical topology. This is inefficient and does not allow joint optimization of resources. In addition, it poses scalability and stability problems, when the logical topology has to be reconfigured, due to the way routing updates are advertised between adjacent nodes by conventional IP routing protocols.

Multilayer Switching and MPLS

To overcome these limitations, alternative architectures, based on the concept of multilayer switching, were investigated and proposed by manufacturers. Two such examples are IP Switching [8] and Tag Switching [9]; but, in general, these solutions share a common principle — the separation of control and forwarding functions. The software-based control component includes layer three routing and additional signaling protocols, while the hardware-based forwarding component uses layer two label switching techniques. A mapping between routes and labels provides the glue between these components, required to build a multilayer switch.

The concept is not restricted to IP and ATM, but when the forwarding component is based on ATM, only the ATM switching fabric is retained (not the ATM-based control protocols).

In this context, the MPLS architecture [10] is the result of the current IETF work to standardize a solution that integrates label swapping forwarding with network layer routing, and that incorporates the basic principles and ideas proposed by manufacturers. Initial efforts are focused on IP, while ATM is a strong but not the unique choice for switching.

MPLS tries to solve most of the critical issues previously identified, with particular emphasis on scalability, fast packet forwarding, and traffic engineering [11]. Although not dealing with specific QoS

© 2005 by CRC Press LLC

mechanisms (such as call admission, traffic shaping and policing, packet scheduling, and discard policies), MPLS provides an appropriate framework for supporting a QoS architecture as well.

26.3 Analysis of Traditional Packet Switching Techniques

In order to better understand how MPLS is built upon and extends the capabilities of existing technologies, it is useful to briefly review traditional connectionless and connection-oriented packet switching techniques.

In conventional IP networks, which operate in a connectionless (datagram) mode, packets are forwarded on a hop-by-hop basis, and each router along the path makes an independent forwarding decision. The next hop for a packet is selected based on the IP destination address and on forwarding information updated by means of routing protocols. The routing (forwarding) table is parsed in search of some address prefix that is the longest match for the packet's destination address.

This approach has a number of limitations, especially when we consider the role that IP networks are expected to play in the coming years.

First, forwarding decisions in each node are only based on information that travels with the packet in its header. Conversely, the packet header is not fully utilized, although it contains much more information than required to simply select the next hop.

Second, packets are typically forwarded along a shortest path route to the destination, usually discovered by routing protocols that use an additive link metric (hop count); the consequence is that paths to a common egress router form a tree rooted at the destination. With heavy loads, links on a shortest path tree may become congested, while others remain underutilized due to uneven traffic distribution. This approach does not exploit alternate paths either to reroute traffic around congested nodes, to perform load balancing, or to support dynamic fall over to backup paths. Although it would be possible to redirect traffic by changing link metrics (based, e.g., on traffic characteristics and capacity constraints), this may lead to undesirable effects, such as changing the path of all packets that traverse congested links. In other words, traffic engineering has not been exploited in IP networks [6,7]. Moreover, destination-based forwarding, as used today in IP networks, seriously limits the network services that can be offered, since it does not allow provisioning paths specific to particular sources or services or with a QoS constraint.

Finally, processing the IP header, which includes looking up the routing table, decrementing the Time To Live (TTL) value, and computing a new Cyclic Redundancy Check (CRC), is computationally more intensive and takes more time than processing a label and using it as an index into the forwarding table. Nevertheless, state-of-the-art gigabit routers use optimized algorithms to speed up the IP header processing in hardware.

On the other hand, connection-oriented packet switching is based on the setup of virtual channel connections (virtual circuits) by means of signaling procedures, before data transfer takes place. Packets on a virtual circuit are forwarded along a fixed path, defined at setup; the virtual circuit is identified by a short label in the packet headers. In ATM, the label is structured into two parts and carries a Virtual Path/Virtual Channel Identifier (VPI/VCI), while in Frame Relay the label is a Data Link Connection Identifier (DLCI).

26.4 MPLS Operation

MPLS overcomes the problems found in conventional IP networks as well as the limitations of overlay models by combining traditional IP routing with a label swapping technique, implemented by separate control and forwarding components. Control functions are responsible for building and maintaining routing tables; routing information is used to create the forwarding tables that define how packets are switched and labels are swapped at each node. Figure 26.1 is a simplified representation of this model.

Forward Equivalence Class

An MPLS label is a short, fixed-length identifier, with local significance, used to identify a Forwarding Equivalence Class (FEC). An FEC simply represents a group of IP packets that are forwarded in the same

© 2005 by CRC Press LLC

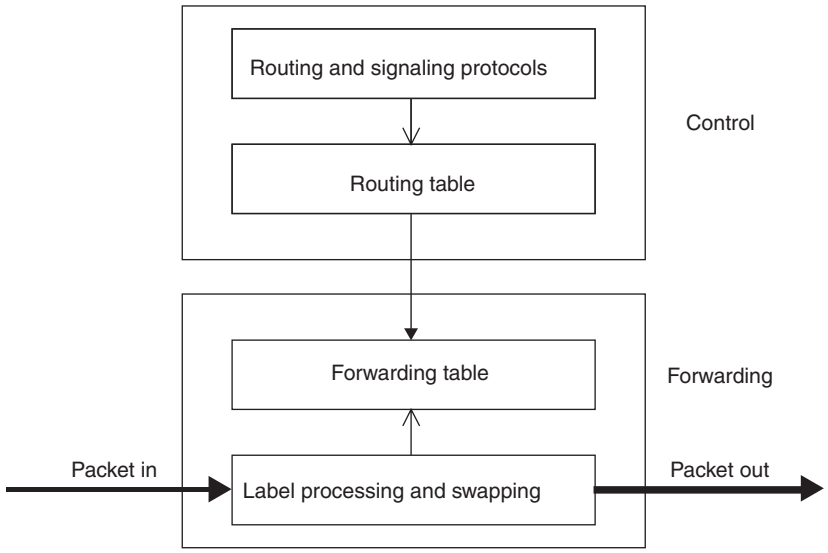

FIGURE 26.1 Mapping between routing and forwarding tables.

manner, that is, over the same path and receiving the same forwarding treatment, since they have similar transport requirements.

The assignment of a packet to an FEC is done just once, at the ingress node of an MPLS domain, where the packet is classified. It is possible to use a variety of forwarding criteria to assign packets to FECs, besides the conventional address prefix used in destination-based routing, such as: Classes of Service (based, for instance, in fields of IPv4 or IPv6 packet headers), Application flows (requiring both source and destination addresses as well as other Network or Transport layer information), IP multicast groups, explicit routing, and VPNs.

An FEC is encoded with a label, which travels with the packet that becomes a "labeled packet." The label may reside in an encapsulation header added for this purpose or may be carried on a layer two header that natively supports labels, such as in ATM or Frame Relay.

Label Switched Paths and Label Switching Routers

Packets in a particular FEC follow a common path through one or more MPLS nodes. This is called a Label Switched Path (LSP), which is defined by the set of labels associated to an FEC at each hop. The forwarding decision taken by each node is simply based on the incoming label, which is used as an index in a table that specifies the next hop and the outgoing label, which is inserted in place of the incoming label (label swapping). An LSP must be set up and labels must be assigned at each hop before traffic can be forwarded.

This is similar to conventional virtual circuit switching, but differs in the way the forwarding tables are created and maintained. We may also say, by analogy, that in hop-by-hop routing an FEC represents a common destination address prefix for a group of packets; but each node makes an independent FEC assignment.

Using LSPs, MPLS can provide many of the advantages of connection-oriented networks, while retaining the simplicity of datagram networks.

MPLS nodes are called Label Switching Routers (LSR); but it is usual to refer to the edge (ingress or egress) nodes as Label Edge Routers (LER). All nodes are aware of MPLS control protocols, run the same layer three routing protocols, and forward packets based on label processing and swapping at wire speed. In addition, an LER performs some specific and more processing-intensive functions, such as interfacing external networks and, in the case of the ingress LER, classifying packets into FECs, assigning the

© 2005 by CRC Press LLC

corresponding labels and adding them to the original packet. Therefore, in MPLS, a single family of devices runs the same set of protocols over a common physical and logical topology shared by all nodes, unlike architectures based on the overlay model.

Figure 26.2 shows an LSP and the basic operations performed on a packet. The ingress LER adds a label to the packet, while the egress LER removes it; labels are assigned independently on each hop and are swapped as the packet moves along the LSP.

Label Assignment and Distribution

A key issue in MPLS is the binding between labels (which represent an FEC) and a route. Three steps are required: allocating a label, binding it to a route (LSP), and distributing label binding information among LSRs.

IETF has standardized a new signaling protocol, called Label Distribution Protocol (LDP) [12], for the setup and maintenance of LSPs. It allows the distribution of label binding information between LSRs, thus ensuring that adjacent nodes share a common FEC to label binding, and allowing the creation of LSPs. The forwarding table (label information base) is constructed as a result of label distribution.

Label assignment and route selection are therefore required to set up an LSP. But when should labels be assigned and bound to routes (FECs), and how are routes discovered or selected?

The need for label creation and binding may be driven by data or control traffic. In the data-driven strategy, the arrival of data at a node triggers the process. In the control-driven approach, two methods may be adopted, depending on the route selection scheme: labels are assigned once routes are discovered by conventional routing protocols (topology-based) or in response to request-based control traffic, such as Reservation Protocol (RSVP) [13] messages. Control-driven methods are preferred due to their better scalability properties.

Label Stack and Hierarchical Routing

In the previous description, it was considered that an IP packet is encapsulated with a single label. However, MPLS supports a more general mechanism, in which a labeled packet can carry a number of labels organized in a last-in, first-out manner. This is called a label stack.

The use of a label stack allows hierarchical routing, with different levels of granularity, possibly across various domains. Label swapping is always based on the current top level of the stack and adding or removing a label corresponds to normal push-and-pop operations on the stack. It is also possible to create LSP tunnels that can nest to any depth; one possible application is for the provision of MPLS-based VPNs.

Label Encoding

MPLS does not rely on a specific layer two technology. The only requirement is that LSRs are able to exchange labeled packets across data links.

The IETF defined a general encoding technique that must be supported by LSRs to produce labeled packets before they are transmitted on a data link [14]. It assumes a label stack and is particularly targeted at data links that do not support labels, such as Point-to-Point Protocol (PPP) or LAN media, although it may be used in Frame Relay or ATM-based LSRs.

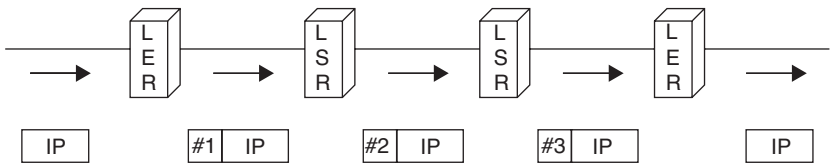

FIGURE 26.2 Label insertion, swapping, and removal.

A label stack is represented as a sequence of label stack entries. An entry is four octets long and includes four fields:

- Label: Label value (20 bits),
- Exp: Experimental use (3 bits),
- S: Bottom of Stack (1 bit),
- TTL: Time To Live (8 bits).

A possible use of the Exp field is as a Class of Service (CoS) identifier.

In PPP and LAN data links, the label stack entries are inserted between layer two and layer three headers, as illustrated in Figure 26.3, and constitute what is usually called a shim header.

In ATM-based LSRs, the top label is directly encoded into the VCI and/or VPI field [15]. In general, when a label stack has to be carried, the label stack entries for a particular packet are carried as a shim header in the ATM Adaptation Layer (AAL 5) frame; the actual value of the top label is encoded in the VPI/VCI field of the ATM cells, and the label value of the top entry in the shim is set to zero.

Route Selection

There are two alternatives to select a route used to set up the LSP for a particular FEC.

The first one is based on hop-by-hop routing; each LSR independently determines the next hop for the LSP based on its IP forwarding table, which is built by traditional IP routing protocols. This is the default, topology-based method and allows the discovery of shortest path routes; a hop-by-hop LSP follows the path that a packet using conventional routing would have used.

The second one is based on explicit routing, which is similar to source routing. In an explicitly routed LSP (ER-LSP), the route for the path is explicitly defined by a single LSR (usually the ingress or egress node) and may include all or only a subset of the LSRs in the path (strict or loose LSP). The route (sequence of LSRs) may be selected by configuration or dynamically and is conveyed in a control message that traverses all nodes along the specified route.

A shortest path tree built by hop-by-hop routing and a single ER-LSP, overlaid on a physical network topology, are represented in Figure 26.4.

26.5 Traffic Engineering and QoS in MPLS Networks

An ER-LSP may be defined and controlled by the network operator or a network management application. Based on administrative or QoS policies or traffic engineering requirements, some traffic can be forced into a path different from the shortest path computed by a routing protocol.

Two approaches have been considered to control (establish, terminate, re-route) ER-LSPs: extending the capabilities of the Label Distribution Protocol to include explicit paths via Constraint-based Routed Label Distribution Protocol (CR-LDP) [16] and extensions to RSVP (MPLS-RSVP) [17]. At an abstract level, the functions of CR-LDP and MPLS-RSVP are rather similar. They both allow an LSR to trigger and control the establishment of an LSP between itself and a remote LER, to strictly or loosely specify the route to be taken by the LSP, and to specify queuing and scheduling parameters to be associated with this LSP at every hop. The relative advantages and disadvantages of these two schemes can be found in [18];

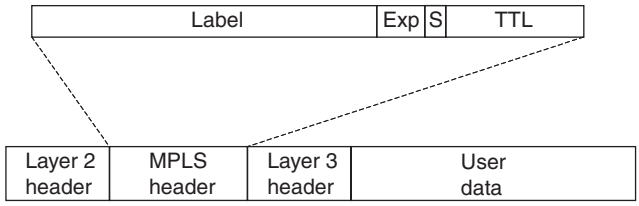

FIGURE 26.3 MPLS header and encapsulation.

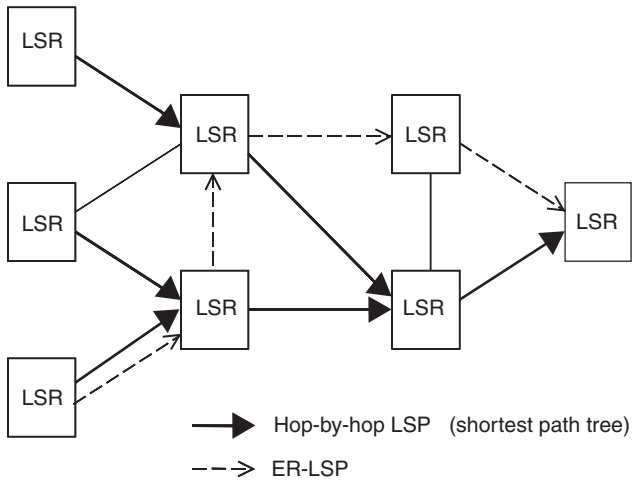

FIGURE 26.4 Hop-by-hop and Explicitly Routed LSPs.

but manageable traffic engineering and QoS control cannot be realized unless one of these protocols is deployed.

By allowing the network to explicitly route an LSP, both traffic engineering techniques [6,7] and provisioning of differentiated services can be supported in an MPLS domain.

Constraint-based Routing and QoS

Explicit routing is a particular case of constraint-based routing, where the constraint is the explicit path. In general, constraint-based routing may take into account link characteristics, such as bandwidth or delay, hop count, or QoS parameters.

MPLS allows setting up explicit paths and forwarding traffic on them; but it does not provide the means to find out paths with constraints. Because MPLS allows traffic engineering and explicit routing, there is keen interest in QoS routing for selecting routes subject to QoS requirements and other policies, instead of the least cost or shortest path route found by traditional routing protocols.

In order to allow the computation of routes with constraints, it is necessary to extend the Interior Gateway Protocols to carry additional information about links that can include, for example, maximum link bandwidth, maximum reservable bandwidth, current bandwidth reservation at different priority levels, default traffic engineering metric, or other attributes used for policy-based routing. Constraint-based routing is just one of the issues being considered by the IETF in the context of Internet Traffic Engineering [19].

MPLS and Differentiated Services

In a DiffServ domain, all packets requiring the same behavior constitute a Behavior Aggregate (BA). At the ingress node of a DiffServ domain, packets are classified and marked with a DiffServ Code Point (DSCP) corresponding to their BA. The DSCP is used in each node visited by the packet to select the Per Hop Behavior (PHB) that determines the treatment it will receive (scheduling, drop precedence, etc.).

MPLS support of Differentiated Services has already been addressed by the IETF [20] and several alternative solutions were considered for mapping BAs onto LSPs. The simplest one consists in using a single LSP to support up to eight BAs of a given FEC. In this case, the Exp field of the MPLS shim header is used by each LSR to determine the PHB to be applied to the packet.

One promising solution for QoS provisioning in IP networks, using currently available IETF standards, consists in combining MPLS with differentiated services and constraint-based routing.

© 2005 by CRC Press LLC

26.6 Conclusions

It is commonly accepted that MPLS offers many advantages over earlier network solutions, as a carrier infrastructure capable of service integration and differentiation. However, some of these advantages are not exclusive of MPLS; on the other hand, MPLS must be combined with other mechanisms, such as QoS, to make use of its features.

Therefore, when evaluating the merits of MPLS, it is useful to adopt a critical view [21], especially when considering competitive solutions, such as gigabit routers, which also promise high throughput and fast switching, as well as traffic and QoS differentiation.

Nevertheless, there are some strong arguments in favor of MPLS. In general, MPLS offers a unique combination of some attractive properties:

- scalability, in terms of number of nodes and traffic flows;
- flexibility, since it is not tied to a single forwarding technology;
- simple and fast label forwarding, which improves network performance; and
- capability to support traffic-engineered paths and service differentiation, essential for QoS provisioning.

Properties like scalability and traffic engineering are especially valuable, when considering short-term deployment of MPLS. This allows offering an efficient transit core network (with high throughput and low latency), improved economy of scale, new services (such as CoS-based forwarding and VPNs), and the ability for fast restoration of data traffic.

Another important issue, in view of the investment many carriers have recently made in ATM equipment, is the possibility of leveraging the installed ATM infrastructure — either using ATM-based LSRs or running MPLS over ATM (overlay model); in the second case, MPLS LSRs communicate over an ATM cloud.

On the other hand, the MPLS paradigm can be extended into the optical domain, by leveraging existing control plane techniques to control optical cross-connects and using wavelengths in place of numerical labels; this is usually called Multiprotocol Lambda Switching (MPλS) [22]. An even more general approach is emerging; the IETF is currently specifying a Generalized Multiprotocol Label Switching (GMPLS) architecture [23] that extends MPLS to include multiple switching dimensions: time (packet and circuit), wavelength (lambda), and spatial (fibre or port) switching. The focus of GMPLS is therefore on a multipurpose control plane architecture that can be applied to a variety of data forwarding techniques, thus requiring further enhancements to existing signaling and routing protocols [24,25].

Although MPLS has been targeted at WAN environments, it can be used in LANs as well. In this case it is an alternative to solutions based on conventional layer two LAN switches and multilayer switches (or router switches) or to ATM LANs based on overlay models, such as LAN Emulation (LANE) and Multiprotocol over ATM (MPOA).

When considering the deployment of MPLS in the Internet, it is necessary to take into account the profound consequences at the architectural level. It changes the basic forwarding model, which has remained essentially unaltered since the early days of the ARPANET. It also impacts the routing architecture, requiring that routing protocols perform new and more complex tasks.

Short-term applications are likely to be within a single network administrative domain; over time, interdomain MPLS is likely to occur, with transit carriers providing services to local or national Internet Service Providers.

The long-term evolution is still unclear. In order to fully exploit the benefits of MPLS (or GMPLS in a broader sense), some open issues still need to be answered and are subjects of intense research. In particular, it is necessary to specify, test, and validate, in operational conditions, the criteria and mechanisms for selecting routes and dynamically establishing paths according to traffic engineering or QoS policies, as well as managing their QoS characteristics.

27.1 Introduction

The Internet is a "best-effort" packet-switched network. It comprises a fundamental trade-off: on the one hand, the bandwidth usage is very efficient using statistical multiplexing of packets on a physical link. Additionally, the network layer protocol (IP) can be easily run on top of several different link layers, because it imposes no requirements for the ability of the link layer to deliver a packet within a certain amount of time or even at all. On the other hand, the properties just pointed out (which were an essential part to make the Internet such a success) make it very difficult to guarantee any type of "Quality of Service" (QoS) to particular packets or flows of packets. Network Quality-of-Service (cf. Chapter 14) means allocating resources (buffers and bandwidth) at the network elements for packets, which match certain criteria resulting in a predictable network performance. This yields a predictable quality at the service level and finally at the level of human perception. Such a predictable quality is particularly needed to meet the requirements of real-time applications like voice and video conferencing.

Several different approaches to enable QoS have been developed in recent years. An approach to QoS always has to be analyzed from two aspects: the achievable quality vs. the overhead (eventually: the costs) imposed by the respective approach. Figure 27.1 shows a taxonomy giving a qualitative classification of the necessary overhead in terms of additional processing and bandwidth consumed at end systems, and network overhead (protocol overhead in terms of operation and deployment and state that has to be maintained).

The schemes designated as "end-to-end" typically do not involve the network at all, but rely on robust end system-based protocols and mechanisms. In contrast, the hop-by-hop approaches require network participation at different levels, thus generally achieving better end-to-end delay properties and lossless service (note the shadings in the figure). Clearly, the associated overhead of both types of approaches

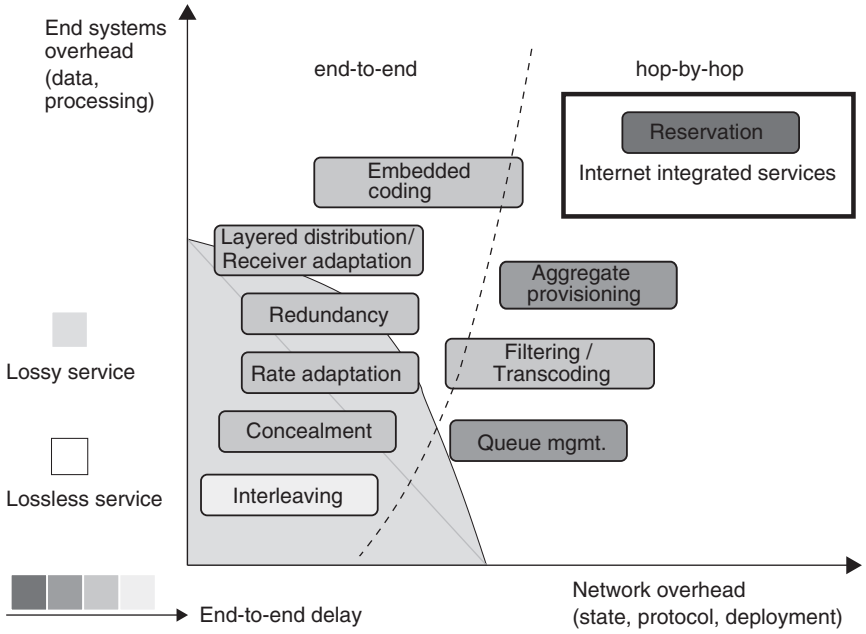

FIGURE 27.1 Qualitative classification of QoS schemes for real-time applications.

influences the scalability and thus the feasibility of deployment. The following categories of QoS-enhancement schemes can be distinguished:

- *Loss alleviation*:
  - interleaving (reordering the sequence of the application data units to spread the potential loss impact),
  - concealment (using audio/video signal processing to conceal the impact of losses at a perceptual level).
- *Loss reconstruction*:
  - redundancy (adding redundancy proactively to the data stream to be able to repair losses at the receiver).
- *Loss avoidance at the application level* (cf. Chapter 22):
  - sender rate adaptation (adapting the transmission rate to the currently achievable throughput in the network),
  - layered distribution/receiver adaptation (splitting the data stream into multiple substreams, which are then selectively subscribed to by a receiver dependent on the (sub-)path properties to this particular receiver; in "embedded coding," the source coding scheme is optimized towards the splitting into substreams),
  - filtering/transcoding (within the network, the transmission rate of the data stream is adapted by exploiting know-how about the particular source coding scheme).
- *Loss avoidance at the network level* (including guarantees on the delay):
  - queue management (optimizing the behavior of individual queues under congestion),
  - aggregate provisioning/per-packet prioritization (cf. Chapter 25) and reservation (explicitly allocating network resources for individual data streams on the entire end-to-end path).

27.2 The Integrated Services Architecture

Integrated Services/RSVP belong to the "reservation" category, which constitutes the "high end" solution to the QoS problem in that real QoS *guarantees* can be provided (Figure 27.1). While reservation is not a new idea in networking, the challenge for the Integrated Services/RSVP is the integration of the necessary mechanisms and protocols into the existing Internet architecture. This implies that the described "best-

© 2005 by CRC Press LLC

effort" datagram model should be preserved while enabling resource reservation, particularly for real-time applications. Resource reservation in the Integrated Services model means service differentiation on a per-flow basis, which is accomplished by providing mechanisms to isolate flows from each other, to establish rate and delay guarantees, and to provide controlled sharing of excess bandwidth [14]. Flows are described by their traffic envelope using token and leaky buckets. If flows violate their contracted traffic profile, packets are delayed, discarded, or treated as best effort.

Figure 27.2 shows the Internet protocol architecture needed to support real-time applications. It consists of protocols that provide basic transport functionality (RTP — Real-Time Transport Protocol, cf. Chapter 28), QoS feedback (RTCP — Real-Time Transport Control Protocol, cf. Chapter 28), call-setup signaling (ITU-T H.323 and SIP — Session Initiation Protocol), and QoS signaling (RSVP — Resource Reservation Protocol). In addition to these protocols (a part of which are relevant to QoS), the enforcement of the QoS on the data flows that pass through a router (or which are emitted from a host) is necessary (Figure 27.2: layer 2/3 adaptation). For QoS-passive media, that is, where the link layer does not implement any QoS control mechanisms, the enforcement is realized by a *traffic control* entity that is typically located between IP and the network device driver on an outgoing interface. For complex link layers like ATM, these mechanisms need to either be mapped on or replaced by the respective means available within the link layer (e.g., in [15] this is described for ATM (cell switching) as a link layer using ATM and IP signaling, respectively).

The functional blocks (Figure 27.3), which are required *at every individual hop along the end-to-end path* to establish the QoS guarantees, can be described as follows:

QoS signaling — registration of senders and receivers: The senders advertise the traffic specifications of their traffic flows. Receivers then use this information to request the desired QoS. The signaling in the Integrated Services architecture is realized by the RSVP, which is treated in more detail in the next section.

Policy Admission Control — admission of reservation requests in terms of administrative regulation: The policy admission control interfaces on one side to the other Integrated Services components (QoS signaling, Capacity Admission Control) and on the other side to the policy infrastructure. The policy infrastructure is a set of protocols, information models, and services that allow administrative intentions to be translated into differential treatment of flows (using, e.g., the Integrated Services architecture and RSVP). It gives the network operator the opportunity to regulate which users/applications/hosts should have access to what resources/services under what conditions. The architecture of the policy system (within one domain) consists of the following three tiers:

1. *Policy enforcement points (PEP)*: The network elements where packets are identified and treated and thus policies must be enforced. The PEP is, for example, colocated with the traffic control module.
2. *Policy decision points (PDP)*: The components responsible for determining what actions are applicable to which packets. A PDP interprets policy rules for one or more PEPs based on information

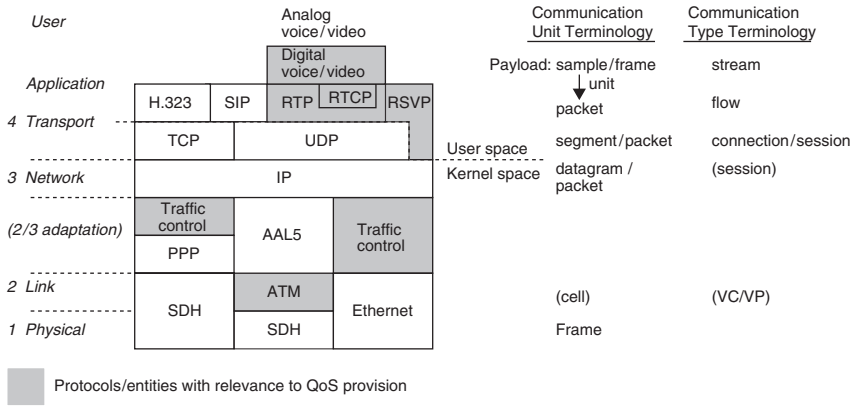

FIGURE 27.2 Integrated Services-enhanced Internet protocol architecture.

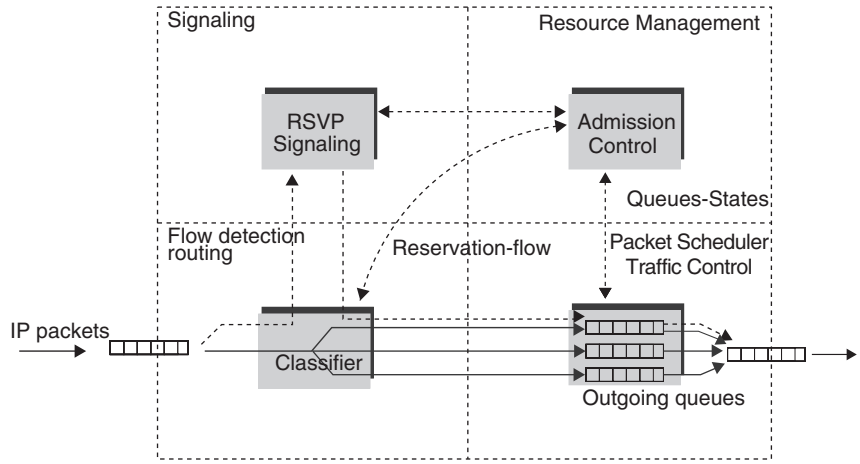

FIGURE 27.3 Functional blocks of a network element in the Integrated Services model.

contained in data and signaling packets, information of current network conditions, account balances, etc.

3. *Policy repository*: The location where the domain policies are stored.

RSVP is able to carry and process "policy objects" together with the conventional reservation requests and responses (see below). These objects may identify and authenticate users, define the relative priorities for reservations, carry accounting and charging information, and much more.

Capacity Admission Control — admission of reservation requests in terms of available resources: Besides global (network domainwide) and local policy constraints, the resource usage at a particular network element needs to be taken into account when admitting reservation requests. A Capacity Admission Control algorithm could use either only the maintained state about the already admitted reservations or it can take into account the actual resource usage (Measurement-Based Admission Control). Another design dimension is if only the current reservation requests/usage is monitored or if future states are taken into account (resource reservation in advance).

Classifier — identification of the association of IP datagrams to flows: The IP layer constitutes a multiplexing layer for packets coming from various network interfaces (at a router) or various local UDP/TCP sockets (at a host). After the routing decision has been taken and the packets are demultiplexed to the correct outgoing interface, it is necessary to associate the packets to the respective flows (or the "best effort'" class) to be able to schedule the departure of the packets over the network interface correctly. For IPv4, the classification is done by matching a packet's IPv4 source and destination address, the protocol ID, as well as the transport layer ports against the parameters obtained via the QoS signaling protocol.

Packet Scheduler — schedules the order in which the queues (to which the packets have been associated by the classifier) are served: A "best-effort" packet-switched network implements simple First-Come-First Served (FCFS) scheduling. To support the Integrated Services' service classes (see below), advanced scheduling algorithms are necessary. The most well-known scheduling algorithm is probably Weighted Fair Queuing (WFQ). Packet scheduling algorithms typically perform two major tasks:

1. *Isolation*: A scheduler needs to assure that all QoS requirements that have been communicated for individual flows are met. Of course, this dynamic process in the data path needs to go hand-in-hand with the static control of the resource allocations in the control path (Capacity Admission Control, see above). Even in the worst case when all reserved flows fully exploit their reserved resources and the network element might be overloaded by additional best effort traffic, packets of an individual flow need to be given access to the link by the scheduler to just meet the QoS requirements of that flow.

© 2005 by CRC Press LLC

2. *Sharing*: While providing isolation of flows (to mimic the performance for reserved flows achievable in a circuit-switched network, which provides inherently full isolation), the key advantage of statistical multiplexing in a packet-switched network must be retained. This implies that bandwidth, which has been allocated to reserved flows but which is temporarily not used by those flows, should be available to other reserved and "best-effort" flows. An additional requirement that may be imposed is to distribute this "excess bandwidth" fairly between these competing flows. Note that there is no universally applicable definition of fairness that could be enforced.

Service Classes

To request resource reservations to the network, *invocation information* needs to be supplied to the network. This information consists of a Traffic Specification (TSpec) of a flow and a Reservation Specification (RSpec) to describe the service required by the flow at every hop inside the network. Together, TSpec and RSpec are called Flow Specification (FlowSpec).

The TSpec describes the traffic profile of a flow. The conceptual model underlying the traffic specification (and the corresponding shaping/policing operations at the edge and inside the network) is a sequence of a token bucket and a leaky bucket with the following parameters:

- Token bucket rate r (bytes/sec): Arrival rate of tokens at the bucket.
- Token bucket depth b (bytes): Number of tokens the bucket can contain. The bucket depth translates to the length of data bursts (back-to-back bytes/packets) that can be emitted.
- Leaky bucket rate p (bytes/sec): The maximum rate at which bytes leave the leaky bucket. The leaky bucket constitutes a peak rate limiter, that is, that back-to-back bursts of data (see bucket depth b above) do not leave the shaper at an infinite rate but rather at the rate p.
- Minimum policed unit m (bytes): This variable constitutes the lower bound of the allowed packetization granularity, that is, every packet that is smaller than m bytes will be counted as consuming m bytes.
- Maximum packet size M (bytes): The maximum packet size that can be handled.

The Integrated Services model comprises two service classes: Guaranteed Service and Controlled Load Service.

Guaranteed Service (GS, [2]): This service, which has been standardized in the IETF, is intended for nonadaptive flows that need a strict delay bound (e.g., distributed simulation tools, distributed games, and hard real-time systems). The end-to-end behavior of a path that supports the GS can be seen as a virtual circuit with a guaranteed bandwidth allocation and guaranteed delay properties. GS does not control minimal or average delay, but the *maximum queuing delay*. Additional delays that arise are the propagation delay on the medium and the delay to police/shape the traffic to the profile communicated in the TSpec (the GS expects the traffic to be conforming to the profile; otherwise packets need to be delayed or dropped to make the flow conformant).

The GS RSpec consists of the following parameters:

Service rate R (bytes/sec): The rate at which the network needs to service the flow.
Slack term S (sec): The extra amount of delay that nodes inside the network may add while still meeting the end-to-end delay bound (this is further explained below).

The service provided is similar to those provided on a dedicated circuit with bandwidth R between the source and the destination. Using the T- and RSpec parameters, the worst-case end-to-end queuing delay for a flow can be computed. For $p \to \infty$ and $R \geq r$ (i.e., that a burst of packets is emitted back-to-back with infinite rate and the reserved rate is larger or equal to the source rate, which needs to be a valid condition to fulfill the reservation at all), we can express the end-to-end worst-case queuing delay as b/R. This means that the queuing delay depends only on the token bucket depth and the service rate. Considering that the data burst of size b is arriving instantaneously to be served, the queue size is b. Therefore, the last

© 2005 by CRC Press LLC

byte in the burst is experiencing a delay of b/R until it is received at the sink (note that we have no notion of a packet in this model; therefore, it is called the "fluid flow" model).

If the peak rate is closer to the values of R and r, the worst-case delay is lowered because the arrival of the data burst is spread over a larger time interval where, until the last byte of the burst is serviced, already some data have been transmitted. In this case, the end-to-end worst case queuing delay is (for $p > R \geq r$):

$$\frac{b(p-R)}{R(p-r)}$$

If the peak rate p is smaller than the service rate R, there will be no queue buildup, as the network can deplete the queue faster than the source is transmitting. If $r > R$, however, there is a constant queue buildup and the queuing delay becomes unbounded.

In contrast to the "fluid flow" model, in a real network the service a flow receives is worse than in the idealized model of a dedicated circuit directly connecting the sender to the receiver. Two error terms have been introduced to express the deviation of the GS from the idealized model.

The error term C (measured in bytes) is dependent on the transmission rate and the packet length and represents the deviation due to the packetization and the therefore necessary store-and-forward operation. An intermediate node needs to receive the complete packet until it is able to forward the packet to the next hop.

D (measured in seconds) is the rate-independent error term, which is usually determined at configuration time. Components of D are per-packet processing delays at a node, for example, to perform a route lookup.

The sums of C and D over an end-to-end path are designated as C_{tot} and D_{tot}. These values are exported over the service interface to applications to support a realistic choice of the desired end-to-end delay. Partial sums of C and D for the delay until an interior node on the path is reached are maintained as reservation state.

When the packetized nature and the error terms are reflected in the model, the end-to-end worst-case queuing delay is computed as follows (cf. Figure 27.4):

$$p > R \geq r: \frac{(b-M)(p-R)}{R(p-r)} + \frac{M+C_{tot}}{R} + D_{tot}$$

$$R \geq p \geq r: \frac{M+C_{tot}}{R} + D_{tot}$$

When the delay-bound requested D_{req} is larger than the *maximum* delay D_{max} in the fluid flow system, a delay budget $S = D_{req} - D_{max}$ can be computed, which may be used to reduce the resource allocations at certain nodes with the network. D_{max} can be computed as follows (note that here the error terms are

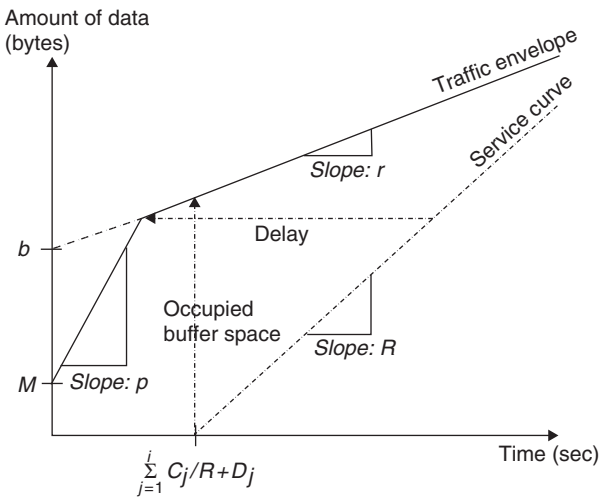

FIGURE 27.4 Delay and buffer calculation for a flow characterized by a (b,r,p,M) traffic envelope serviced with rate R (cf. [14]).

© 2005 by CRC Press LLC

considered and the service rate R is replaced with the flow's rate r): $D_{max} = b/r + C_{tot} / r + D_{tot}$. S is the second parameter in the RSpec (see above) called "slack."

With the GS, it is possible to achieve a mathematically provable bound on the delay and no (congestion-induced) packet losses. A key element of GS is the information exchange at every network element to update the "error terms" for the delay computation, which on the one hand enables to achieve a minimal delay characteristic but also makes it feasible to exploit differences between the desired delay and the minimal delay (slack term) on the other.

Controlled Load Service (CLS, [3]): While the Guaranteed Service comes close to the optimal performance feasible within a packet-switched network, it requires considerable overhead within the network and reserves resources in a conservative way (considering the worst case). Particularly for bursty traffic sources, this will lead to a reduced overall network utilization and high costs for the customer reserving resources. In addition, the exact requirements with regard to the burstiness/delay requirements of a flow are often not known in advance and are therefore difficult to communicate to the network. For many (if not the majority of) applications, a service model with less tight guarantees incurring lower costs is needed. The Controlled Load service, which has also been standardized in the IETF, aims at filling the gap between "best-effort" and a high-end service like the Guaranteed Service by providing a "better-than-best-effort" service. CLS specifies that the behavior of the service should approximate the behavior in a lightly loaded network. This implies that the mean loss seen over time intervals, which are large compared to the flow's burst intervals, should approximate the link error rate, that is, virtually no congestion losses should occur. However, no quantitative commitment about the expected end-to-end delay is made. It is only specified that the delays over time scales significantly larger than the flow's burst intervals should be low on average. These characteristics fit well with adaptive applications, which exhibit some tolerance to losses and delays but need at least some statistical QoS assurance. The CLS is invoked using the TSpec definition introduced above.

27.3 RSVP

If an application wants to receive preferential treatment for its packets, it needs to set up a reservation along the path before it starts to transmit. This requires an additional protocol to be added to the existing TCP/IP protocol suite (Figure 27.2). The protocol developed by the IETF for this purpose is called RSVP [7,10]. The RSVP protocol is employed by hosts to communicate service requirements to the network and to routers to exchange (and subsequently establish) reservation state along the path.

Basic Properties/Design Choices

Uni-directional reservation: RSVP establishes a reservation in only one direction (simplex). Although communicating applications may each act as both sender and receiver, logically the reservation from host A to host B is distinct from the reservation in the opposite direction (B to A). Thus, in this two-way communication scenario, two reservations have to be established.

Receiver orientation: Particularly to support multicast communications (implying large multicast groups, heterogeneous receivers, and dynamic group membership, cf. Chapter 21), the receiver initiates the resource reservation and decides on the amount of resources to be reserved. In a multicast scenario, the reservations travel "upstream" toward the sender, building up a reservation tree that corresponds to (a subset of) the multicast tree.

Soft state: RSVP applies the "soft state" approach to maintain reservations inside the network. "Soft state" means that a timer is associated with the respective state blocks. When this timer expires, the state is automatically deleted. Triggered by the RSVP entity of the host on which the reservation has been requested by the application, the RSVP protocol periodically refreshes the reservation state to allow for continuously maintaining the reservation along the entire path. This allows RSVP to cope with host failures/crashes (where the application cannot communicate that certain resources are not needed any more) and to adapt to changing network topologies (e.g., link outages followed by re-routing) as well changing group membership in the multicast case.

© 2005 by CRC Press LLC

Reservation styles: RSVP provides different styles of reservation, which express how a reservation should be treated. Again, this is of particular importance only for a multicast session. Reservation styles can be used to share a reservation among flows from all senders contributing to a session (Wildcard Filter (WF) style) or to select a specific sender within the shared reservation (Shared Explicit Filter (SE) style). If there is a one-to-one mapping between the sender and the receiver (in either a uni- or multicast session), the reservation style is called Fixed Filter (FF).

Independence of particular policy and traffic control mechanisms: RSVP can be considered to be a general signaling protocol to distribute and maintain state within a network. The data, which are carried in the RSVP messages, are opaque for the RSVP entities. These data are passed over the respective interfaces of the RSVP implementation (cf. Figure 27.3) to other entities for processing. Such an entity is, for example, the Admission Control module, which decides based on the transmitted control data if a reservation request can be granted or not.

RSVP Operation

Figure 27.5 shows the basic mode of operation of RSVP. In RSVP, there are two basic categories of messages: PATH and RESV (reservation) messages. PATH messages are sent from senders toward the receivers ("downstream"). They convey much information: to receivers, they distribute the properties of the sender's flow; they also collect and distribute hop-by-hop characteristics of the path taken. Finally, the PATH messages trigger the establishment of state along the path (and provide the necessary parameters), which can then be used by the RESV messages to actually set up a reservation.

The RESV messages travel "upstream" (from receivers toward the senders). They convey the resource requirements of the receivers (which are based on the state information received with the PATH messages) and actually trigger the installation of reservations on the network interfaces. (Note that the installation/enforcement of the reservation is then again "downstream" — in the direction from the sender toward the receiver.) When the sender has finally received an RESV message, it knows that the reservation has now been established on the end-to-end path and can now transmit data, which are protected within the network.

The path of the PATH messages is determined by the IP unicast and multicast routing protocols (an RSVP implementation has an interface to retrieve the necessary routing information). As paths may be asymmetric (which means that the downstream and upstream paths found by the IP routing may be different), the RESV messages rely on established PATH state information rather than the routing information to follow the exact reverse path taken by the PATH message.

Further RSVP messages are PATHErr and RESVErr to indicate that the establishment of PATH or RESV state has not been successful (e.g., when the admission control has failed). To explicitly tear down the established state inside the network, the PATHTear and RESVTear messages are used (these messages complement the soft state mechanism where outdated state is automatically deleted).

A feature of RSVP with regard to the support for multicast is *merging*, that is, reservations coming from different receivers for the same session are combined (*RESV* (*E,I*) in Figure 27.5). Merging is required to

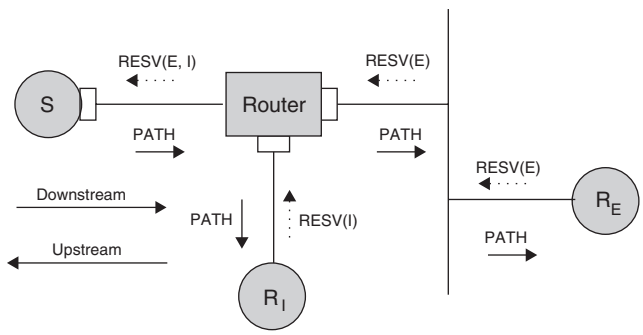

FIGURE 27.5 RSVP operation.

© 2005 by CRC Press LLC

match the RSVP upstream operation with the way multicast forwarding works in the downstream path: replicating packets that have to be delivered to different branches of the multicast tree. Thus, at such replication points, RSVP must merge the reservation requests and compute the maximum of the FlowSpecs of the different receivers. Note that merging FlowSpecs can be very difficult as there are numerous, not necessarily ordered parameters. Different reservation styles cannot be merged as they are fundamentally incompatible. Guidelines for ordering of the parameters and merging are contained in the service class specifications (Controlled Load and Guaranteed Service) rather than the RSVP specification as RSVP itself treats the FlowSpecs as opaque objects.

27.4 Applicability of Integrated Services and RSVP

The Integrated Services Architecture and RSVP have often been described as being very complex and possessing poor scaling properties. To a large extent, the complexity and lack of scalability are due to the approach of dealing with QoS signaling and enforcement at a per-flow granularity inside the network to achieve the "high-end" QoS goals, which have been the original motivation for the Integrated Services Architecture. The resource requirements (processing power, memory) of RSVP (and the corresponding operations and state that need to be maintained in the Integrated Services traffic control) scale with the number of sessions, which may become prohibitive the closer a network element is located to the network core. The development of the IETF Differentiated Services (DiffServ) Architecture (Chapter 25) has followed the design of Integrated Services coming from this conclusion. It aims at treating only flow aggregates inside the network achieving better scalability, which has of course been traded against a less stringent support of QoS guarantees. The operation of Int Serv over DiffServ-enabled network clouds aiming at the combination of per-flow QoS treatment at the network edge and scalable, efficient QoS enforcement in the network core is described in [5]. To reduce the resource requirements of RSVP itself, aggregation of several RSVP reservations into a single one inside the network is proposed [8].

It should also be noted that RSVP started off as a rather simple protocol and became increasingly complex due to inherent difficulties of providing per-hop QoS signaling along the data path (problems that also have to be encountered by alternative signaling protocols). The design of RSVP has been significantly influenced by the predicted importance of IP multicasting: a vision that has not become a reality. The strong support for multicast is today considered rather a burden than an important feature. The merging of reservations coming from different receivers of a multicast session is very complex and can even be counterproductive in that one extremely large reservation request might impair the acceptance of a concurrently issued reservation request by another receiver ("killer reservation problem"). To solve this problem, a complex detection mechanism ("blockade state") had to be integrated into the protocol.

The scalability problem is particularly an issue for Voice-over-IP (which could be seen as the most popular and thus most important application requiring QoS support from the network) as the per-flow bandwidth is low and thus the state overhead to flow bandwidth ratio is high. Additionally, due to the similarity of voice flows, some options of RSVP (which are very useful for other flow types) are again rather a burden than a feature. An example is the initial exchange of sender and receiver TSpecs in PATH and RESV messages, where the sender advertises its traffic properties (which are most probably well known at the receiver anyway through, e.g., the RTP payload type). The receiver then typically reserves exactly with these parameters. The near-immediate setup of a connection in a circuit-switched network should be approximated in a packet-switched network as far as possible. However, the two-way end-to-end reservation setup might take significantly longer (RSVP processing/state update, admission control, traffic control configuration). A sender-based approach to a reservation protocol (see, e.g., [11]) thus seems much better suited to accommodate voice flows.

While the Integrated Service Architecture has not seen significant deployments, RSVP is used as a signaling protocol for Multi Protocol Label Switching (MPLS — cf. Chapter 13) to perform label distribution and support explicit routing (RSVP-TE, [9]). RSVP-TE is intended to be used by label switching routers (LSRs) to establish and maintain label-switched path (LSP) -tunnels and to reserve network resources for such LSP tunnels.

© 2005 by CRC Press LLC

RSVP is also proposed to be used for Third Generation Mobile Networks. In [12], the QoS signaling procedures and policy control within the Universal Mobile Telecommunications System (UMTS) end-to-end QoS architecture are specified. The usage of RSVP is specified as follows: the signaling source and/or destination are the User Equipment (UEs: terminals). The RSVP signaling process can either trigger or be triggered by the Policy Decision Point (PDP) context establishment process. The authorization token and flow identifiers in a policy data object should be included in the RSVP messages sent by the UE. When both RSVP and service-based local policy are used, the Gateway GPRS Support Node (GGSN, the point of interconnection of the 3G network with the Internet) should use the policy information to decide whether to accept and forward RSVP messages.

27.5 Concluding Remarks

Ten years have passed since the basic concepts of RSVP have been devised; meanwhile, the requirements have changed: instead of multicast as an advanced communication model, the issues of node mobility and security are increasingly important for the evolution of the Internet. RSVP has not been designed to accommodate mobility at all; therefore, the following problems may arise: the movement of the mobile nodes may not properly trigger a reservation refresh for the new path and therefore a mobile node may be left without a reservation up to the length of the refresh timer. IntServ/RSVP also does not work properly if the IP address of a mobile node changes or traffic is tunneled toward a mobile node away from its home network, because the classifiers are not able to identify the flow that had a reservation.

From a security point of view, RSVP provides the basic building blocks for deploying the protocol in various environments to protect its messages from forgery and modification, that is, hop-by-hop protection is provided. However, current RSVP security mechanisms do not provide nonrepudiation and protection against message deletion: the two-way peer authentication and key management procedures are missing.

Future QoS architectures and signaling protocols [16] must address the shortcomings of Integrated Services/RSVP that have just been described. Additional requirements are to take inter-domain signaling explicitly into account (where several administrative domains with potentially different per-domain QoS solutions are traversed). Another aspect is a more modular design of the architecture and protocols, which extend the applicability particularly of the signaling protocol well beyond the QoS area. The Next Steps in Signaling (NSIS) Working Group in the IETF is addressing these issues currently.

The margin where QoS mechanisms really lead to a differentiation in the efficiency of how data are carried in the network is relatively small [13] considering the parameters of today's Internet (available bandwidths, typical applications), that is, only when parts of the network are close to being fully loaded, the effect of the QoS mechanisms are visible at all. Then, of course, the differentiation is extremely significant and may provide the distinction between an almost undisturbed operation and complete breakdown of connectivity.

For the development of future Internet QoS schemes, it is important to consider the (predicted) mix of applications used in the network. If there will be a significant portion of applications that are delay-sensitive and at the same time applications will be present that emit very bursty traffic flows, then support for QoS inside the network is almost inevitable. Finally, the economic background for QoS deployment needs to be considered throughout the research and development process, that is, the QoS case where the capacity is maintained and the complexity increased need to be continuously validated against the solution of "overprovisioning," which consists of increasing capacity and maintaining or even reducing the complexity of the network.

28.1 Multimedia over the Internet

The Internet was originally designed to support data communications. Most of the traffic initially included data such as e-mails and files. Voice traffic was served exclusively by telephone networks. As the Internet grew in terms of number of nodes, applications, and users, the need for multimedia communication over the Internet emerged. Animation, voice, and video clips are now common on the Internet. Multimedia networking products like Internet telephony, Internet TV, and video conferencing are available in the market. In the near future, people will enjoy other multimedia products in distance learning, distributed simulation, distributed work groups, and other areas. Multimedia traffic poses new requirements to the Internet architecture and its protocols. In response to this, researchers have designed a family of protocols, including Real-Time Transmission Protocol (RTP), its control part Real-Time Transmission Control Protocol (RTCP), and Real-Time Streaming Protocol (RTSP), that are the object of this chapter.

For transporting textual data, the best-effort service model of the IP-based Internet was shown to have been an adequate solution. In this service model, IP makes every effort to deliver packets, but does not provide guarantees. Thus, packets can be lost or delivered out of order, and the delay is unpredictable. The advantage of such a model is that it keeps routers as simple as possible and keeps the network architecture very scalable — features that have been crucial for the spectacular success of the Internet. To increase the

© 2005 by CRC Press LLC

reliability of the end-to-end services, data packets are transported by TCP, which is one of the most common transport layers used in IP networks. TCP has mechanisms to conceal the unreliability of IP and presents a reliable network channel to applications. For example, TCP retransmits lost packets and keeps them in order. TCP also has mechanisms to keep network congestion under control and to avoid congestion collapse. Hence, TCP is an optimal solution for data traffic. IP, which is implemented in all nodes, is simple and scalable, and TCP, which is implemented only at the end-user nodes, provides the needed reliability for the applications. This solution, however, has problems when attempting to transport multimedia traffic. Many multimedia applications are highly sensitive to end-to-end delay and delay variation (jitter); but can tolerate some data loss. TCP takes care of losses by retransmitting the lost packets, but does not guarantee the delay or its variation. That is why multimedia traffic does not work well with TCP. For example, if some packets carrying part of a video scene are lost, having them retransmitted by TCP could worsen the situation. Such retransmitted video traffic could overlap over a new video scene and may also damage it. To avoid such problems with TCP, most of the multimedia traffic is transported by UDP to make use of its multiplexing and checksum services. UDP is the other transport layer over IP.

Multimedia applications can be divided in two classes: real-time interactive applications and noninteractive streaming applications.

In real-time applications such as voice over the Internet and video conferencing, all communication has to be in real time and the data cannot be buffered for long to smooth out network delay or jitter. There are hundreds of Internet interactive multimedia products currently available such as Microsoft NetMeeting, PC-to-phone and PC-to-PC, H-323 based applications, and MBone tools [1]. Such applications are very delay and jitter sensitive. For example, voice application cannot accept delays more than 250–300 ms and jitter more than 75 ms; otherwise, the conversation becomes almost unintelligible. Some new types of applications are emerging in this category, such as Distributed Virtual Environments (DVE) for collaboration, scientific exploration, instrument operation, and data visualization by supporting continuous media flows, data transfers, and data manipulation tools within virtual environment interfaces. Other specialized equipment, such as haptic devices or head-mounted displays, is used to enable manipulation of instruments or navigation within virtual worlds. These collaborative, distributed, immersive environments pose new requirements to the network in terms of data transfer bit-rates, short one-way delay for real-time operation, and reliable transfer of data. One example of DVE application is a system developed by the National Tele-immersion Initiative, which uses 3D real-time acquisition to capture accurate dynamic models of humans. The system combines these models with a static 3D background (3D model of an office, e.g.), and it also adds synthetic 3D graphic objects that may not exist at all. These objects may be used as a basis for a collaborative design process that users immersed in the system can work on. The system can also be described as a mix of virtual reality and 3D videoconferencing, and can be used in tele-diagnosis and tele-medicine.

Noninteractive applications class can be divided into two subclasses: streaming stored audio/video and streaming live audio/video. Streaming stored applications deliver audio and video streams stored in a server to clients. Examples of such stored files include lectures, songs, movies, and video clips. In streaming stored applications, the user begins to play out of the file, while the file is being received. The main requirement of such applications is that once the playout begins, it should proceed according to the original timing of the recording. This is translated in a requirement for the end-to-end network delay; but such a requirement is less stringent compared to that of interactive applications. Because the playout is not in real time, the file can be buffered to smooth out the effects of random network delay. Examples of streaming stored applications include RealPlayer [2], Apple's Quick Time [3], and Microsoft Windows Media [4]. Streaming live audio and video applications are similar to radio and television broadcasts. Even though the files are not stored in servers, they can be stored locally at clients. In the streaming stored applications, local buffering allows reducing the network jitter and delay compared to interactive applications.

Among the multimedia requirements discussed so far, the requirements for delay and jitter from interactive, real-time applications are the most stringent. The best-effort service of today's Internet cannot satisfy these requirements, and this is one of the reasons why multimedia applications are not yet the new

© 2005 by CRC Press LLC

killer applications on the Internet. There is a vivid debate among researchers about how to satisfy such multimedia requirements [5]. Some researchers argue that the Internet's service model should be changed to allow resource reservations, which would enable predictable delays and jitter. A large amount of research work is dedicated to such solutions and protocols, such as RSVP (part of IntServ), that signal the needed resource reservations. The main problem with this approach is that it increases the complexity of protocols and routers, which could lead to scalability issues. Other researchers propose to use more bandwidth (overprovisioning) with the best-effort service. This is still an open debate but for the time being, the proposal to use reservations or other QoS solutions is not being applied and multimedia applications use the best-effort service of the Internet.

Besides the limited delay and jitter, multimedia applications need some transport services with characteristics different from those of TCP, and with more functionality than UDP. The protocol designed to provide services for data with real-time characteristics is called Real-time Transport Protocol (RTP). In the following, we discuss some common needs of real-time applications considered in the design of RTP.

The large variety of multimedia applications of both classes use different coding schemes, each with its own trade-offs between quality, bandwidth, and computational cost. One of the basic requirements such applications have is the ability to interoperate with each other. For example, it should be possible for two independently developed Voice over IP applications to talk to each other. Instead of imposing a given voice-encoding scheme, RTP enables these applications to negotiate and select a scheme that is available to both parties. The same is true for video applications.

In the best-effort service provided by the Internet, the delay in routers is random and the end-to-end delays fluctuate; this phenomenon is called jitter. Jitter can change the original spacing between multimedia packets. If the receiver ignores the presence of jitter and plays the voice or video as soon as they arrive, the result could be unintelligible. Fortunately, jitter can be smoothed out by using a playback buffer, where the arriving packets are stored before being played. In order to play these packets at the right time, the receiver needs to know the timing relationships among the received packets. RTP enables the recipient of the packet stream to determine this information.

Related to the media timing is the need of multimedia applications for synchronization among various media, for example, between voice and video streams in a conference. These streams could have originated at one or more sources. Another important requirement of multimedia applications is to identify packet loss. Then, the specific application can deal in an appropriate manner with such losses.

The output data rate of multimedia applications depends on the information content. Because such applications do not use TCP, they are not congestion sensitive. Therefore, they do not reduce their data rate in response to network congestion, leading to packet loss and more congestion. Yet, many multimedia applications are capable of responding to congestion, for example, by changing parameters in coding schemes to reduce the consumed bandwidth during congestion periods. In order for this to occur, the sender needs the congestion feedback from receivers.

Another requirement for multimedia applications is the concept of frame indication at the application level. For example, it is important to notify a receiver video application that a set of packets belong to the same video scene, so that they can be treated in an appropriate way.

Based on the experience with existing multimedia products over the Internet, researchers have designed RTP.

28.2 RTP

RTP is the Internet-standard protocol for the transport of real-time data, including audio and video [6, 7]. It can be used for media-on-demand as well as interactive services such as Internet telephony. RTP was developed by the Internet Engineering Task Force (IETF) and is in widespread use. The RTP standard actually defines a pair of protocols: RTP and RTCP. RTP is used for the exchange of multimedia data, while RTCP is the control part and is used to periodically obtain feedback control information regarding the quality of transmission associated with the data flows. RTP usually runs over UDP/IP; but efforts are under way to make it transport-independent so that it could be used over other protocols. RTP and the

© 2005 by CRC Press LLC

associated RTCP use consecutive transport-layer ports, when used over UDP. Figure 28.1 shows a schematic diagram illustrating the use of RTP. The video/audio is digitized using a particular codec. The blocks formed by such bit streams are encapsulated in RTP packets and then in UDP and IP packets.

The data part of RTP is a thin protocol providing support for applications with real-time properties such as continuous media (e.g., audio and video), including timing reconstruction, loss detection, security, and content identification. RTP does not reserve bandwidth or guarantee Quality of Service (QoS).

The control part of the protocol, RTCP, provides support for real-time conferencing of groups of any size within the Internet. It offers QoS feedback from receivers to the multicast group as well as support for the synchronization of different media streams. RTCP also conveys information about participants in a group session.

Attempts to send voiceover networks began in the early 1970s. Several patents on packet transmission of speech, time stamp, and sequence numbering were granted in the 1970s and 1980s. In 1991, a series of voice experiments were completed on DARTnet. In August 1991, the Network Research Group of Lawrence Berkeley National Laboratory released an audio conference tool **vat** for DARTnet use. The protocol used was referred later as RTP version 0.

In December 1992, Henning Schulzrinne, then at GMD Berlin, published RTP version 1. It underwent several states of Internet Drafts, and was finally approved as a Proposed Standard on November 22, 1995 by the IESG. This version was called RTP version 2 and was published as

- RFC 1889, updated in July 2003 by RFC 3550 RTP: A Transport Protocol for Real-Time Applications.
- RFC 1890, updated in July 2003 by RFC 3551 RTP Profile for Audio and Video Conferences with Minimal Control.

On January 31, 1996, Netscape announced "Netscape LiveMedia" based on RTP and other standards. Microsoft NetMeeting conferencing software also supports RTP.

The design of RTP was made following an architectural principle known as Application Level Framing (ALF). This principle was proposed by Clark and Tennenhouse in 1990 [8] as a new way to design protocols for emerging multimedia applications. ALF is based on the belief that applications understand their own needs better, which means that the intelligence should be placed in applications and the network should be kept simple. For example, an MPEG video application knows better how to recover from lost frames, and how to react to it if an I or a B frame is lost.

RTP is designed to support a wide variety of applications. It provides flexible mechanisms by which new applications can be developed without repeatedly revising RTP itself. For each class of applications, RTP defines a profile and one or more payload formats. The profile provides a range of information that ensures a common understanding of the fields in the RTP header for that application class. A profile can

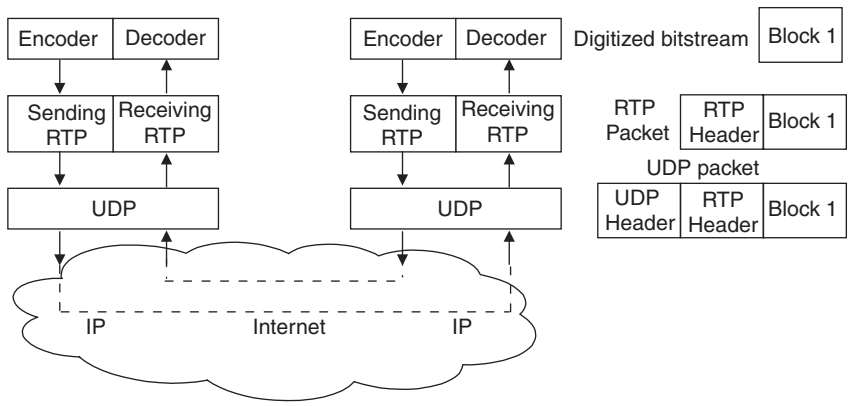

FIGURE 28.1 Real-time Transport Protocol.

© 2005 by CRC Press LLC

also define extensions or modifications to RTP that are specific to a particular class of applications. The payload format specification explains how the data that follow the RTP header are to be interpreted.

Mixers and Translators

Besides the sender and receiver, RTP defines two other roles for systems, those of a translator and a mixer. They reside in between senders and receivers, and process the RTP packets as they pass through. The translators are used to translate from one payload to another. For example, suppose some of the participants in the audio–video conference have lower access bandwidth than that required for the conference. In this case, a translator could convert the stream to audio and video formats that require less bandwidth.

Mixers, on the other hand, are used to combine multiple source streams into one. An example is a video mixer that combines the images of individual people into one video stream to simulate a group scene.

Header Format

Figure 28.2 shows the header format used by RTP. The first 12 bytes are always present, whereas the contributing source identifiers are only used in certain circumstances. After this header, there may be optional header extensions. Finally, the RTP payload, whose format is determined by the application, follows the header. This header contains only the fields that are likely to be used by most of the multimedia applications. Information specific to a single application is carried in the RTP payload.

V — version: *2 bits*: The first two bits are a version identifier, which contains the value 2 for the RTP version used at the time of this writing.

P — padding: *1 bit*: If the padding bit is set, the packet contains one or more additional padding octets at the end, which are not part of the payload. The last octet of the padding contains a count of how many padding octets should be ignored, including itself. RTP data might be padded to fill up a block of certain size as required by an encryption algorithm.

X — extension: *1 bit*: If the extension bit is set, exactly one extension header follows the fixed header.

CC — CSRC count: *4 bits*: The CSRC count contains the number of CSRC identifiers that follow the fixed header. This number is more than one if the payload of the RTP packet contains data from several sources.

M — marker: *1 bit*: The interpretation of the marker is defined by a profile. The marker is intended to allow significant events such as frame boundaries to be marked in the packet stream.

PT — payload type: *7 bits*: PT identifies the format of the RTP payload and determines its interpretation by the application. One possible use of this field would be to enable an application to switch from one coding scheme to another based on the information about resource availability on the network of feedback on application quality. Default payload types are defined in RFC 3551, as shown in Table 28.1.

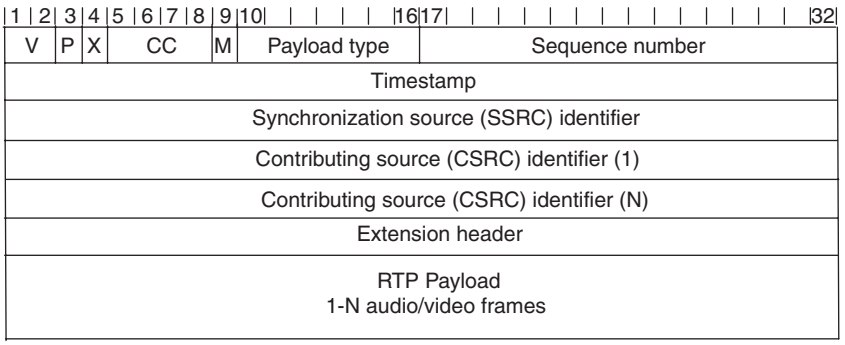

FIGURE 28.2 RTP header format.

© 2005 by CRC Press LLC

Example specifications include PCM, MPEG1/MPEG2 audio and video, JPEG video, Sun CelB video, H.261 video streams, etc. More payload types can be added by providing a profile and payload format specification. The exact usages of marker bit and the payload type are determined by the application profile.

Sequence number: *16 bits*: The sequence number increments by one for each RTP data packet sent, and can be used by the receiver to detect missing and misplaced packets. The initial value is randomly set to make crypto analysis attacks on possible encryption more difficult. RTP does not take any action when it detects a lost packet. It is left to the application to decide what to do when a packet is lost. For example, a video application could replay the previous frame if a frame is lost. Another application, however, could decide to change encoding parameter in order to reduce the needed bandwidth. These decisions need some intelligence, which is left to the applications themselves.

Timestamp: *32 bits*: The timestamp indicates the sampling instant of the first octet in the RTP data packet. Its function is to enable the receiver to play back samples at the appropriate intervals and to enable different media streams to be synchronized. It can also be used for calculations in jitter smoothing. The resolution of the clock used should be sufficient for the desired synchronization accuracy and for measuring packet jitter.

The initial value is randomly set. Because different applications may require different granularities of timing, RTP does not specify the units in which time is measured. The timestamp is just a counter of ticks, and the time between ticks is application specific. The clock granularity is specified in the RTP profile or payload format for an application.

SSRC — Synchronization source: *32 bits*: This field identifies synchronization sources within the same RTP session. It is chosen randomly to avoid two sources in the same RTP session to have the same SSRC identifier. It indicates where the data were combined, or the source of the data if there is only one source. The sources could be in the same node or in different nodes, such as during a conference.

CSRC — Contributing source list: *0 to 15 items, 32 bits each*: The CSRC list identifies the contributing sources for the payload contained in this packet. The CC field gives the number of identifiers. It is used

TABLE 28.1 Payload Types (PT) for Some Audio and Video Encodings

PT	Encoding name	Media type	Clock rate [kHz]

only when a number of RTP streams pass through a mixer. A mixer can be used, for example, in a conference to combine data received from many sources and to send it as a single stream to reduce the needed bandwidth.

To set up an RTP session, the application defines a particular pair of destination transport addresses (one network address plus a pair of ports for RTP and RTCP). In a multimedia session, each medium is carried in a separate RTP session, with its own RTCP packets reporting the reception quality for that session. For example, audio and video would travel on separate RTP sessions, enabling a receiver to select whether or not to receive a particular medium. An audio–video conferencing scenario presented below illustrates the use of RTP.

Example of an Audio and Video Conference

Audio and video media, used in the conference, are transmitted on separate RTP sessions. That is, separate RTP and RTCP packets are transmitted for each medium using two different UDP port pairs. In the pair of ports used for audio, one port is used for data and the other for RTCP. The same is true for other pair of ports used for video pair. The conference can also use Internet multicast service. In this case, two multicast group addresses are needed: one for voice and one for video. There is no direct coupling at the RTP level between the audio and the video sessions, except that a user participating in both sessions should use the same canonical name in the RTCP packets for both so that the sessions can be associated. This separation between audio and video allows users in the conference to receive only audio. The synchronization playback of a source's audio and video can be achieved using timing information carried in RTCP packets for both sessions.

Both audio and video applications used by each participant send chunks of data. Each of these chunks is carried in RTP packets. Each packet has an RTP header that indicates what type of audio or video encoding is contained in the packet. This information is used by the receiver to select the appropriate decoding scheme.

The RTP header contains timing information and a sequence number that allow the receivers to reconstruct the timing produced by the source for both audio and video. The timing reconstruction is done separately for each source of RTP packets in the conference.

Each participants' audio and video application periodically multicasts a reception report plus the identification information name of its user on the RTCP port. The reception report indicates the quality of reception of the current source and could be used to control the adaptive encodings. A participant sends an RTCP BYE packet when it leaves the conference.

28.3 Real-time Transport Control Protocol — RTCP

RTCP is the control protocol designed to work in conjunction with RTP. It is specified in RFC 3550. RTCP's relationship with other layers is shown in Figure 28.3.

In an RTP session, participants periodically send RTCP packets to all the members in the same RTP session using IP multicast. RTCP packets contain sender and/or receiver reports that announce statistics such as the number of packets sent, number of packets lost, and inter-arrival jitter. This function may be useful for adaptive applications that can use this feedback to send high- or low-quality data depending on the network congestion. Such applications will increase the compression ratio when there is little available bandwidth, and will reduce the compression ratio, which will result in higher multimedia quality when there is more available bandwidth. This feedback information can also be used for diagnostic purposes to localize eventual problems.

RTCP provides a way to correlate and synchronize different media streams that have come from the same sender. When collisions of SSRC occur, it is necessary to change the SSCR value of a given stream. This is done using RTCP.

In applications that involve separate multimedia streams, a common system clock is used for their synchronization. The system that initiates the session provides this function, and the RTCP messages enable all systems to use the same clock.

© 2005 by CRC Press LLC

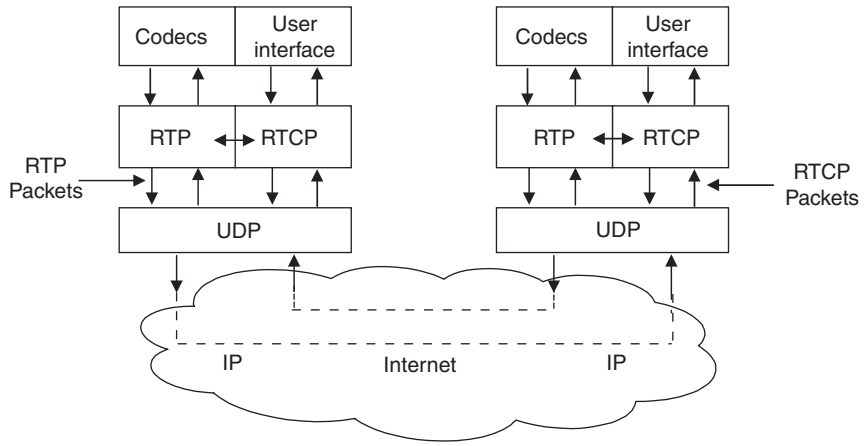

FIGURE 28.3 Real-time Transport Control Protocol.

RTCP is also used to deliver information about the membership in the session.

RFC 3550 defines five RTCP packet types to carry control information. These five types are as follows:

RR (Receiver Report): Receiver reports are generated by participants that are not active senders. They contain reception quality feedback about data delivery, including the highest packets number received, the number of packets lost, interarrival jitter, and timestamps to calculate the round-trip delay between the sender and the receiver.

SR (Sender Report): Sender reports are generated by active senders. In addition to the reception quality feedback as in RR, they contain a sender information section, providing information on inter-media synchronization, cumulative packet counters, and number of bytes sent.

SDES (Source Description Items): They contain information to describe the sources. In RTP data packets, sources are identified by randomly generated 32-bit identifiers. These identifiers are not convenient for human users. RTCP SDES (source description) packets contain textual information called *canonical names* as globally unique identifiers of the session participants. It may include the user's name, telephone number, e-mail address, and other information.

BYE: Indicates end of participation.

APP (Application specific functions): These are intended for experimental use as new applications and new features are developed.

RTCP packets are sent periodically among participants. When the number of participants increases, it is necessary to balance between getting up-to-date control information and limiting the control traffic. In order to scale up to large multicast groups, RTCP has to prevent the control traffic from overwhelming network resources. RTCP limits the control traffic to at most 5% of the overall session traffic. This is enforced by adjusting the RTCP packet generation rate according to the number of participants.

RTP Implementation Resources

RTP is an open protocol that does not provide preimplemented system calls. Implementation is tightly coupled to the application itself. Application developers have to add the complete functionality in the application layer by themselves. It is, however, always more efficient to share and reuse code rather than starting from scratch. The RFC 3550 specification itself contains numerous code segments that can be used directly in the applications. There are some implementations with source code available on the web for evaluation and educational purposes. Many modules in the source code can be used with minor modifications. The following is a list of useful resources:

© 2005 by CRC Press LLC

vat (http://www-nrg.ee.lbl.gov/vat/),
rtptools (ftp://ftp.cs.columbia.edu/pub/schulzrinne/rtptools/),
NeVoT (http://www.cs.columbia.edu/~hgs/rtp/nevot.html).

RTP Library (http://www.bell-labs.com/project/RTPlib/DOCS/rtp_api.html) provides a high-level interface for developing applications that make use of the RTP.

RTP page (http://www/cs.columbia.edu/~hgs/rtp) maintained by Henning Schulzrinne is a very complete reference. Readers might also want to visit the Free Phone site [9], which documents an Internet phone application that uses RTP.

28.4 RTSP

RTSP, defined in RFC 2326, is an application-level protocol that enables control over the delivery of data with real-time properties over IP. Such control includes pausing playback, repositioning playback to future or past point of time, fast forwarding, and rewinding playback. These functionalities are similar to those of a DVD player. RTSP does not typically deliver the continuous media itself, although interleaving of the continuous media stream with the control stream is possible. In the words of the authors: "RTSP acts as a network remote control for multimedia servers"[10]. Sources of data include both live data feeds and stored clips.

RTSP is a client–server multimedia presentation protocol. There is no notion of RTSP connection. Instead, a server maintains a session labeled by an identifier. An RTSP session is in no way tied to a transport-level protocol. During an RTSP session, an RTSP client may open and close many reliable transport connections to the server in order to issue RTSP requests. It may alternatively use a connectionless transport protocol such as UDP.

RTSP is designed to work with lower-level protocols like RTP and RSVP to provide a complete streaming service over the Internet. It provides a means for choosing delivery channels (such as UDP, multicast UDP, and TCP), and delivery mechanisms based on RTP. The RTSP messages are sent out-of-band of the media stream. RTSP works for large-audience multicast as well as single-viewer unicast.

RTSP was jointly developed by RealNetworks, Netscape Communications, and Columbia University. It was developed from the streaming practice and experience of RealNetworks' RealAudio and Netscape's LiveMedia. The first draft of RTSP protocol was submitted to IETF on October 9, 1996 for consideration as an Internet Standard. Since then, it has gone through significant changes, and it was approved by IETF as a Proposed Standard on April 1998.

Numerous products using RTSP are available today. Major online players, such as Netscape, Apple, IBM, Silicon Graphics, VXtreme, Sun, and other companies, have announced their support for RTSP.

RTSP establishes and controls streams of continuous audio and video media between the media servers and the clients. A *media server* provides playback or recording services for the media streams, while a *client* requests continuous media data from the media server. RTSP supports the following operations:

Retrieval of media from the media server: The client can request a presentation description via HTTP or some other method. If the presentation is being multicasted, the presentation description contains the multicast addresses and ports to be used for the continuous media. If the presentation is to be sent only to the client, the client provides the destination for security reasons. The client can also ask the server to set-up a session to send the requested data.

Invitation of a media server to a conference: A media server can be invited to join an existing conference, either to play back media into the presentation or to record all or a subset of the media in a presentation. This method is useful for distributed applications such as distance learning. Several parties in the conference may take turns "pushing the remote control buttons."

Adding media to an existing presentation: The server or the client can notify each other about any additional media becoming available. This is particularly useful for live presentations.

© 2005 by CRC Press LLC

RTSP aims to provide the same services on streamed audio and video just as HTTP does for text and graphics. It is intentionally designed to have similar syntax and operations, so that most extension mechanisms to HTTP can be added to RTSP.

Each presentation and media stream in RTSP is identified by an RTSP URL. The overall presentation and the properties of the media are defined in a presentation description file, which may include the encoding, language, RTSP URLs, destination address, port, and other parameters. The client can also obtain the presentation description file using HTTP, e-mail, or other means.

RTSP, however, differs from HTTP in several aspects. First, while HTTP is a stateless protocol, an RTSP server has to maintain "session states" in order to correlate RTSP requests with a stream. Second, HTTP is an asymmetric protocol where the client issues requests and the server responds; but in RTSP, both the media server and the client can issue requests. For example, the server can issue a request to set playing back parameters of a stream.

The services and operations in the current version are supported through the following methods:

OPTIONS: The client or the server informs the other party about the options it can accept.

DESCRIBE: The client retrieves the description of a presentation or media object identified by the request URL from the server.

ANNOUNCE: When sent from client to server, Announce posts the description of a presentation or media object identified by the request URL to a server. When sent from server to client, Announce updates the session description in real time.

SETUP: The client asks the server to allocate resources for a stream and start an RTSP session.

PLAY: The client asks the server to start sending data on a stream allocated via SETUP.

PAUSE: The client temporarily halts the stream delivery without freeing server resources.

TEARDOWN: The client asks the server to stop delivery of the specified stream and free the resources associated with it.

GET_PARAMETER: Retrieves the value of a parameter of a presentation or a stream specified in the URI.

SET_PARAMETER: Sets the value of a parameter for a presentation or stream specified by the URI.

REDIRECT: The server informs the clients that it must connect to another server location. The mandatory location header indicates the URL that the client should connect to.

RECORD: The client initiates recording a range of media data according to the presentation description.

Note that some of these methods can either be sent from the server to the client or from the client to the server; but others can only be sent in one direction. Not all these methods, however, are necessary in a fully functional server. For example, a media server with live feeds may not support the PAUSE method.

RTSP requests are usually sent on a channel independent of the data channel. They can be transmitted in persistent transport connections, or as a one-connection per request/response transaction, or in connectionless mode.

RTSP Implementation Resources

Several RTSP implementations are available on the web. The following is a collection of useful implementation resources:

RTSP Reference Implementation (http://www.real.com/devzone/library/fireprot/rtsp/reference.html): This is a source code testbed for the standards community to experiment with RTSP compatibility.

RealMedia SDK (http://www.realnetworks.com/devzone/tools/index.html): This is an open, cross-platform, client–server system that allows implementers to create RTSP-based streaming applications. It includes a working RTSP client and server, as well as the components to quickly create RTSP-based applications that stream arbitrary data types and file formats.

W3C's Jigsaw (http://www.w3.org/Jigsaw/): A Java-based web server. The RTSP server in the latest beta version was written in Java.

© 2005 by CRC Press LLC

IBM's RTSP Toolkit (http://www.research.ibm.com/rtsptoolkit/): IBM's toolkits derived from tools developed for ATM/video research and other applications in 1995–1996. Its shell-based implementation illustrates the usefulness of the RTSP protocol for nonmultimedia applications.

28.5 Summary

This chapter discusses the three related protocols for real-time multimedia data over the Internet.

RTP is the transport protocol for real-time data. It provides timestamp, sequence number, and other means to handle the timing issues in real-time data transport.

RTCP is the control part of RTP that helps with quality of service and membership management.

RTSP is a control protocol that initiates and directs delivery of streaming multimedia data from media servers. It is the "Internet VCR remote control protocol." Its role is to provide the remote control; however, the actual data delivery is done separately, most likely by RTP.

29.1 Mail Transfer Protocols

Introduction

It is useful to use the analogy of the old postal system to explain current mail transfer protocols. For example, suppose Tom wanted to send a message to Peter. Tom writes a message on a piece of paper, puts the paper in an envelope, and writes Peter's address details on the front of the envelope and Tom's address details on the back of the envelope (the return address). It is common practice to always put a return address on the envelope, in case the postal service found that Peter's address as specified on the envelope was incorrect; it would need to return the letter to the sender. Tom then puts the letter in a post box. The postal service retrieves the mail from the post box, determines which geographical location the letter is destined to, and *forwards* the letter to Peter's post box where it is *stored* until Peter physically retrieves the letter. A few days later, when Peter checks his post box, he finds the letter addressed to him from Tom.

Current electronic mail transfer protocols use a similar store and forward technology to send e-mail. This means that a person can write a message, which is saved to a file that is addressed to a particular person at a particular computer connected to the Internet. This file is then transferred to a remote computer, where it is stored in the recipient's mailbox, until the person it is addressed to is available to read the file.

As with postage mail, e-mail requires the recipient's address details. An e-mail address is divided into two components that are separated by the @ sign. The left component is the name of the e-mail mailbox and the right component is the name of the computer that contains the mailbox. The name of the host computer is called the domain name. For example, consider a fictional person called John Smith, who works at a fictional company called AlphaWorx. Assume that the AlphaWorx mail server on which each employee is allocated a mailbox is called Alphaworx.com. In addition, assume that there are three other persons by the name of John working at Alphaworx. If Alphaworx uses their surnames to distinguish

© 2005 by CRC Press LLC

between the different people called John, and allocates John the mailbox directory "John.Smith," then the e-mail address of John Smith will be John.Smith@Alphaworx.com.

Routers and switches along the Internet use the domain name to send mail to the correct computer (mail server). When the mail server receives the e-mail message, it uses the mailbox name to locate the correct mailbox on the server. If it is unable to find the mailbox, the e-mail is returned to the sender with a message stating that the mailbox is unknown.

Because mail servers are relatively expensive and require more resources, it is not feasible to have a mail server application on each user's computer. Instead, each user in a company is allocated space (the user's mailbox) on a single company mail server. To retrieve mail from the mailbox, a person normally uses a client mail application (which requires fewer resources), to connect to the mail server and retrieve mail from the user's mail box.

A mailbox is actually a directory on the mail server; similar to a folder on a computer's hard disk Host (mail server), computer names are not case sensitive. However, mailbox user names are dependent on the file naming conventions of the underlying operating system and are therefore case sensitive.

Figure 29.1 illustrates the basic mail transfer process.

Sending Mail — How Does Mail Get Transferred from the Sender to the Mailbox?

The Simple Mail Transfer Protocol (SMTP) provides mechanisms for the transmission of mail from the sending user's host to the receiving user's host. SMTP is independent of the particular transport service and requires only a reliable ordered data stream channel. A transport service is an interprocess communication environment that may cover one network, several networks, or a subset of a network.

If the source and destination hosts are not connected to the same transport service, one or more relay SMTP-servers is used. To be able to provide the relay capability, the SMTP-server must be supplied with the name of the ultimate destination host as well as the destination mailbox name [1].

E-mail applications on the Internet typically use a single TCP connection established between the sender process port[1] and the receiver process port, to transfer both control commands and the actual mail data. Since SMTP data are only 7-bit ASCII characters, but TCP is sent in 8-bit bytes, SMTP transmits each character as an 8-bit byte with the high-order bit cleared to zero. There is a predefined standard for sending electronic mail messages over the Internet (RFC 822). An SMTP-application should adhere to this standard when transporting mail messages over the Internet.

How Does SMTP Work?

After a user has typed in a mail message and clicked send, the sender-SMTP application establishes a full duplex TCP (assuming Internet) connection to the receiver-SMTP application. The sender-SMTP application generates and sends commands in sequential order to the receiver-SMTP application that responds to these commands and sends a reply back to the server-SMTP application in response to each command received. The sequence of commands is described in Figure 29.2.

SMTP Command–Response Sequence:

1. SMTP applications establish a TCP connection and send *HELO* greeting and response.
2. Sender-SMTP application sends a *MAIL* command indicating the sender of the mail.
3. If the receiver-SMTP application can accept mail, it returns an *OK* response and a numeric code.
4. Sender-SMTP application sends an *RCPT* command identifying a recipient of the mail.
5. If the receiver-SMTP application can accept mail for that recipient, it returns an *OK* response and a numeric code. If not, it responds with a reply rejecting that recipient (but not the whole mail transaction).
6. If an OK response is received from the receiver-SMTP application, the sender-SMTP application sends the mail *DATA*, terminating with a special sequence. The mail data are text based and may

[1]Usually, vendors use the port specified in the RFC821, that is, port 25.

© 2005 by CRC Press LLC

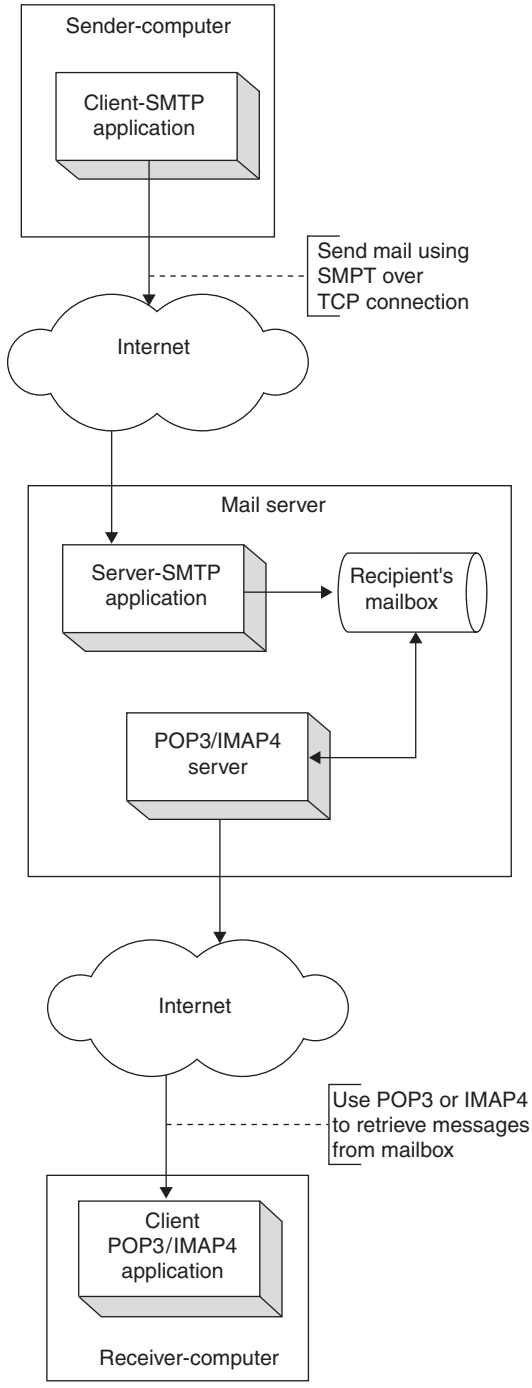

FIGURE 29.1 Overview of mail transfer from sender to receiver.

contain any of the 128 ASCII character codes. A line containing only a period terminates the mail data. This is the end of mail data indication.

7. If the receiver-SMTP application successfully processes the mail data, it responds with an OK reply and a numeric code.

© 2005 by CRC Press LLC

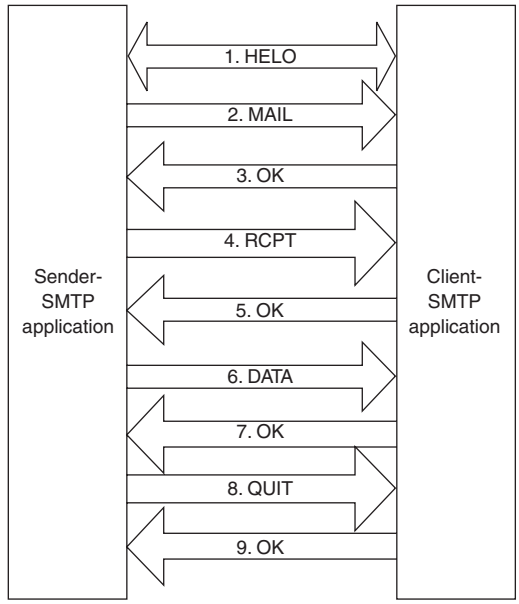

FIGURE 29.2 Basic SMTP Command–Response Sequence.

8. To close the TCP connection, the sender-SMTP application sends a *QUIT* command.
9. The receiver-SMTP application first sends an OK response to the sender-SMTP application, and only then closes the TCP connection.

Note that the sender- and receiver-SMTP applications may negotiate several recipients. When the same message is sent to multiple recipients, the sender-SMTP application tries to transmit only one copy of the data for all the recipients at the same destination host [1].

SMTP Commands

All mail applications developed by vendors have to adhere to the SMTP command and response syntax specified in the standard (RFC821). Commands and replies are not case sensitive. That is, a command or reply word may be upper case, lower case, or any mixture of upper and lower cases. Commands and replies are composed of characters from the ASCII character set. Table 29.1 provides a brief summary of the SMTP commands [1].

There are restrictions on the order in which these command may be used. The first command in a session must be the HELO command. The NOOP, HELP, EXPN, and VRFY commands can be used at any time during a session. The MAIL, SEND, SOML, or SAML commands begin a mail transaction. Once started, a mail transaction consists of one of the transaction beginning commands, one or more RCPT commands, and a DATA command, in that order. A mail transaction may be aborted by the RSET command. There may be zero or more transactions in a session. The last command in a session must be the QUIT command. The QUIT command cannot be used at any other time in a session [1].

Relaying

The *forward-path* consists of the recipient's mailbox identifier and the host name in which the mailbox resides. Sometimes, the forward-path consists of an optional list of hosts and a required destination mailbox. When the list of hosts is present, it is a source route and indicates that the mail must be relayed to the next host on the list. The mailbox is an absolute address, and the route presents information about how to get there.

A receiver-SMTP application checks the host name to determine if the message is intended for itself. If the host name differs from the receiving host's identifier, then the receiver-SMTP can decide to either relay the message or to reject the message.

© 2005 by CRC Press LLC

TABLE 29.1 SMTP Commands

Command	Argument(s)	Description
HELO	The argument field contains the *host name* of the sender-SMTP application.	Identifies the sender-SMTP to the receiver-SMTP.
MAIL	The *reverse-path* is a reverse source routing list of hosts and source mailbox (i.e., a source route from the current location of the message to the originator of the message). This list is used as a source route to report errors and send nondelivery notices to the sender. Refer to section on relaying for more information.	Initiates a mail transaction in which the mail data are delivered to one or more mailboxes. Informs the SMTP-receiver that a new mail transaction is about to begin and to reset all its state tables and buffers, including any recipients or mail data.
RCPT	The *forward-path* consists of an optional list of hosts and a required destination mailbox. When a list of hosts is present, it is a source route and indicates that the mail must be relayed to the next host on the list. Refer to the section on relaying for more information.	Identifies an individual recipient of the mail data. Multiple recipients use multiples of this command.
DATA	The receiver treats the lines following this command as mail data from the sender. This command causes the mail data from this command to be appended to the mail data buffer.	Contains the mail data. A line containing only a period and a carriage-return-line feed indicates the end of mail data.
SEND	Same as for MAIL.	Initiates a mail transaction in which the mail data are delivered to each recipient's terminal. If the recipient is not active (or not accepting terminal messages) on the host, a 450 reply may be returned to an RCPT command. The mail transaction is successful if the message is delivered to the recipient's terminal.
SOML	Same as for MAIL.	SEND or MAIL — Initiates a mail transaction in which the mail data are delivered to each recipient's terminal if the recipient is active (and accepting terminal messages) on the host. If the recipient is not active (or not accepting terminal messages), then the mail data are entered into the recipient's mailbox. The mail transaction is successful if the message is delivered either to the terminal or the mailbox.
SAML	Same as for MAIL.	SEND AND MAIL — Initiates a mail transaction in which the mail data are delivered to the recipient's terminal if the recipient is active (and accepting terminal messages) on the host. The mail data are entered into the recipient's mailbox. The mail transaction is successful if the message is delivered to the mailbox.
RSET	N/A	RESET — specifies that the current mail transaction be aborted.
VRFY	*Destination mail address.*	VERIFY — asks the receiver to confirm that the argument identifies a user.
EXPN	*Destination mail address.*	EXPAND — asks the receiver to confirm that the argument identifies a mailing list, and if so, to return the membership of that list.
HELP	Optional	Causes the receiver to send helpful information to the sender of the HELP command.
NOOP	N/A	Specifies no action other than that the receiver sends an OK reply.
QUIT	N/A	Specifies that the receiver must send an OK reply, and then close the transmission channel.
TURN	N/A	Specifies that the receiver must either (1) send an OK reply and then take on the role of the sender-SMTP or (2) send a refusal reply and retain the role of the receiver-SMTP.

© 2005 by CRC Press LLC

As the message is relayed from one SMTP application to another, the relay host must remove itself from the beginning forward-path and put itself at the beginning of the *reverse-path*. If the relaying host is known by different names in different environments, then the SMTP application uses the name it is known by in the environment it is sending into, not the environment the mail came from. When mail reaches its ultimate destination (the forward-path contains only a destination mailbox), the receiver-SMTP inserts it into the destination mailbox.

If the SMTP application does not implement the relay function, it may use the same reply it would for an unknown local user (550).

If the SMTP application has accepted the task of relaying the mail and later finds that the forward-path is incorrect or that the mail cannot be delivered for whatever reason, then it must construct an "undeliverable mail" notification message and send it to the originator of the undeliverable mail (as indicated by the reverse-path) [1].

Multipurpose Internet Mail Extension (MIME)

SMTP only transmits ASCII text-based messages. It cannot handle non-ASCII messages. To solve this problem, the MIME standard was developed. MIME specifies how attachments and other non-ASCII textual messages are to be associated with e-mail. MIME is a very flexible format, permitting one to include virtually any type of file or document in an e-mail message. To ensure that e-mail messages containing images or other nontext information will be delivered with maximum protection against corruption, MIME provides a way for nontext information to be encoded as text. The encoding method used is known as base64.

How Does MIME Work?

As described previously, an e-mail message consists of a group of bits. The first few bits identify the recipient and sender, followed by the e-mail message and bits that indicate the end of the e-mail. Between the last bit of the e-mail message and the bit that identifies the end of the e-mail are bits that represent the attachment.

An MIME-Version header field uses a version number to declare a message to be conformant with MIME and allows mail-processing agents to distinguish between such messages and those generated by older or nonconformant software, which are presumed to lack such a field. The first few bits of the attachment identify the beginning of it and the type of file that is attached.

A Content-Type header field is used to specify the media type and subtype of data in the body of a message and to fully specify the native representation, (e.g., text, multipart, image, audio, video, or application) of such data. A Content-Transfer-Encoding header field can be used to specify both the encoding transformation that was applied to the body and the domain of the result. Encoding transformations other than the identity transformation are usually applied to data in order to allow it to pass through mail transport mechanisms that may have data or character set limitations. Two additional header fields that can be used to further describe the data in a body are the Content-ID and Content-Description header fields [2].

The five discrete top-level media types are: text, image, audio, video, and application. The two composite top-level media types are: (1) multipart,[2] and (2) message.[3] The five discrete media types provide a standardized mechanism for tagging entities as "audio," "image," or several other kinds of data. The composite "multipart" and "message" media types allow mixing and hierarchical structuring of entities of different types in a single message [3].

When a sender-SMTP application sends a nontext message, it inserts the additional MIME header lines into the message and encodes the binary data in "printable ASCII." The mail message is then transmitted like a text message using SMTP. The receiver-SMTP application interprets the header lines and extracts and decodes the nontext-based part of the message.

[2] Multipart — data consisting of multiple entities of independent data types.

[3] Message — an encapsulated message.

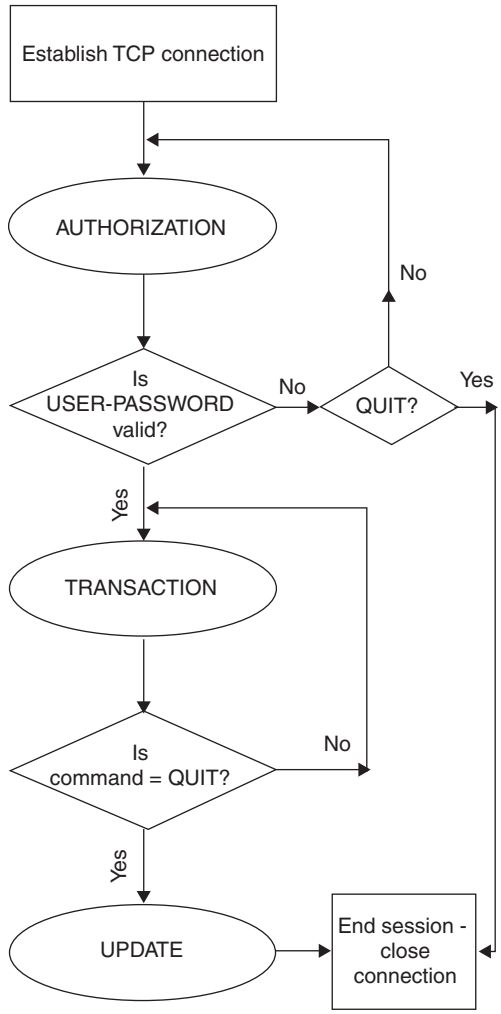

FIGURE 29.3 POP3 session state changes.

Reading Mail — How to Retrieve Mail from the Mailbox?

If every computer required a mail server application running on it in order to receive and send mail, it would turn into a very expensive exercise for most companies and individual user's. A typical user's workstation does not have sufficient resources (cycles, disk space) in order to permit an SMTP server and associated local mail delivery system to be kept resident and continuously running. Also, for individual users, it is expensive to keep a personal computer connected to the Internet for long periods of time.

To solve this problem, a mailbox service was developed, which allows users to use a single dedicated mail server to handle the SMTP send and receive commands. The received mail is stored in individual user's mailboxes. When the user wants to read (or delete) their mail, their client mail application uses either the Post Office Protocol3 (POP3) or Internet Message Access Protocol 4 (IMAP4) to retrieve messages from the user's mailbox on the server system (Figure 29.3).

Post Office Protocol3 (POP3)

POP3 stands for Post Office Protocol Version 3. POP3 allows a client workstation to retrieve mail that the server is holding for it. POP3 is not intended to provide extensive manipulation operations of mail on the server; normally, mail is downloaded and then deleted.

© 2005 by CRC Press LLC

The POP3 architecture requires a POP3 server to be resident on the host computer where the mailboxes are stored. The POP3 server on the host computer runs continuously and listens on TCP port 110. When a client host wishes to make use of the service, it establishes a TCP connection with the server host. When the connection is established, the POP3 server sends a greeting. The client and POP3 server then exchange commands and responses (respectively) until the connection is closed or aborted.

A POP3 session progresses through a number of states during its lifetime. Once the TCP connection has been opened and the POP3 server has sent the greeting, the session enters the AUTHORIZATION state. In this state, the client must identify itself to the POP3 server.

Once the client has been successfully authenticated, the POP3 server acquires an exclusive-access lock on the mailbox. This is necessary to prevent messages from being modified or removed before the session enters the UPDATE state. If the lock is successfully acquired, the POP3 server responds with a positive status indicator. If a lock cannot be acquired or the client is denied access to the appropriate mailbox, the POP3 server returns a negative status indicator. The POP3 server may close the connection. If the server does not close the connection, the client may issue a new authentication command and start again, or the client may issue the QUIT command. After the POP3 server has opened the mailbox, it assigns a message-number to each message, and notes the size of each message in octets.

The POP3 session now enters the TRANSACTION state, with no messages marked as deleted.

The client may now repeatedly issue any of the POP3 commands shown in Table 29.2:

After each command, the POP3 server issues a response. When the client issues the QUIT command, the POP3 session enters the UPDATE state. In this state, the POP3 server releases any resources acquired during the TRANSACTION state and closes the TCP connection [5].

Internet Message Access Protocol 4 (IMAP4)

IMAP4 stands for the Internet Message Access Protocol, Version 4. IMAP4 allows a client to access and manipulate electronic mail messages on a server and supports multiple folders on the server. IMAP4 also provides the capability for an offline client to resynchronize with the server, allows the client to use the mailbox as a semipermanent repository, and can poll an existing connection for newly arrived messages. IMAP4 includes operations for creating, deleting, and renaming mailboxes; checking for new messages; permanently removing messages; setting and clearing flags; RFC 822 and MIME parsing; searching; and selective fetching of message attributes, texts, and portions thereof. Messages in IMAP4 are accessed by the use of numbers [6].

TABLE 29.2 POP3 Commands in the TRANSACTION State

Command	Arguments	Description of POP3 Server response	Restrictions
STAT	None	Server returns information about the mailbox.	Only valid if in TRANSACTION state
LIST [optional]	Message number	Returns information about the specified message, or if no message number specified, returns the total number of messages and a list of the messages.	Only valid if in TRANSACTION state
RETR	Message number	Sends the specified message.	Only valid if in TRANSACTION state
DELE	Message number	Marks specified message as deleted.	Only valid if in TRANSACTION state
NOOP	None	Server does nothing, returns positive response	Only valid if in TRANSACTION state
RSET	None	Unmarks any messages marked as deleted.	Only valid if in TRANSACTION state
QUIT	None	Removes all messages marked as deleted from the mailbox, releases the exclusive lock on the mailbox, and closes the TCP connection.	None

© 2005 by CRC Press LLC

TABLE 29.3 IMAP4 Commands in the AUTHENTICATED States

Command	Argument(s)	Description
SELECT	Mailbox name	Selects a mailbox so that messages in the mailbox can be accessed.
EXAMINE	Mailbox name	Select a mailbox for read-only access.
CREATE	Mailbox name	Creates a mailbox with a given name.
DELETE	Mailbox name	Remove the specified mailbox.
RENAME	Existing mailbox name, new mailbox name	Changes the name of a mailbox.
SUBSCRIBE	Mailbox name	Adds specified mailbox name to server's set of "active" mailboxes to prevent a mailbox from being deleted after its contents expire.
UNSUBSCRIBE	Mailbox name	Remove specified mailbox name from server's set of "active" mailboxes.
LIST	Reference name or mailbox name	Returns a subset of mailbox names from the complete set of all names available to the client.
LSUB	Reference name or mailbox name	Returns a subset of mailbox names from the set of names the user has declared as being "active."
STATUS	Mailbox name and status data items	Requests the status, that is, number of messages, size, etc., of the specified mailbox.
APPEND	Mailbox name and message literal	Appends the literal argument as a new message to the end of the specified destination mailbox.

The IMAP4 architecture requires an IMAP4 server to be resident on the host computer where the mailboxes are stored. The IMAP4 server on the host computer runs continuously and listens on TCP port 143. When a client host wishes to make use of the service, it establishes a TCP connection with the server host. When the connection is established, the IMAP4 server sends a greeting. The client and IMAP4 server then exchange commands and responses (respectively) until the connection is closed or aborted. IMAP4 uses textual commands and responses. Most commands are valid in only certain states.

An IMAP4 session can be in one of four states during the lifetime of the connection. After a connection is established, the IMAP4 server is in a NON-AUTHENTICATED state. In this state, the client can issue either an AUTHENTICATE command, which indicates the authentication mechanism the client would like to use, or the LOGIN command, which identifies the client to the server with a user name and password.

If the client provides valid authentication credentials, the server moves to the AUTHENTICATED state. In this state, the commands shown in Table 29.3 are permitted.

If the client/user sends either the SELECT or EXAMINE command to the server, the server moves to the SELECTED state. A valid mailbox must be selected; if the client/user does not select a valid mailbox, the server stays in the AUTHENTICATED state. In the SELECTED state, the server will accept the commands shown in Table 29.4.

When the client/user has finished, he requests that the session be terminated. The server moves to the LOGOUT state and closes the connection.

Figure 29.4 provides an overview of the IMAP4 session state changes [6].

The state changes in Figure 29.4 are as follows:

1. Connection without pre-authentication (OK greeting).
2. Pre-authenticated connection (PREAUTH greeting).
3. Rejected connection (BYE greeting).
4. Successful LOGIN or AUTHENTICATE command.
5. Successful SELECT or EXAMINE command.
6. CLOSE command, or failed SELECT or EXAMINE command.
7. LOGOUT command, server shutdown, or connection closed [6].

TABLE 29.4 IMAP4 Commands in the SELECTED State

Command	Argument(s)	Description
CHECK	None	Requests a system resource type check of the selected mailbox. This checkpoint refers to any implementation-dependent housekeeping associated with the mailbox (e.g., resolving the server's in-memory state of the mailbox with the state on its disk) that is not normally executed as part of each command.
CLOSE	None	Permanently removes from mailbox all messages that have the deleted flag set and returns to the AUTHENTICATED state.
EXPUNGE	None	Permanently removes from mailbox all messages that have the deleted flag set.
SEARCH	Searching criteria [optional]	Searches a mailbox for messages that match the given search criteria.
FETCH	Message set and message data items	Retrieves either all data or specific data items (e.g., header) associated with a message.
STORE	Message set, message data items, and value for message data item	Alters data associated with a message in the mailbox.
COPY	Mailbox name and message set	Copies the specified message(s) to the end of the specified destination mailbox.

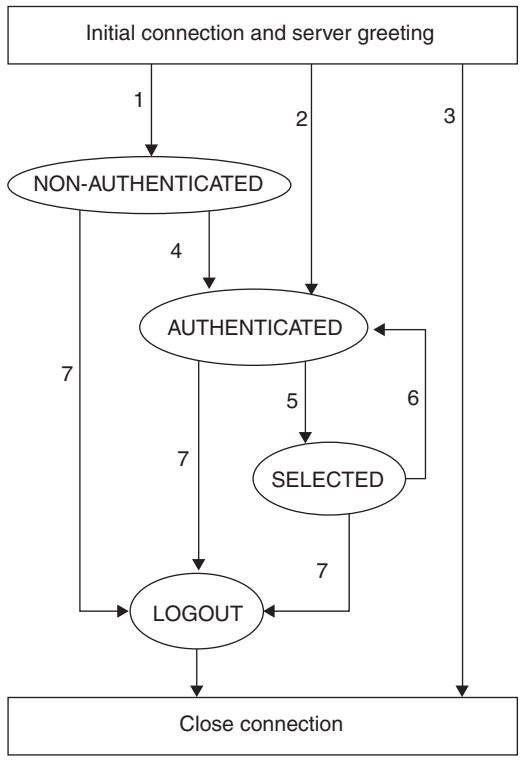

FIGURE 29.4 IMAP4 session state changes.

29.2 File Transfer Protocol

Introduction

The File Transfer Protocol (FTP) is a protocol used for transferring files between interconnected computers. FTP makes use of TCP/IP as the mechanism for communicating between the networked computers.

© 2005 by CRC Press LLC

The main FTP objectives are to [7]

- promote sharing of files (computer programs and/or data),
- encourage indirect or implicit (via programs) use of remote computers,
- shield a user from variations in file storage systems among hosts, and
- transfer data reliably and efficiently.

FTP Model

FTP is a client–server-type application. The FTP server resides on the computer that stores the files. The FTP client can reside on any workstation. The FTP server listens for client connection requests on the specified port number (default is port 21). The FTP client needs to log in to both hosts (e.g., client workstation and remote host) in order to transfer a file from one to the other. To retrieve a specific file, the FTP client needs to know the host the file is located on, and the path name (the directory and possibly subdirectories and the file name) of the file. A user of the FTP client also needs to know if the user's machine uses ASCII, EBCDIC, or other character set to specify the data representation when transferring information.

A typical FTP session includes:

- Initiate a connection to the host, using an FTP client. The host name could either be the domain name or the host's IP address.
- Log into the FTP server, providing a valid user name and password for the server. A valid user name may also include the anonymous user name for servers that provide anonymous access.
- Issue the necessary FTP commands. Some command would be navigation commands and some actual transfer commands.
- When done, quit the client or the close the connection to the host.

Figure 29.5 shows the FTP model.

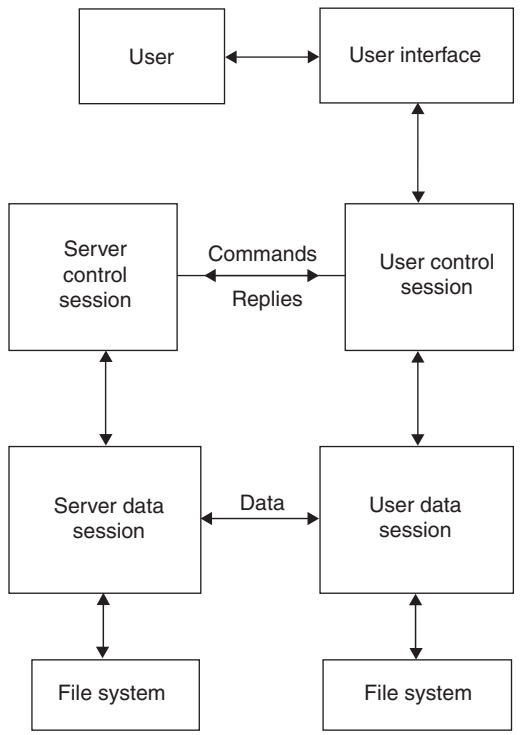

FIGURE 29.5 FTP model [7].

© 2005 by CRC Press LLC

The FTP protocol has two sessions: a control and a data session; both sessions are implemented using TCP/IP connections.

The control session is initiated by the client and is used for client commands and server responses. It is over this session that all user commands are sent and over this session that the client gets the necessary server feedback. The FTP user interacts with this session. The control session's commands and responses are text commands.

The data session is initiated by the server and is used for transferring the actual data from the server to the required destination. A data session does not have to connect to the originating client; in fact, the client can initiate a transfer between two servers.

Data Types

FTP requires the user to specify the representation of data contained in a file when a file is transferred between two computers. The default data type is ASCII; but a user can specify other file types such as EBCDIC, IMAGE, or BINARY data types.

Transmission Mode

The transfer byte size is 8-bit bytes. The completion of all data transfers is indicated either by an end-of-file (EOF) or by closing the data connection.

The following transmission modes are defined in FTP:

Stream Mode: transmits data as a stream of bytes, with little or no processing.

Block Mode: formats data into a series of data blocks and allows for restarts.

Compressed Mode: compresses data for efficient data transfer.

Common FTP Commands

FTP has many commands, and those listed in Table 29.5 are a subset of the most commonly used commands out of all commands available from the FTP specification.

The commands are Telnet character strings transmitted over the control connections. The commands begin with a command code followed by an argument field.

Note that the filenames in brackets are optional. If they are omitted, the receiving file will be created with the same name it has on the originating machine. Other commands can be found by typing *help* at the FTP command prompt.

TABLE 29.5 Common FTP Commands

Command	Argument(s)	Description
Ascii	None	Set the file transfer type to network ASCII (use when transferring text files).
binary	None	Set the file transfer type to support binary image transfer (use for all other files).
Cd	remote_directory	Change the working directory on the remote machine.
Dir	[remote_directory]	Print a local directory listing. Include size and date information.
Ls	[remote_directory]	Print a listing of the directory contents in remote_directory.
Get	remote_file [local_file]	Retrieves remote_file and stores it locally. If local_file is not specified, give it the same name it has on the remote machine.
Mget	remote_file1 remote_file2 …	Retrieve multiple remote files and stores them locally.
Help	[command]	Print an informative message about the meaning of command or a list of known commands.
Put	local_file [remote_file]	Store a local file on the remote machine. If remote_file is left unspecified, give it the same name it has on the local machine.
Mput	local_file1 local_file2 …	Store multiple local files on the remote machine.
Quit	None	Quit FTP and return to the shell.

© 2005 by CRC Press LLC

Anonymous FTP

Certain servers provide a service to clients where archives and files are publicly available. The archives are accessible using FTP. Since the data are provided as a public service, general access to the archive sites is allowed. The archive site implements what is known as anonymous FTP.

Anonymous FTP is actually FTP; but the user name and password are publicly available. The common user name for anonymous FTP is "anonymous" and the password may be any string (it is usually the user's e-mail address).

The anonymous user on the archive site is created with limited rights to the host; normally, the only operations allowed are logging in using FTP, listing the contents of a limited set of directories, and retrieving files. A user is not normally allowed to transfer files to the archive site [8].

29.3 Conclusion

The mail transfer protocols, SMTP, POP3, and IMAP4, provide the functionality required to send and receive e-mail. This mail system works in a manner very similar to the postal system except that instead of a physical letter enclosed in a physical envelope and transported via road, rail, or air transport systems, the e-mail message consists of electronic bits enclosed in a digital envelope, which is transported over a digital communications network called the Internet.

Most vendors wrap a user interface around the mail transfer protocols, thus hiding most of the underlying functionality from the user. Typical examples of vendor mail applications are Microsoft Outlook and Netscape Mail. These applications provide additional functionality such as meeting requests, meeting reminders, and planning tools that do not form part of the mail transfer protocol specification.

The FTP is still widely used by users on the Internet to retrieve files from remote archive storage sites. Users also use FTP on local networks to easily move files between computers.

30.1 Introduction

The Hypertext Transfer Protocol (HTTP) is an application-level protocol for distributed, collaborative, hypermedia information systems. It is a generic, stateless, protocol that can be used for many tasks beyond its use for hypertext, such as name servers and distributed object management systems, through extension of its request methods, error codes, and headers. A feature of HTTP is the typing and negotiation of data representation, allowing systems to be built independent of the data being transferred. This chapter explains HTTP by example and also considers the Uniform Resource Identifiers (URIs, aka URLs) as short strings that identify resources in the Web.

© 2005 by CRC Press LLC

30.2 The Context of the Hypertext Transfer Protocol

During the early Internet days, information was gathered using File Transfer Protocol (FTP) and Telnet was used for sessions, which proved to be a user-unfriendly way of interaction or searching information. However, since the majority of people on the net were computer literate, this did not prove to be too much of a problem. Things became quite different with the Web: Tim Berners-Lee proposed the first version of Hypertext Markup Language (HTML) in 1989,[1] and the first server and browser prototypes came into existence between 1990 and 1992. From then on, the Web led to an exponential growth of the Internet: in June 1991, about 500.000 nodes were recorded worldwide. As of June 1998, there were about 35 millions nodes recorded, and the monthly growth rate was about 1 million worldwide. Thus, the monthly growth rate far exceeded the total number of nodes only 7 years ago.

The main reasons for the exponential growth rate that the Web caused were the easy-to-use point-and-click graphical user interface and the integration of all relevant services into one tool — the Web browser. As more and more Web servers appeared all over the world, the number of users accessing them also increased.

Mainly, three concepts make up the Web and are responsible for its success: The Hypertext Markup Language (HTML), the Uniform Resource Locator (URL), and the Hypertext Transfer Protocol (HTTP). As HTML is described in a separate chapter, here, we briefly introduce the concept of URLs before focusing on HTTP.

30.3 Uniform Resource Locator and Identifier

Titled "Naming and Adressing," the W3C defines the more general term "Uniform Resource Identifier" (URI) as "the generic set of all names/addresses that are short strings that refer to resources" (http://www.w3.org/Addressing/):

> *The Web is an information space. Human beings have a lot of mental machinery for manipulating, imagining, and finding their way in spaces. URIs are the points in that space. Unlike web data formats, where HTML is an important one, but not the only one, and web protocols, where HTTP has a similar status, there is only one Web naming/addressing technology: URIs.*
>
> *Uniform Resource Identifiers (URIs, aka URLs) are short strings that identify resources in the web: documents, images, downloadable files, services, electronic mailboxes, and other resources. They make resources available under a variety of naming schemes and access methods such as HTTP, FTP, and Internet mail addressable in the same simple way. They reduce the tedium of "log in to this server, then issue this magic command ..." down to a single click.*
>
> *It is an extensible technology: there are a number of existing addressing schemes, and more may be incorporated over time.*

Another important term is the "Uniform Resource Name" URN:

1. A URI that has an institutional commitment to persistence, availability, etc. Note that this kind of URI may also be a URL. See, for example, PURLs.
2. A particular scheme, `urn:`, specified by RFC 2141 and related documents, intended to serve as persistent, location-independent, resource identifiers.

Consequently, the URL becomes an informal term (no longer used in technical specifications) associated with popular URI schemes for specifying Internet resources: `http, ftp, mailto,` etc.

The "generic URI" syntax (RFC 2396) consists of a sequence of four main components:

```
<scheme>://<authority><path>?<query>
```

The *scheme* covers all major Internet protocols, typically `http` or `https` (HTTP over Secure Sockets Layer SSL), but also `file` (Host-specific file names), `ftp` (File Transfer Protocol), `ldap` (Lightweight

[1] Although the term hypertext was initially coined in the 1960s, its popularity first grew when the Web was invented.

© 2005 by CRC Press LLC

Directory Access Protocol), mailto (Electronic mail address), news (USENET news), nfs (Netfork File System), nntp (Network News Transfer Protocol), pop (Post Office Protocol v3), sip (Session Initiation Protocol), and telnet (Reference to interactive sessions). As of October 2002, the W3C lists 85 schemes, with only some of them being registered (http://www.w3.org/Addressing/schemes). RFCs 2717 and 2718 provide registration procedures for scheme names and guidelines for new schemes, respectively.

For schemes that involve the direct use of an IP-based protocol to a specified server on the Internet, the *authority* looks like <userinfo>@<host>:<port>, where <userinfo> may consist of a user name and optionally, scheme-specific information about how to gain authorization to access the server.[2] The parts <userinfo>@ and:<port> may be omitted. The host is a domain name of a network host (RFCs 1034, 1123), or its IPv4 address as a set of four decimal digit groups separated by dots. The port is the network port number for the server. Most schemes designate protocols that have a default port number. Another port number may optionally be supplied, in decimal, separated from the host by a colon. If the port is omitted, the default port number ("well-known port") is assumed, for example, 80 for HTTP or 443 for HTTPS.

The *path* component contains data, specific to the authority, identifying the resource within the scope of that scheme and authority. In the case of HTTP, it is either a file system path relative to the document root of the respective Web server, or the path has a special, preconfigured meaning for the Web server (e.g., a server-side application).

The *query* component is a string of information to be interpreted by the resource. In the case of HTML and HTTP, this may be a set of name–value pairs resulting from a FORM with the GET method, a list of names separated by plus signs resulting from an ISINDEX query, or a comma-separated pair of *x*- and *y*-pixel coordinates resulting from an active server-side imagemap (ISMAP).

It is often the case that a group or "tree" of documents has been constructed to serve a common purpose; the vast majority of URI in these documents point to resources within the tree rather than outside of it. Similarly, documents located at a particular site are much more likely to refer to other resources at that site than to resources at remote sites.

Relative addressing of URI allows document trees to be partially independent of their location and access scheme. For instance, it is possible for a single set of hypertext documents to be simultaneously accessible and traversable via each of the file, http, and ftp schemes if the documents refer to each other using relative URI. Furthermore, such document trees can be moved, as a whole, without changing any of the relative references. Experience within the WWW has demonstrated that the ability to perform relative referencing is necessary for the long-term usability of embedded URI.

A URI reference may therefore be absolute or relative, and may have additional information attached in the form of a fragment identifier (following the hash character #). However, "the URI" that results from such a reference includes only the absolute URI after the fragment identifier (if any) is removed and after any relative URI is resolved to its absolute form.

The following examples show typical HTTP URIs:

```
http://some.where.edu/path/mydocument.html#fragment_id
```

This URI accesses the server some.where.edu via "well-known" port 80 with the protocol HTTP. Considering a standard Web server configuration, this would result in the delivery of the document mydocument.html in the directory path relative to the document root of the Web server. The browser would then open the page and jump to the place in the document, which is marked with the appropriate anchor tag <a name="fragment_id">.

```
../stuff/other.html
```

Based on the previous URI, this relative URI would result in the following absolute URI:

```
http://some.where.edu/stuff/other.html
```

[2] This practice of using passwords within the URI is *not recommended*, because the passing of authentication information in clear text (such as URI) has proven to be a security risk in almost every case where it has been used.

© 2005 by CRC Press LLC

The following three URIs show possible usages of the query string: the first URI results from pressing the "submit" button of an HTML `FORM`, which is declared using the `GET` method. In this case, the name/value pairs of the form inputs are described. The second URI results from an `ISINDEX` query and enumerates the arguments, and the third URI from a server-side active imagemap `(ISMAP)`, which provides the coordinates in pixels from the upper left corner, where within the image the "click" took place.

```
http://some.where.edu:33333/app/program?a=1&b=2
```

```
http://some.where.edu:33333/app/search?arg1+arg2+arg3
```

```
http://some.where.edu:33333/app/imagemap?123,45
```

Usually, the resources in these cases are server-side applications prepared to process the incoming query string in order to generate the following HTML document.

30.4 Overall Operation of HTTP

The HTTP is an application-level protocol for distributed, collaborative, hypermedia information systems. It is a generic, stateless protocol that can be used for many tasks beyond its use for hypertext, such as name servers and distributed object management systems, through extension of its request methods, error codes, and headers. A feature of HTTP is the typing and negotiation of data representation, allowing systems to be built independent of the data being transferred. HTTP has been in use by the World Wide Web global information initiative since 1990.

This definition and parts of further explanations are taken from RFC 2616, which defines the protocol referred to as "HTTP/1.1," and is an update to RFC 2068. An overview of the RFCs and other documents relevant for HTTP is provided by the World Wide Web Consortium under `http://www.w3.org/Protocols/`.

The HTTP protocol is a request/response protocol. A client sends a request to the server in the form of a request method, URI, and protocol version, followed by a MIME-like message containing request modifiers, client information, and possible body content over a connection with a server. The server responds with a status line, including the message's protocol version and a success or error code, followed by a MIME-like message containing server information, entity metainformation, and possible entity-body content. An entity is the information transferred as the payload of a request or response. An entity consists of metainformation in the form of entity-header fields and content in the form of an entity-body.

Most HTTP communication is initiated by a user agent and consists of a request to be applied to a resource on some origin server. In the simplest case, this may be accomplished via a single connection between the user agent and the origin server.

A more complicated situation occurs when one or more intermediaries are present in the request/response chain. There are three common forms of intermediary: proxy, gateway, and tunnel. A proxy is a forwarding agent, receiving requests for a URI in its absolute form, rewriting all or part of the message, and forwarding the reformatted request toward the server identified by the URI. A gateway is a receiving agent, acting as a layer above some other server(s) and, if necessary, translating the requests to the underlying server's protocol. A tunnel acts as a relay point between two connections without changing the messages; tunnels are used when the communication needs to pass through an intermediary (such as a firewall) even when the intermediary cannot understand the contents of the messages.

A request or response message that travels the whole chain will pass through several separate connections. This distinction is important because some HTTP communication options may apply only to the connection with the nearest, nontunnel neighbor, only to the end points of the chain, or to all connections along the chain. Moreover, each participant in a certain chain may be engaged in multiple, simultaneous communications.

Any party to the communication that is not acting as a tunnel may employ an internal cache for handling requests. The effect of a cache is that the request/response chain is shortened if one of the partici-

© 2005 by CRC Press LLC

pants along the chain has a cached response applicable to that request. Not all responses are usefully cacheable, and some requests may contain modifiers that place special requirements on cache behavior.

In fact, there are a wide variety of architectures and configurations of caches and proxies currently being experimented with or deployed across the World Wide Web. These systems include national hierarchies of proxy caches to save transoceanic bandwidth, systems that broadcast or multicast cache entries, organizations that distribute subsets of cached data via CD-ROM, and so on. HTTP systems are used in corporate intranets over high-bandwidth links, and for access via PDAs with low-power radio links and intermittent connectivity. The goal of HTTP/1.1 is to support the wide diversity of configurations already deployed while introducing protocol constructs that meet the needs of those who build Web applications that require high reliability and, failing that, at least reliable indications of failure.

HTTP communication usually takes place over TCP/IP connections. The default port is TCP 80 (RFC 1700); but other ports can be used. This does not preclude HTTP from being implemented on top of any other protocol on the Internet, or on other networks. HTTP only presumes a reliable transport; any protocol that provides such guarantees can be used; the mapping of the HTTP/1.1 request and response structures onto the transport data units of the protocol in question is beyond the scope of this specification.

In HTTP/1.0, most implementations used a new connection for each request/response exchange. In HTTP/1.1, a connection may be used for one or more request/response exchanges, although connections may be closed for a variety of reasons. Therefore, HTTP should be treated as a connection-oriented but stateless protocol.

30.5 Protocol Parameters

The HTTP uses various parameters; the following section explains the most important ones, and details can be found in RFC 2616.

HTTP Version

HTTP request and response messages include an HTTP protocol version number. The protocol versioning policy is intended to allow the sender to indicate the format of a message and its capacity for understanding further HTTP communication, rather than the features obtained via that communication. No change is made to the version number for the addition of message components that do not affect communication behavior or that only add to extensible field values. The HTTP version of an application is the highest HTTP version for which the application is at least conditionally compliant. Proxy and gateway applications need to be careful when forwarding messages in protocol versions different from that of the application, because converting between versions of HTTP may involve modification of header fields required or forbidden by the versions involved. See RFC 2145 for a more complete explanation.

URI

As far as HTTP is concerned, URI are simply formatted strings which identify — via name, location, or any other characteristic — a resource.

Date/Time

HTTP applications have historically allowed three different formats for the representation of date/time stamps, but a fixed-length subset of that defined by RFC 1123 (an update to RFC 822) is preferred as an Internet standard. All HTTP date/time stamps must be represented in GMT (Greenwich Mean Time), without exception. For the purposes of HTTP, GMT is exactly equal to Universal Time Coordinated (UTC). The format looks like:

```
Sat, 26 Oct 2002 15:58:04 GMT
```

© 2005 by CRC Press LLC

Character Sets

HTTP uses the same definition of the term "character set" as that described for MIME, which is more commonly referred to as a "character encoding." HTTP character sets are identified by case-insensitive tokens. The complete set of tokens is defined by the IANA Character Set registry (RFC 1700), for example: `charset=iso-8859-1`.

Content Codings

Content-coding values indicate an encoding transformation that has been or can be applied to an entity. Content codings are primarily used to allow a document to be compressed or otherwise usefully transformed without losing the identity of its underlying media type and without loss of information. Frequently, the entity is stored in coded form, transmitted directly, and only decoded by the recipient. HTTP/1.1 uses content-coding values in the `Accept-Encoding` and `Content-Encoding` header fields. Although the value describes the content-coding, what is more important is that it indicates what decoding mechanism will be required to remove the encoding. Examples are `gzip` (RFC 1952), `compress` (UNIX file compression program), and `deflate` (RFCs 1950, 1951).

Transfer-Codings

Transfer-coding values are used to indicate an encoding transformation that has been, can be, or may need to be applied to an entity-body in order to ensure "safe transport" through the network. This differs from a content coding in that the transfer-coding is a property of the message, not of the original entity. An example is `Transfer-Encoding: chunked`, which modifies the body of a message in order to transfer it as a series of chunks, each with its own size indicator, followed by an optional trailer containing entity-header fields. This allows dynamically produced content to be transferred along with the information necessary for the recipient to verify that it has received the full message.

Media Types

HTTP uses Internet Media Types in the `Content-Type` and `Accept` header fields in order to provide open and extensible data typing and type negotiation. Media-type values are registered with the Internet Assigned Number Authority (RFC 1700). The media-type registration process is outlined in RFC 1590. The use of nonregistered media types is discouraged. Typical media types for use with HTTP are: `text/html`, `image/gif`, `message/http` (e.g., response on `TRACE` request), `multipart/byteranges` (`HTTP 206 (Partial Content)` response), and `application/x-www-form-urlencoded` (`POST` request resulting from an HTML `FORM`).

Product Tokens

Product tokens are used to allow communicating applications to identify themselves by software name and version. Examples are as follows:

```
User-Agent: Mozilla/4.0 (compatible; MSIE 5.01; Windows NT 5.0)
Server: Apache/1.3.23 (Unix) (Red-Hat/Linux) mod_ssl/2.8.7 OpenSSL/0.9.6b
DAV/1.0.3 PHP/4.1.2 mod_perl/1.26
```

Quality Values

HTTP content negotiation uses short "floating point" numbers to indicate the relative importance ("weight") of various negotiable parameters. A weight is normalized to a real number in the range 0 through 1, where 0 is the minimum and 1 is the maximum value. If a parameter has a quality value of 0,

© 2005 by CRC Press LLC

then content with this parameter is 'not acceptable' for the client. "Quality values" is a misnomer, since these values merely represent relative degradation in desired quality.

Language Tags

A language tag identifies a natural language spoken, written, or otherwise conveyed by human beings for communication of information to other human beings. Computer languages are explicitly excluded. HTTP uses language tags within the `Accept-Language` and `Content-Language` fields. The syntax and registry of HTTP language tags are the same as those defined by RFC 1766. Example tags include: `en, en-us, de-at`, where any two-letter primary-tag is an ISO-639 language abbreviation and any two-letter initial subtag is an ISO-3166 country code.

30.6 HTTP Message

HTTP messages consist of requests from client to server and responses from server to client. Request and response messages use the generic message format of RFC 822 for transferring entities (the payload of the message). Both types of message consist of a start-line, zero, or more header fields (also known as "headers"), an empty line (i.e., a line with nothing preceding the CRLF) indicating the end of the header fields, and possibly a message-body.

HTTP header fields, which include general- , request- , response- , and entity-header fields, follow the same generic format as that given in Section 3.1 of RFC 822. Each header field consists of a name followed by a colon (":") and the field value. General-header fields have general applicability for both request and response messages, but do not apply to the entity being transferred. These header fields apply only to the message being transmitted. Entity-header fields define metainformation about the entity-body or, if no body is present, about the resource identified by the request. Some of this metainformation is *optional*; some might be *required*. Request and response header fields are described in the next section.

The message-body (if any) of an HTTP message is used to carry the entity-body associated with the request or response. The message-body differs from the entity-body only when a transfer coding has been applied, as indicated by the `Transfer-Encoding` header field. The rules for when a message-body is allowed in a message differ for requests and responses. The transfer-length of a message is the length of the message-body as it appears in the message, that is, after any transfer-codings have been applied.

30.7 Request and Response

A request message from a client to a server includes, within the first line of that message, the method to be applied to the resource, the identifier of the resource, and the protocol version in use. Figure 30.1 shows a simple GET request:

The request-line begins with a method token, followed by the request-URI, and the protocol version. The method token indicates the method to be performed on the resource identified by the request-URI. Possible method tokens are `GET`, `HEAD`, `POST`, `OPTIONS`, `TRACE`, `CONNECT`, `PUT`, and `DELETE`.

```
GET /first.html HTTP/1.1
Accept: image/gif, image/x-xbitmap, image/jpeg, image/pjpeg, application/vnd.ms-
powerpoint, application/vnd.ms-excel, application/msword, */*
Accept-Language: de-at
Accept-Encoding: gzip, deflate
User-Agent: Mozilla/4.0 (compatible; MSIE 5.01; Windows NT 5.0)
Host: gutemine.ict.tuwien.ac.at:33333
Connection: Keep-Alive
```

FIGURE 30.1 Simple GET Request.

© 2005 by CRC Press LLC

The `GET` method means retrieve whatever information (in the form of an entity) is identified by the request-URI. If the request-URI refers to a data-producing process, it is the produced data that shall be returned as the entity in the response and not the source text of the process, unless that text happens to be the output of the process.

The request-header fields allow the client to pass additional information about the request, and about the client itself, to the server. These fields act as request modifiers, with semantics equivalent to the parameters on a programming language method invocation.

The `Accept` request-header field can be used to specify certain media types that are acceptable for the response. Accept headers can be used to indicate that the request is specifically limited to a small set of desired types, as in the case of a request for an in-line image. The `Accept-Language` request-header field is similar to `Accept`, but restricts the set of natural languages that are preferred as a response to the request. The `Accept-Encoding` request-header field is similar to `Accept`, but restricts the content-codings that are acceptable in the response.

The `User-Agent` request-header field contains information about the user agent originating the request. This is for statistical purposes, the tracing of protocol violations, and automated recognition of user agents for the sake of tailoring responses to avoid particular user-agent limitations.

The `Host` request-header field specifies the Internet host and port number of the resource being requested, as obtained from the original URI given by the user or referring resource (generally an HTTP URL). The Host field value must represent the naming authority of the origin server or gateway given by the original URL. This allows the origin server or gateway to differentiate between internally ambiguous URLs, such as the root "/" URL of a server for multiple host names on a single IP address (virtual hosting).

The `Connection` general-header field allows the sender to specify options that are desired for that particular connection and must not be communicated by proxies over further connections. Although since HTTP/1.1 persistent connections are the default behavior of any HTTP connection, this header field explicitly demands a persistent connection by using the original HTTP/1.0 form of persistent connections (RFC 2068).

Persistent HTTP connections have a number of advantages:

- By opening and closing fewer TCP connections, CPU time is saved in routers and hosts (clients, servers, proxies, gateways, tunnels, or caches), and memory used for TCP protocol control blocks can be saved in hosts.
- HTTP requests and responses can be pipelined on a connection. Pipelining allows a client to make multiple requests without waiting for each response, allowing a single TCP connection to be used much more efficiently, with much lower elapsed time.
- Network congestion is reduced by reducing the number of packets caused by TCP opens, and by allowing TCP sufficient time to determine the congestion state of the network.
- Latency on subsequent requests is reduced since there is no time spent in TCP's connection opening handshake.
- HTTP can evolve more gracefully, since errors can be reported without the penalty of closing the TCP connection. Clients using future versions of HTTP might optimistically try a new feature, but if communicating with an older server, retry with old semantics after an error is reported.

The response onto the request of Figure 30.1 then may look like Figure 30.2, resulting in a browser view given in Figure 30.3.

After receiving and interpreting a request message, a server responds with an HTTP response message. The first line of a response message is the status-line, consisting of the protocol version followed by a numeric status code and its associated textual phrase. The status-code element is a 3-digit integer result code of the attempt to understand and satisfy the request. These codes are fully defined in RFC 2616. The reason-phrase is intended to give a short textual description of the status-code. The status-code is intended for use by automata and the reason-phrase is intended for the human user. The client is not required to examine or display the reason-phrase. The first digit of the status-code defines the class of response. The last two digits do not have any categorization role. There are 5 values for the first digit:

       of my collection.
  </BODY>
</HTML>
```

FIGURE 30.2 Response.

FIGURE 30.3 Resulting browser view.

- 1xx: Informational — Request received, continuing process.
- 2xx: Success — The action was successfully received, understood, and accepted.
- 3xx: Redirection — Further action must be taken in order to complete the request.
- 4xx: Client Error — The request contains bad syntax or cannot be fulfilled.
- 5xx: Server Error — The server failed to fulfill an apparently valid request.

The response-header fields allow the server to pass additional information about the response, which cannot be placed in the status-line. These header fields give information about the server and about further access to the resource identified by the request-URI.

The `Date` general-header field represents the date and time at which the message was originated, having the same semantics as orig-date in RFC 822. The field value is an HTTP-date; it *must* be sent in RFC 1123-date format.

The `Server` response-header field contains information about the software used by the origin server to handle the request. The field can contain multiple product tokens and comments identifying the server and any significant subproducts. The product tokens are listed in order of their significance for identifying the application. *Note*: Revealing the specific software version of the server might allow the server machine to become more vulnerable to attacks against software that is known to contain security holes. Server implementors are therefore encouraged to make this field a configurable option.

The `Keep-Alive` and `Connection` headers are used here only for compatibility reasons with HTTP/1.0 Persistent Connections (see RFC 2068).

The `Content-Type` entity-header field indicates the media type of the entity-body sent to the recipient or, in the case of the `HEAD` method, the media type that would have been sent had the request been a `GET`.

The message body finally contains the HTML page displayed in Figure 30.3.

FIGURE 30.4 Request.

30.8 Authentication: Basic and Digest Access

Authentication is described in RFC 2617. The "basic" authentication scheme is based on the model that the client must authenticate itself with a user-ID and a password for each realm. The realm value should be considered an opaque string, which can only be compared for equality with other realms on that server. The server will service the request only if it can validate the user-ID and password for the protection space of the request-URI. There are no optional authentication parameters. Assume that the link in Figure 30.3 is utilized, resulting in the following request (Figure 30.4).

The `Referer` request-header field allows the client to specify, for the server's benefit, the address (URI) of the resource from which the request-URI was obtained (the "referrer," although the header field is misspelled). The `Referer` request-header allows a server to generate lists of back-links to resources for interest, logging, optimized caching, etc. It also allows obsolete or mistyped links to be traced for maintenance. The Referer field *must not* be sent if the request-URI was obtained from a source that does not have its own URI, such as input from the user keyboard. Therefore, we can see the `Referer` here for the first time.

Now we assume the resource `second.html` to be protected in a protection space called "`Administration Group`." Upon receipt of an unauthorized request for a URI within the protection space, the origin server may respond with a challenge like the following (see Figure 30.5):

```
WWW-Authenticate: Basic realm="Administration Group"
```

The `WWW-Authenticate` response-header field must be included in 401 (Unauthorized) response messages. The field value consists of at least one challenge that indicates the authentication scheme(s) and parameters applicable to the request-URI. Usually, the client now has to prompt the user for his username and password (see Figure 30.6). If the client is not capable of promting the user or if the request fails for any other reason, the HTML page is displayed, since that entity might include relevant diagnostic information.

To receive authorization, the client sends the userid and password, separated by a single colon (":") character, within a base64-encoded string in the credentials. If the client wishes to send the userid "myname" and the password "mypasswd," it would use the following header field:

```
Authorization: Basic bXluYW1lOm15cGFzc3dk
```

The following request would be similar to Figure 30.4, with the above header line added. If username and password were correct, the server would respond appropriately. The Basic Access Authentication scheme is not considered to be a secure method of user authentication (unless used in conjunction with some external secure system such as SSL), as the user name and password are passed over the network as uuencoded cleartext. Therefore, a scheme based on cryptographic hashes, referred to as "Digest Access Authentication," is proposed for better security (RFC 2617).

30.9 Caching and Proxies

HTTP is typically used for distributed information systems, where performance can be improved by using response caches. The HTTP/1.1 protocol includes a number of elements intended to make caching

    </ADDRESS>
  </BODY>
</HTML>
```

FIGURE 30.5 Authorization required.

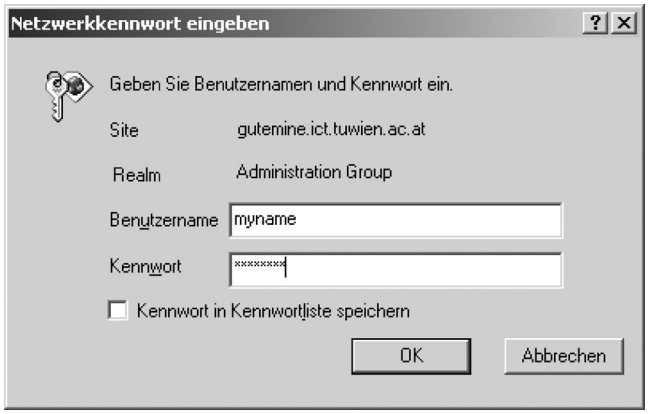

FIGURE 30.6 The client prompts the user for username and password.

work as well as possible. Caching would be useless if it did not significantly improve performance. The goal of caching in HTTP/1.1 is to eliminate the need to send requests in many cases, and to eliminate the need to send full responses in many other cases. The former reduces the number of network round-trips required for many operations; the protocol uses an "expiration" mechanism for this purpose. The latter reduces network bandwidth requirements; the protocol uses a "validation" mechanism for this purpose.

Figure 30.7 shows a `GET` request being sent to a proxy server instead of being sent to the origin server `gutemine.ict.tuwien.ac.at`; therefore, the request-URI in the request-line contains not just path and query, but also scheme and authority. In general, a chain of proxy servers is possible. In our example, the proxy server now forwards the request to the origin server, which is shown in Figure 30.8.

We recognize a new header field: the `Via` general-header field *must* be used by gateways and proxies to indicate the intermediate protocols and recipients between the user agent and the server on requests,

Connection: Keep-Alive
```

FIGURE 30.8 GET request forwarded from proxy server to origin server.

and between the origin server and the client on responses. It is analogous to the Received field of RFC 822 and is intended to be used for tracking message forwards, avoiding request loops, and identifying the protocol capabilities of all senders along the request/response chain.

Following the `Via` header field, the received-protocol indicates the protocol version of the message received by the server or client along each segment of the request/response chain. The received-protocol version (1.1 in our example) is appended to the `Via` field value when the message is forwarded so that information about the protocol capabilities of upstream applications remains visible to all recipients.

The received-by field (`ADPROSRV01` in our example) is normally the host and optional port number of a recipient server or client that subsequently forwarded the message. However, if the real host is considered to be sensitive information, it *may* be replaced by a pseudonym. If the port is not given, it *may* be assumed to be the default port of the received-protocol.

Multiple `Via` field values represent each proxy or gateway that has forwarded the message. Each recipient *must* append its information such that the end result is ordered according to the sequence of forwarding applications. For example, a request message could be sent from an HTTP/1.1 user agent to an internal proxy code-named `ADPROSRV01`, which uses HTTP/1.0 to forward the request to a public proxy at `some.where.com`, which completes the request by forwarding it to the origin server. The request received by the origin server would then have the following `Via` header field:

```
Via: 1.1 ADPROSRV01, 1.0 some.where.com
```

As there is only one proxy in our example, the origin server now responses as shown in Figure 30.9, the proxy stores the response in its cache, and forwards the response to the user agent as shown in Figure 30.10.

If the same request of Figure 30.7 is now sent to the proxy again, the proxy server will verify the validity of its cache regarding the request and if it is valid will answer immediately without first contacting the origin server as shown in Figure 30.11.

The `Age` response-header field conveys the sender's estimate of the amount of time since the response (or its revalidation) was generated at the origin server. A cached response is *fresh* if its age does not exceed its freshness lifetime. Age values are nonnegative decimal integers, representing time in seconds. Age values are calculated as specified in RFC 2616 and are used for cache expiration control.

30.10 Further HTTP Request Methods by Example

This section provides further examples for HTTP request methods.

FIGURE 30.11 Response of the proxy, when the requested information is retrieved from a valid cache.

© 2005 by CRC Press LLC

OPTIONS

The OPTIONS method represents a request for information about the communication options available on the request/response chain identified by the request-URI. This method allows the client to determine the options and/or requirements associated with a resource, or the capabilities of a server, without implying a resource action or initiating a resource retrieval. In Figure 30.12, the server allows the methods GET, HEAD, TRACE, and OPTIONS.

HEAD

The HEAD method is identical to GET except that the server *must not* return a message-body in the response (see Figure 30.13). The metainformation contained in the HTTP headers in response to a HEAD request should be identical to the information sent in response to a GET request. This method can be used for obtaining metainformation about the entity implied by the request without transferring the entity-body itself. This method is often used for testing hypertext links for validity, accessibility, and recent modification.

POST

The POST method is used to request that the origin server accepts the entity enclosed in the request as a new subordinate of the resource identified by the request-URI in the request-line. POST is designed to allow a uniform method to cover the following functions:

- Annotation of existing resources.
- Posting a message to a bulletin board, newsgroup, mailing list, or similar group of articles.
- Providing a block of data, such as the result of submitting a form, to a data-handling process.
- Extending a database through an append operation.

FIGURE 30.13 The HEAD method request and an appropriate response.

© 2005 by CRC Press LLC

The actual function performed by the POST method is determined by the server and usually depends on the request-URI. The posted entity is subordinate to that URI in the same way in which a file is subordinate to a directory containing it, a news article is subordinate to a newsgroup to which it is posted, or a record is subordinate to a database.

Consider a Web form, like in Figure 30.14: the FORM Tag is important, describing the request-URI and the request method for submitting the form. Pressing the submit button then causes the user agent to initiate a POST request as shown in Figure 30.15.

The Content-Type application/x-www-form-urlencoded used for submitting Web form data to server-side applications is notable. The Content-Length is also important, because unlike most

FIGURE 30.16 GET request resulting from the Web form in Figure 30.14, if GET is used as FORM action instead of POST.

other requests, the POST request usually does have a content. If the FORM action GET would be used instead of POST, the resulting GET request is shown in Figure 30.16. Now, the query string is not delivered within the message content but rather appended to the request-URI. Therefore, no Content-Type or Content-Length is necessary.

TRACE

The TRACE method is used to invoke a remote, application-layer loop-back of the request message. The final recipient of the request *should* reflect the message received back to the client as the entity-body of a 200 (OK) response. A TRACE request *must not* include an entity. TRACE allows the client to see what is being received at the other end of the request chain and use that data for testing or diagnostic information. The value of the Via header field is of particular interest, since it acts as a trace of the request chain. The use of the Max-Forwards header field allows the client to limit the length of the request chain, which is useful for testing a chain of proxies forwarding messages in an infinite loop. If the request is valid, the response *should* contain the entire request message in the entity-body, with a Content-Type of message/http. Responses to this method *must not* be cached. Figure 30.17 shows an example of a TRACE request to a proxy (PAULI) and the respective response.

30.11 Further HTTP Response Status Codes by Example

This section provides further examples for HTTP response status codes. For a complete list of all status codes, please refer to RFC 2616.

Informational 1xx

This class of status code indicates a provisional response, consisting only of the Status-Line and optional headers, and is terminated by an empty line. There are no required headers for this class of status code. A client must be prepared to accept one or more 1xx status responses prior to a regular response, even if

Via: 1.0 PAULI
```

FIGURE 30.17 The TRACE method.

the client does not expect a 100 (Continue) status message. Unexpected 1xx status responses may be ignored by a user-agent.

Successful 2xx

This class of status code indicates that the client's request was successfully received, understood, and accepted.

Redirection 3xx

This class of status code indicates that further action needs to be taken by the user-agent in order to fulfill the request. The action required may be carried out by the user-agent without interaction with the user if and only if the method used in the second request is GET or HEAD. A client should detect infinite redirection loops, since such loops generate network traffic for each redirection.

302 Found

The requested resource resides temporarily under a different URI. Since the redirection might be altered on occasion, the client should continue to use the request-URI for future requests. The temporary URI should be given by the Location field in the response. Unless the request method was HEAD, the entity of the response should contain a short hypertext note with a hyperlink to the new URI(s). If the 302 status code is received in response to a request other than GET or HEAD, the user-agent must not automatically redirect the request unless it can be confirmed by the user, since this might change the conditions under which the request was issued. For example, the simple request from Figure 30.4 may result in a response shown in Figure 30.18.

The Location response-header field is used to redirect the recipient to a location other than the request-URI for completion of the request or identification of a new resource. For 3xx responses, the location should indicate the server's preferred URI for automatic redirection to the resource. The field value consists of a single absolute URI. If the user-agent understands the response, it will immediately send the following request to the new destination as shown in Figure 30.19. Otherwise, the user-agent will display the HTML content of Figure 30.18 to the user as shown in Figure 30.20.

304 Not Modified

If the client has performed a conditional GET request and access is allowed, but the document has not been modified, the server should respond with this status code. The 304 response must not contain a message-body, and thus is always terminated by the first empty line after the header fields. Figure 30.21 shows a conditional GET request to a proxy server.

situation, and whether it is a temporary or permanent condition. These status codes are applicable to any request method. User-agents should display any included entity to the user.

404 Not Found

Unfortunately, one of the most common response status codes is as follows: the server has not found anything matching the request-URI. No indication is given of whether the condition is temporary or permanent. The `410 (Gone)` status code should be used if the server knows, through some internally configurable mechanism, that an old resource is permanently unavailable and has no forwarding address. This status code is commonly used when the server does not wish to reveal exactly why the request has been refused, or when no other response is applicable. Figure 30.22 shows the HTTP response and Figure 30.23 shows the respective display for the user.

407 Proxy Authentication Required

This code is similar to `401 (Unauthorized)` explained in Section 30.7, but indicates that the client must first authenticate itself with the proxy. The proxy must return a `Proxy-Authenticate` header field containing a challenge that indicates the authentication scheme and parameters applicable to the proxy for this request-URI. The client may repeat the request with a suitable `Proxy-Authorization` header field (Section 30.8). HTTP access authentication is explained in RFC 2617 (Figures 30.24 and 30.25).

```

FIGURE 30.27 Proxy Error response (HTML content shortened).

FIGURE 30.28 504 information (proxy error) displayed to the user.

© 2005 by CRC Press LLC

Server Error 5xx

Response status codes beginning with the digit "5" indicate cases in which the server is aware that it has erred or is incapable of performing the request. Except when responding to a `HEAD` request, the server should include an entity containing an explanation of the error situation, and whether it is a temporary or permanent condition. User-agents should display any included entity to the user. These response codes are applicable to any request method.

504 Gateway Timeout

The server, while acting as a gateway or proxy, did not receive a timely response from the upstream server specified by the URI. This status code is also used for cache control. Consider a request to a proxy server using the `Cache-control` header field (see Figure 30.26).

The `Cache-Control` general-header field is used to specify directives that must be obeyed by all caching mechanisms along the request/response chain. The directives specify behavior intended to prevent caches from adversely interfering with the request or response. These directives typically override the default caching algorithms. Cache directives are unidirectional in that the presence of a directive in a request does not imply that the same directive is to be given in the response.

In our example, the cache-request-directive `only-if-cached` is used: in some cases, such as times of extremely poor network connectivity, a client may want a cache to return only those responses that it has currently stored, and not to reload or revalidate with the origin server. To do this, the client may include the `only-if-cached` directive in a request. If it receives this directive, a cache should either respond using a cached entry that is consistent with the other constraints of the request, or respond with a `504 (Gateway Timeout)` status (see Figure 30.27), which is then displayed to the user (see Figure 30.28).

The cache-response-directive `no-cache` has the following meaning in this example: if the `no-cache` directive does not specify a field-name, then a cache must not use the response to satisfy a subsequent request without successful revalidation with the origin server. This allows an origin server to prevent caching even by caches that have been configured to return stale responses to client requests.

The `Pragma` general-header field is used to include implementation-specific directives that might apply to any recipient along the request/response chain. All pragma directives specify optional behavior from the viewpoint of the protocol; however, some systems may require that behavior be consistent with the directives.

When the no-cache directive is present in a request message, this pragma directive has the same semantics as the `no-cache` cache-directive and is defined for backward compatibility with HTTP/1.0. HTTP/1.1 caches should treat `Pragma: no-cache` as if the client had sent `Cache-Control: no-cache`. No new `Pragma` directives will be defined in HTTP. As the meaning of `Pragma: no-cache` as a response header field is not actually specified, it does not provide a reliable replacement for `Cache-Control: no-cache` in a response.

31.1 Introduction

Computer networks and distributed processing systems continue to grow in scale and diversity in business, government, and other organizations. Three facts become evident. First, new networks are added and existing ones are expanded almost as rapidly as new network technologies and products are introduced. The problems associated with network expansion affect day-to-day network operation management. Second, the network and its resources and distributed services become indispensable to organizations. Third, more things can go wrong, which disable the network or degrade the performance to an unacceptable level. Such inhomogeneous large networks cannot be put together and managed by human effort alone. Instead, their complexity dictates the use of a rich set of automated network management tools and applications.

In response, the International Standard Organization (ISO) began work in 1978 to establish a standard for network management, the Open System Interconnection (OSI) Network Management including the management model, functional areas, Common Management Information Services (CMIS), the Common Management Information Protocol (CMIP), and Management Information Base (MIB). The network management model describes the main components of a network management tool for a

© 2005 by CRC Press LLC

managed network. For a given managed network, it is necessary to know which problem areas have to be considered. These problem areas are specified as the ISO management functions, which were already contained in the first ISO working draft of the management framework and gradually evolved into what is presently known as the five functional areas of the ISO management framework (performance, faults, configuration, accounting, and security). The important pieces of the ISO management are CMIP and CMIS, which managing and managed devices use for their communication. The CMIP protocol consists of a set of services, the so-called CMIS that define the types of requests and responses and the actions they should invoke. In addition to being able to pass information and backforth, the managing and managed devices need to agree on a set of variables and means to initiate actions. The collection of this information is referred to as the MIB.

Because of the slowness of the ISO standardization process, the complexity of the proposed new standard, and the urgent need for management tools, the IETF has devised the Simple Network Management Protocol (SNMP) [RFC1157], which was originally regarded as a provisional means for network management until the OSI management standards would be completed, but subsequently became a *de facto* standard because of its dissemination and its simplicity. The SNMP consists of three parts: the SNMP protocol, the structure of management information (SMI), and the MIB. The SNMP protocol includes the SNMP operations, the format of messages, and how messages are exchanged between a manager and an agent. The SMI is a set of rules allowing a user to specify the desired management information, for example, by providing a means of naming and declaring the types of variables. Finally, the MIB is a structured collection of all managed objects maintained by a device. The managed objects are structured as a hierarchical tree. In order to address several weaknesses within SNMP, the SNMP version 2 (SNMPv2) was initiated around 1994. SNMPv2 provides more functionality and greater efficiency than the original version of SNMP; but due to various reasons, SNMPv2 did not succeed. Finally, the SNMP version 3 (SNMPv3) was issued in 1998. SNMPv3 describes an overall framework for present and future versions of SNMP and defines security features to SNMP.

This chapter focuses on the basic notions and frameworks of network management standards, which have been developed by ISO and IETF. It aims to serve as a comprehensive survey of conceptual models, protocols, services, and management information bases of these management standards. The chapter is organized as follows. Section 31.2 describes the network management model developed by ISO and IETF. The ISO network management framework is discussed briefly in Section 31.3, while Section 31.4 presents the IETF management framework. These management standards are compared in Section 31.5. Section 31.6 concludes the chapter with an overview of the open problems in network management.

31.2 Network Management Architecture

The network management architecture used in ISO and IETF frameworks is called manager–agent architecture and includes the following key components:

- managed devices,
- management stations,
- management protocols, and
- management Information.

These are shown in Figure 31.1 and described below.

Network management is done from *management stations*, which are computers running special management software. These management stations contain a set of management application processes called *managers* for data analysis, fault recovery, and so on. The manager is the locus of activity for network management; it provides or monitors information to users; issues requests to managed devices in order to ask them to take some action; receives responses to the requests; and receives unsolicited reports from managed devices concerning the status of the devices — these reports are referred to as notification and are frequently used to report problems, anomalies, or changes in the agent environment.

© 2005 by CRC Press LLC

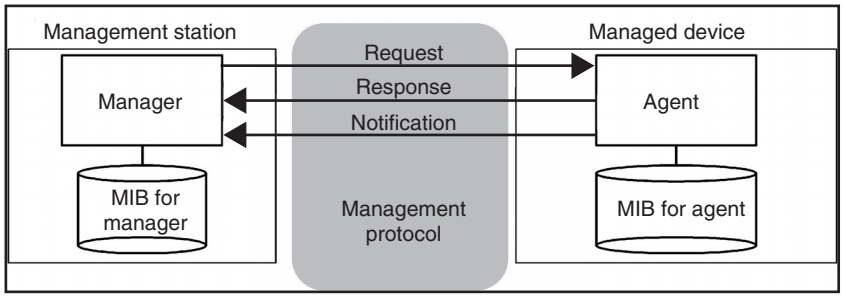

FIGURE 31.1 Manager–Agent architecture.

A *managed device* is a piece of network equipment that resides in a managed network. The managed devices might be hosts, routers, switches, bridges, or printers. To be managed from a management station, a device must be capable of running a management process, called (*management*) *agent*. These agents communicate with managers running on the management station and take local actions on the managed device under the command and control of the managers. An agent can act upon and respond to request from a manager; furthermore, it can provide unsolicited notifications to a manager.

Each managed device maintains one or more variables (e.g., a network interface card or a set of configuration parameters for a piece of hardware or software) that describe its state. In the ISO and IETF management frameworks, these variables are called *managed objects*. The collection of these managed objects is referred to as a *MIB*. These variables can be viewed and optionally modified by the managers.

The *network management protocol* is needed for communication between managers and agents. This protocol allows the manager to query the status of managed devices and to initiate actions at these devices by triggering the agents. Furthermore, agents can use the network management protocol to report exceptional events to the management stations.

When describing any framework for network management, the following aspects must be addressed:

- *The functional aspect* specifies management functional areas supported by managers and agents. This aspect relates to specific management functions that are carried out by the manager or agent.
- *The information aspect* defines the kind of information that will be exchanged between the manager and agent. The information aspect deals with MIBs and SMI.
- *The communication aspect* addresses the communication protocol between the manager and agent for exchanging this information.
- *The organization aspect* deals with the definition of the principal structural components and the management architecture for a managed network.

The OSI and IETF management frameworks are discussed in the following subsections from the view point of these aspects.

31.3 ISO Systems Management Framework

The first standard for network management was ISO 7498-4, which specifies the network management framework for the OSI model [ISO7498-4]. Although the production of this framework took considerable time, it was not generally accepted as an adequate starting point. It was therefore decided to issue an additional standard, which was called the System Management Overview [ISO10040]. Subsequently, ISO has issued a set of other additional standards for network management. Together, these standards provide the basis for the OSI management framework.

© 2005 by CRC Press LLC

Functional Aspects

OSI Systems Management standardization followed a top-down approach, with a number of system management functional areas (SMFA) identified first. The intention was not to describe exhaustively all relevant types of management activity but rather to investigate the key requirements and to address these through a generic management model. The identified areas were Fault, Configuration, Accounting, Performance and Security Management, and collectively referred to as FCAPS from their initials [Sta93a].

Fault Management

Fault management deals with the mechanisms for the detection, isolation, and correction of abnormal operations. Fault management includes functions to:

- maintain and examine error logs,
- trace and identify faults,
- accept and act upon error notifications, and
- to carry out diagnostic tests and correct faults.

Configuration Management

Configuration management is the set of facilities that allow network managers to exercise control over the configuration of the network components and OSI-layer entities. Configuration management includes functions to:

- record the current configuration,
- record changes in the configuration,
- initialize and close down managed objects,
- identify the network components, and
- to change the configuration of managed objects (e.g., routing table).

Accounting Management

Accounting management deals with the collection and processing of accounting information and for charging and billing purposes. It should enable accounting limits to be set and costs to be combined when multiple resources are used in the context of a service. Accounting management includes functions to:

- inform users of the cost thus far,
- inform users of the expected cost in the future, and
- to set cost limits.

Performance Management

Performance management is the set of facilities that enable the network managers to monitor and evaluate the performance of the system and layer entities. Performance management involves three main steps. First, performance data are gathered on variables of interest to network administrators. Second, the data are analyzed to determine normal (baseline) levels. Finally, appropriate performance thresholds are determined for each important variable so that exceeding these thresholds indicates a network problem worthy of attention. Management entities continually monitor performance variables. When a performance threshold is exceeded, an alert is generated and sent to the network management system. Performance management provides functions to:

- collect and disseminate data concerning the current level of performance of resources and to
- maintain and examine performance logs for planning and analysis purposes.

Security Management

Security management addresses the control of the access to network resources according to local guidelines so that the network cannot be damaged and persons without appropriate authorization cannot

© 2005 by CRC Press LLC

access sensitive information. A security management subsystem, for example, can monitor users logging on to a network resource and can refuse access to those who enter inappropriate access codes. Security management provides support for management of:

- authorization facilities,
- access control,
- encryption and key management,
- authentication, and
- security logs.

Soon after the first working drafts of the management framework appeared, ISO started to define protocol standards for each of the five SMFA. After sometime, an interesting observation was made that most of the functional area protocols used a similar set of elementary management functions. ISO decided, therefore, to stop further progression of the five functional area protocols and concentrate on the definition of elementary management functions. Following this, a set of standards, for example, object management, state management, relationships management, alarm reporting, event-report management, and log control, have been issued as the general category systems-management functions (SMF). Each SMF standard defines the functionality to support SMFA requirements. Moreover, these standards provide a mapping between the CMIS services (discussed below) and SMF.

Information Aspects

The information aspects of the OSI system management deal with the resources that are being managed by agents. OSI systems management relies on object-oriented concepts. Therefore, each resource being managed is represented by a managed object. A managed object may represent either a logical resource such as a user account, or a real resource like an ATM switch. Managed objects that refer to resources specific to an individual layer are called (*N*)-layer-managed objects. Managed objects that refer to resources that encompass more than one layer are called systems-managed objects. According to the OSI Management Information Model [ISO10165-1], a managed object is defined in terms of the *attributes* that it possesses, *operations* that may be performed on it, *notifications* that it may issue, and *its interactions* with other managed objects. The managed objects are defined using two standards: *Abstract Syntax Notation One* (ASN.1) is used to define data types and *Guidelines for definition of managed objects* (GDMO) to define managed objects [ASN90, ISO10165-1].

Under systems management, all the managed objects are represented in the so-called *MIB.* The managed object concept is refined in a number of additional standards that are called the *Structure of Management Information (SMI)* standards [ISO10165-1, ISO10165-2, ISO10165-4, ISO10165-5, and ISO10165-7]. The SMI identifies the data types that can be used in the MIB and how the resources within the MIB are represented and named [Sta93b].

Organization Aspects

The key elements of the OSI architectural model include system-management application process (SMAP), system-management application entity (SMAE), layer-management entity, and management information base. SMAP is the process within a managing device that is responsible for executing the network-management functions; it has access to all parameters of managed devices and can therefore manage all aspects of a managed network and may coordinate with SMAPs on other managed networks. An SMAE is responsible for communication with other devices, especially with devices exercising control functions; CMIP is used as a standardized application-level protocol by SMAE. Layer-management entity is the logic embedded into each layer of OSI architecture to provide network management functions that are specific for this layer.

To provide management of a distributed system, the elements in this architectural model must be implemented in a distributed manner across all the devices in a managed network. The OSI system

© 2005 by CRC Press LLC

management is organized in a central manner. According to this scheme, a single manager may control several agents. Each agent contains a number of objects. Each object is a data structure that corresponds to an actual piece of device to be managed. The SMAP is allowed to take on either a manager's or an agent's role. The manager's role for an SMAP occurs in a device that acts as a network control center. The agent's role for an SMAP occurs in managed devices. The manager performs operations upon the agents and the agents forward notifications to the managers. Because of the expansion of the open system, the OSI management environment may be partitioned into a number of management domains. The partition cannot just be based on the required management functions (security, accounting, performance, etc.) but also on other requirements (e.g., geographical).

Communication Aspects

The communication aspect deals with the exchange of SMI between managers and agents within a managed network. With respect to this aspect, ISO has issued two standards; the CMIS and the CMIP [ISO9595, ISO9596].

CMIS provides OSI management services to management applications. It defines a set of management services, specifies types of requests and responses, and defines what each request and response can do. The management processes initiate these services in order to communicate remotely. Seven services used to handle management information have been standardized. Table 31.1 lists the CMIS services with their type and function.

The CMIP provides the information-exchange capability to support CMIS; it defines a set of protocol data units that implement the CMIS services [ISO9596]. In particular, CMIP defines how the requests, responses, and notifications are encoded into messages and specifies which bearer service is used to transport those encoded messages between managers and agents. A CMIP request typically specifies one or more managed objects to which the request is to be sent. The correspondence between CMIS primitives and CMIP data units is described in [Sta99].

31.4 Internet Management Framework

An interesting difference between the IETF and ISO is that the IETF adopts a more pragmatic and result-driven approach than ISO. In the IETF, it is, for instance, unusual to spend much time on architectural discussions; people prefer to use their time for the development of protocols and implementations. This difference explains why no special standards management architecture and function areas have been defined in the first two versions of SNMP; only the communication aspect (as SNMP protocol), the information aspect (as SMI and MIB), and the security aspect have been standardized.

SNMP is an application-layer protocol that facilitates the exchange of management information between network devices. It is a part of the TCP/IP protocol suite and operates over UDP. As described

TABLE 31.1 CMIS Services

CMIS services	Type	Functions
Notification services		
M-EVENT-REPORT	Confirmed/not confirmed	Gives notification of an envent occurring on a managed object
Opertion services		
M-GET	Confirmed	Request for
M-SET	Confirmed/not confirmed	Modification of management data
M-ACTION	Confirmed/not confirmed	Execution of action on a managed object
M-CREATE	Confirmed	Creation of a managed object
M-DELETE	Confirmed	Deletion of a managed object
M-CANCEL-GET	Confirmed	Request to cancel any new responses to a previous request for M-GET services

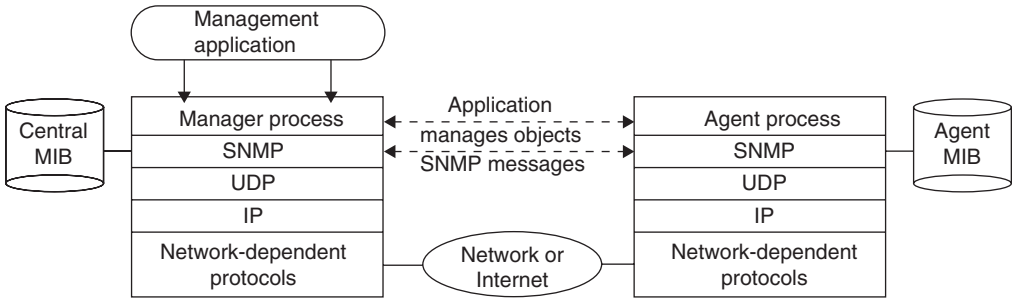

FIGURE 31.2 Internet management architecture.

in Section 31.2, IETF network management is based on the manager–agent architecture. Figure 31.2 shows the architecture of Internet management. In this architecture, a manager process controls access to a central MIB at the management station and provides an interface to the management application. Furthermore, a manager may control many agents, whereby each agent interprets the SNMP messages and controls the agent's MIBs.

In Section 31.2, we have provided an overview of the basic components of a management architecture used by ISO and IETF. The IETF network management framework consists of:

SNMP: SNMP is a management protocol for conveying information and commands between a manager and an agent running in a managed network device [KR01].

MIB: Resources in networks may be managed by representing them as objects. Each object is a data variable that represents one aspect of a managed device. In the IETF network management framework, the representation of a collection of these objects is called MIB [RFC1157, RFC1212]. An MIB object might be a counter such as the number of IP datagrams discarded at a router due to errors, descriptive information such as generic information about the physical interfaces of the entity, or protocol-specific information such as the number of UDP datagrams delivered to UDP users.

SMI: SMI [RFC1155] allows to formally specify the data types that are used in an MIB and specifies how resources within an MIB are named. The SMI is based on the Abstract Syntax Notation One (ASN.1) [ASN90] object-definition language, however, since many SMI-specific data types have been added, SMI should be considered a data-definition language of its own right.

Security and administration is concerned with monitoring and controlling access to managed networks and access to all or part of management information obtained from network nodes.

In the following sections, an overview of several SNMP versions (SNMPv1, SNMPv2, and SNMPv2) with respect to protocol operations, MIB, SMI, and security is given.

SNMPv1

The original network management framework is defined in the following documents:

- RFC 1155 and RFC 1212 define SMI, the mechanisms used for specifying and naming managed objects. RFC 1215 defines a concise description mechanism for defining event notifications that are called traps in SNMPv1.
- RFC 1157 defines SNMPv1, the protocol used for network access to managed objects and event notification.
- RFC 1213 contains definition for a specific MIB (MIB I) covering TCP, UDP, IP, routers, and other inhabitants of the IP world.

SMI

The RFCs 1155, 1212, and 1215 describe the SNMPv1 structure of management information and are often referred to as "SMIv1." Note that the first two SMI documents do not provide the definition of event

© 2005 by CRC Press LLC

notifications (traps). Because of this, the last document specifies a straightforward approach toward defining event notifications used with the SNMPv1 protocol.

Protocol Operations

In SNMPv1, communication between manager and agent is done in a confirmed way. The manager at the network management station takes the initiative by sending one of the following SNMP PDUs: *GetRequest*, *GetNextRequest,* or *SetRequest*. The *GetRequest* and *GetNextRequest* are used to obtain management information from the agent; the SetRequest is used to change management information at the agent. After receiving one of these PDUs, the agent responds with a response PDU, which carries the requested information or indicates failure of the previous request (Figure 31.3). It is also possible that the SNMP agent takes the initiative. This happens when the agent detects some extraordinary event such as a status change at one of its links. As a reaction to this, the agent sends a trap PDU to the manager. The reception of the trap is not confirmed (Figure 31.3(d)).

MIB

As noted above, the MIB can be thought of as a virtual information store, holding managed objects whose values collectively reflect the current "state" of the network. These values may be queried and/or set by a manager by sending SNMP messages to the agent. Managed objects are specified using the SMI discussed above.

The IETF has been standardizing the MIB modules associated with routers, hosts, and other network equipment. This includes basic identification data about a particular piece of hardware, and management information about the device's network interfaces and protocols. With the different SNMP standards, the IETF needed a way to identify and name the standardized MIB modules, as well as the specific managed objects within an MIB module. To do this, the IETF adopted ASN.1 as a standardized object identification (naming) framework. In ASN.1, object identifiers have a hierarchical structure, as shown in Figure 31.4.

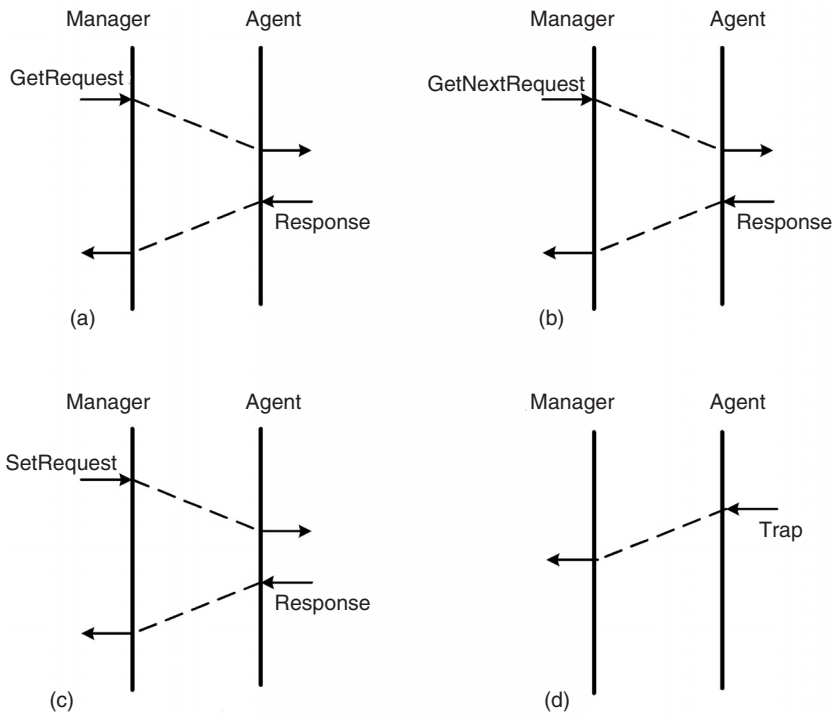

FIGURE 31.3 Initiative from manager (a, b, c) and agent (d).

© 2005 by CRC Press LLC

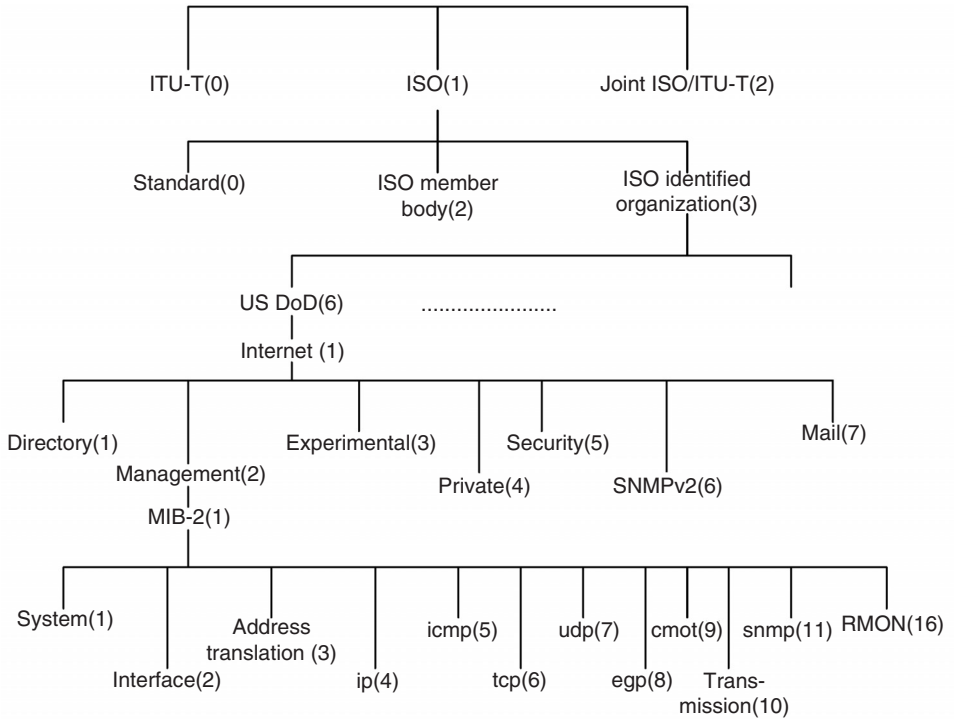

FIGURE 31.4 ASN.1 Object identifier tree.

The global naming tree illustrated in Figure 31.4 allows for unique identification of objects, which correspond to leaf nodes. Describing an object identifier is accomplished by traversing the tree, starting at the root, until the intended object is reached. Several formats can be used to describe an object identifier, with integer values separated by dots being the most common approach.

As shown in Figure 31.4, ISO and the Telecommunication Standardization Sector of the International Telecommunication Union (ITU-T) are at the top of the hierarchy. Under the Internet branch of the tree (1.3.6.1), there are seven categories. Under the management (1.3.6.1.2) and MIB-2 branch (1.3.6.1.2.1) of the object identifier tree, we find the definitions of the standardized MIB modules. The lowest level of the tree shows some of the important hardware-oriented MIB modules (system and interface) as well as modules associated with some of the most important Internet protocols. RFC 2400 lists all standardized MIB modules.

Security

The security capabilities deal with mechanisms to control the access to network resources according to local guidelines so that the network cannot be damaged (intentionally or unintentionally) and persons without appropriate authorization have no access to sensitive information.

SNMPv1 has no security features. For example, it is relatively easy to use the *setRequest* command to corrupt the configuration parameters of a managed device, which in turn could seriously impair network operations. The SNMPv1 framework only allows to assign different access rights to variables (READ-ONLY, READ–WRITE), but performs no authentication. This means that anybody can modify READ–WRITE variables. This is a fundamental weakness in the SNMPv1 framework.

Several proposals have been presented to improve SNMP. In 1992, IETF issued a new standard, the SNMPv2.

© 2005 by CRC Press LLC

The SNMPv2

Like SNMPv1, the SNMPv2 Network Management Framework consists of four major components:

- RFC 1441 defines the SMI, the mechanisms used for describing and naming objects for the purpose of management.
- RFC 1213 defines MIB-II, the core set of managed objects for the Internet suite of protocols.
- RFC 1445 defines the administrative and other architectural aspects of the framework.
- RFC 1448 defines the protocol used for network access to managed objects.

The main achievements of SNMPv2 are the improved performance, better security, and the possibility to build a hierarchy of managers.

Performance: SNMPv1 includes a rule, which states that if the response to a GetRequest or *GetNextRequest* (each of which can ask for multiple variables) would exceed the maximum size of a packet, no information will be returned at all. Because managers cannot determine the size of response packets in advance, they usually take a conservative guess and request just a small amount of data per PDU. To obtain all information, managers are required to issue a large number of consecutive requests. To improve performance, SNMPv2 introduced the *GetBulk* PDU. In comparison with *Get* and *GetNext*, the response to *GetBulk* always returns as much information as possible in lexicographic order.

Security: The original SNMP had no security features. To solve this deficiency, SNMPv2 introduced a security mechanism that is based on the concepts of "parties" and "contexts." The SNMPv2 *party* is a conceptual, virtual execution environment. When an agent or manager performs an action, it does so as a defined party, using the party's environment as described in the configuration files. By using the party concept, an agent can permit one manager to do a certain set of operations (e.g., read, modify), and another manager to do a different set of operations. Each communication session with a different manager can have its own environment. The "context" concept is used to control access to the various parts of an MIB; each context refers to a specific part of an MIB. Contexts may be overlapping and are dynamically configurable, which means that contexts may be created, deleted, or modified during the network's operational phase.

Hierarchy of managers: Practical experience with SNMPv1 protocol showed that in several cases managers are unable to manage more than a few hundred agent systems. The main cause for this restriction is due to the polling nature of SNMPv1. This means that the manager must periodically poll every system under his control, which takes time. To solve this problem, SNMPv2 introduced the so-called "intermediate-level managers" concept, which allows polling to be performed by a number of intermediate-level managers under control of top-level managers via the *InformRequest* command provided by SNMPv2. Figure 31.5 shows an example of hierarchical managers: before the intermediate-level managers start polling, the top-level manager tells the intermediate-level managers which variable must be polled from which agents. Furthermore, the top-level manager informs the intermediate-level manager of the

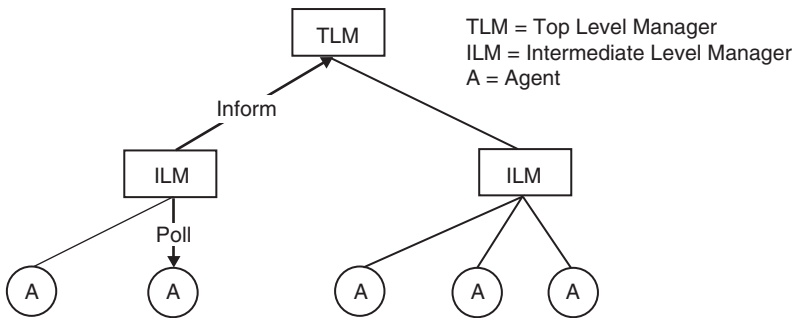

FIGURE 31.5 Hierarchy of managers.

© 2005 by CRC Press LLC

events he wants to be informed about. After the intermediate-level managers are configured, they start polling. If an intermediate-level manager detects an event of interest to the top-level manager, a special *Inform* PDU is generated and sent to the TLM. After receiving this PDU, the TLM directly operates upon the agent, which caused the event.

SNMPv2 dates in 1992, when the IETF formed two working groups to define enhancements to SNMPv1. One of these groups focused on defining security functions, while the other concentrates on defining enhancements to the SNMP protocol. Unfortunately, the group tasked with developing the security enhancements broke into separate camps with diverging views concerning the manner by which security should be implemented. Two proposals (SNMPv2μ and SNMPv2*) for the implementation of encryption and authentication have been issued. Thus, the goal of the SNMPv3 working group was to continue the effort of the disbanded SNMPv2 working group to define a standard for SNMP security and administration.

SNMPv3

The third version of the Simple Network Management Protocol (SNMPv3) was published as proposed standards in RFCs 2271 to 2275, which describe an overall architecture plus specific message structure and security features, but do not define a new SNMP PDU format. This version is based upon the first two versions of SNMP and so it reuses the SNMPv2 standard documents (RFC 1902 to RFC 1908). SNMPv3 can be thought of as SNMPv2 with additional security and administration capabilities [RFC2570]. This section focuses on the management architecture and the security capacities of SNMPv3.

The Management Architecture

The SNMPv3 management architecture is also based on the manager–agent principle. The architecture described in RFC 2271 consists of a distributed, interacting collection of SNMP entities. Each entity implements a part of the SNMP capabilities and may act as an agent, a manager, or a combination of both.

The SNMPv3 working group defines five generic applications for generating and receiving SNMP PDUs: Command generator, command responder, notification originator, notification receiver, and proxy forwarder; a command generator application generates the GetRequest, GetNextRequest, GetBulkRequest and SetRequest PDUs, and handles Response PDUs; a command responder application executes in an agent and receives, processes, and replies to the received getRequest, GetNextRequest, GetBulkRequest, and SetRequest PDUs; a notification originator application also executes within an agent and generates Trap PDUs; a notification receiver accepts and reacts on incoming notifications; and finally a proxy forwarder application forwards request, notification, and response PDUs.

The architecture shown in Figure 31.6 also defines an SNMP engine that consists of four components: dispatcher, Message Processing Subsystem, Security Subsystem, and Access control Subsystem; this SNMP engine is responsible for preparing PDU messages for transmission, extracting PDUs from incoming messages for delivery to the applications, and for carrying out security-related processing of outgoing and incoming messages.

Security

The security capabilities of the SNMPv3 are defined in RFC 2272, RFC 2274, and RFC 2275. These specifications include message processing, user-based security model, and view-based access control model.

The message processing can be used with any security model as follows. For outgoing messages, the message processor is responsible for constructing the message header attached to outgoing PDUs, and for passing the appropriate parameters to the security entity so that it can perform authentication and privacy functions, if required. For incoming messages, the message processor is used for passing the appropriate parameters to the security model for authentication and privacy processing and for processing and removing the message headers of incoming PDUs.

© 2005 by CRC Press LLC

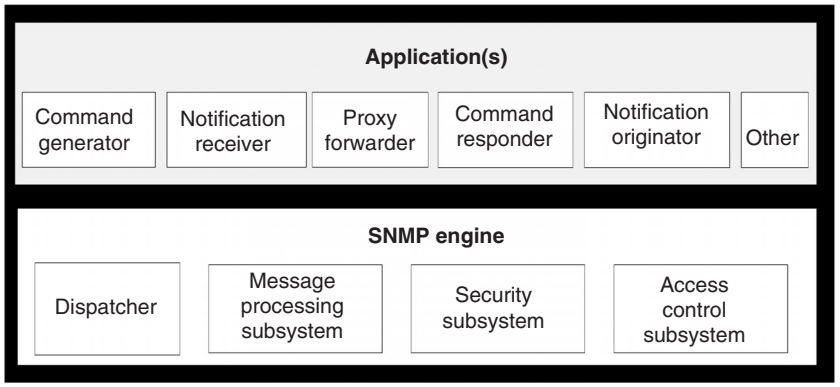

FIGURE 31.6 SNMPv3 entity.

The user-based security model (USM) specified in RFC 2274 uses data encryption standard (DES) for encryption and hashed message authentication codes (HMAC) for authentication [Sch95]. USM includes means for defining procedures by which one SNMP engine obtains information about another SNMP engine, and a key management protocol for defining procedures for key generation, update, and use.

The view-based access control model implements the services required for an access control subsystem [RFC 2275]. It makes an access control decision that is based on the requested resource, the security model, and security level used for communicating the request, the context to which access is requested, the type of access requested, and the actual object for which access is requested.

31.5 ISO and Internet Management Standards: Analysis and Comparison

The purpose of this section is to compare the two different network management frameworks described in the previous sections. This comparison focuses on the four management aspects described above (functional, information, communication, and organization). In particular, the network management protocols (SNMP and CMIP), the MIB and the management functions, management architectures, and security capabilities of these two frameworks are discussed. Possible solutions to some disadvantages are also presented.

SNMP and CMIP

The biggest advantage of SNMP over CMIP is its simple design, which makes it easy to implement and as easy to use on a small network as on a large one. Users can specify the variables to be monitored in a straightforward manner. From a low-level perspective, each variable consists of the following information:

- variable name,
- its data type,
- its access attributes (read-only or read-write), and
- its value.

Another advantage of SNMP is that it is in wide use today around the world. It became very popular; no other network management protocols appeared to replace SNMP. The result of this is that almost all major vendors of network hardware, such as bridges and routers, design their products to support SNMP, making it very easy to implement.

© 2005 by CRC Press LLC

SNMP also has several disadvantages. The first deficiency with SNMP is that it has some large security leaks that can give network intruders access to managed devices. Intruders could also potentially shut down some terminals. To solve this problem, SNMPv2 and SNMPv3 have added some security mechanisms as described above that help combat the security problems.

In comparison with SNMP, CMIP has several advantages. The biggest advantage of CMIP is that an agent not only relays information to and from a terminal as in SNMP, but in CMIP an agent can perform management functions on its own instead of restricting to gather information for remote processing by a manager. Another advantage of the CMIP approach is that it addresses many of the shortcomings of SNMP. For instance, it has built-in security management devices that support authorization, access control, and security logs. The result of this is a safer system from the beginning; no security upgrades are necessary.

CMIP has many advantages, but has not been implemented yet. One problem of the CMIP protocol is that it needs more system resources than SNMP. Furthermore, a full implementation of CMIP requires to add additional processes to network elements. One possible workaround is to decrease the size of the protocol by changing its specifications. Another problem with CMIP is that it is very difficult to program.

MIBs and SMI

MIB and SMI represent the information aspects of a network management framework. In the ISO management framework, managed objects within the MIB are complex and have sophisticated data structures with three attributes: variable attributes that represent the variable characteristics, variable behaviors that define what actions can be triggered on that variable, and notifications that generate an event report whenever a specific event occurs [Sta99]. In contrast, in the SNMP framework, variables are only used to relay information to and from managers.

The SNMP MIB concept has two important disadvantages. The first one is that the user has to know the names and meanings of (thousands of) different variables, which can be a daunting task. The second problem is the lack of variable aggregation: when the user wants to inquire the values contained in an array, he has to ask separately for each element instead of naming the array at once.

The latter problem has been fixed in the newer releases of SNMP, the SNMPv2, and SNMPv3. These versions provide means for aggregating variables, for example, by the new *GetBulkRequest* service. In fact, so many new features have been added that the formal specifications for SNMP MIBs have expanded considerably.

Network Management Functions

One advantage of ISO management framework over the IETF framework is that ISO has issued the five specific management functional areas, which are useful for users to develop management applications. In contrast, the IETF management framework has not defined any specific functions and procedure to do, for example, performance management. These have to be provided entirely by the user. In fact, the IETF management standards explain how individual management operations should be performed; but they do not specify, however, the sequence in which these operations should be carried out to solve particular management problems.

Conclusions

We have surveyed the management architecture, protocols, services, and management information base of the network management frameworks standardized by ISO and IETF. Within each of these frameworks, standards relating to four fundamental aspects of network management (functional aspect, information aspect, communication aspect, and organization aspect) are addressed.

Both management frameworks have their advantages and disadvantages. However, the key decision factor between the two frameworks is in their implementation: it is until now almost impossible to find

© 2005 by CRC Press LLC

a system with the necessary resources to support the ISO framework, although it is conceptually superior to SNMP (v1, v2 and v3) in both design and operation.

32.1 Introduction

The term "management application" can describe any solution ranging from a cyclically invoked command line tool to a fully integrated, multi-user, and operating system-independent system platform with a graphical user interface. Probably, the most widely used tool for network management is "ping." It provides an easy test if a device is operational and can be reached. But it is limited to exactly that one purpose. Another well-known application to remotely manage network nodes is "telnet." While quite powerful to control a small number of nodes, telnet is highly dependent on the target node. These two samples are standard solutions for network management that are widely used but are not feasible to handle large and diverse networks. Others exist using proprietary solutions or various other open standard protocols.

If a central management system shall gather data about a large and heterogeneous network, a common protocol is needed. At least it should be possible to read data from all the network devices and to trigger actions at these nodes. In addition, the solution should have a method to determine which data is accessible at a remote device. All these requirements have been well addressed by SNMP. The developed standards had evolved through several generations. All these versions of SNMP will be reviewed in this paper.

The remainder of this publication starts with a short historical review followed by a description of the different SNMP versions.

© 2005 by CRC Press LLC

32.2 History

Reviewing the Internet timeline (Figure 32.1) from the first four hosts that formed the core of the ARPA net in the year 1969 [1], one can easily see that the development of SNMP started immediately after data transfer (ftp), remote control of hosts (telnet) and the mailing system protocol (SMTP) were addressed. In 1987, the Simple Gateway Monitoring Protocol SGMP was specified [RFC1028] — it was the predecessor of SNMP. One year later, the first RFCs describing SNMP were made public and shortly afterwards were reviewed and released as SNMPv1.

According to official host counts [1], the number of hosts in the Internet was still quite small in 1990 (some 300.000) but it became clear that a standardized, easy-to-use solution that can be integrated into each and every network device is necessary to manage the fast-growing heterogeneous networks. At this time, only proprietary solutions if any existed for management tasks, mainly based on UNIX. The needs of an approach for a common management solution were filled by SNMPv1, followed by the development of tools having different complexities ranging from simple command-line tools up to integrated management platforms.

In the beginning, SNMP was only intended as a short-term solution until specification of the OSI management framework [2] would be finished and used for all network management tasks. But history has shown that SNMP nowadays not only still exists but can also be found in nearly every network device, while the OSI framework is mostly used for academic purposes. This resembles the situation of OSI and TCP/IP. The phrase "OSI is a beautiful dream and TCP/IP is living it" clearly describes this situation [3].

Only 3 years after SNMPv1, a new version of SNMPv2 was released that should improve security, speed and configuration capabilities. The Internet now had grown to some 1.5 million hosts and mixed-technology environments could be found everywhere. SNMPv2 added new protocol operations, extended the language used for the description of managed objects and addressed the area of security. At this time, the acceptance for the use of SNMP as a common management protocol had reached the

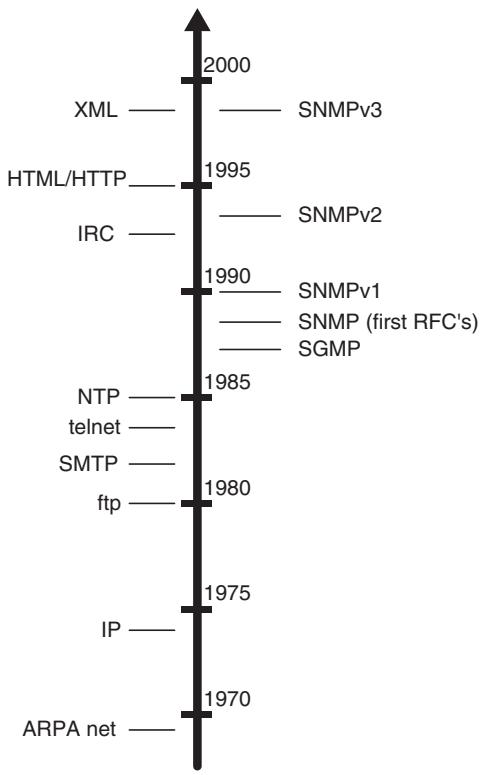

FIGURE 32.1 Internet timeline.

© 2005 by CRC Press LLC

critical mass — standard extensions, integration into different device types, development of management solutions, etc. had broad support.

A complete new set of RFCs was released in 1998, forming SNMPv3. This version redefined security aspects, clarified the structure of the management framework and split the specification into smaller portions that could be replaced or adapted for future needs.

Until now, SNMPv1 still has a large market share while SNMPv2 and SNMPv3 only stepwise begin to take over. It is expected that future networks will consist of a mixture of devices, supporting different types of SNMP. But since the main structure has remained the same, integration is possible and supported by management solutions. Between [RFC1] and [RFC3400], more than 160 RFCs were released for SNMP most of them describing management information bases (about 130 RFCs), while the remainder addresses general parts of the management framework.

32.3 SNMP v1

Many definitions about the components of the SNMP management framework exist. According to a good definition in [RFC 2742], it consists of the following five major components:

- Overall architecture.
- Mechanisms for describing and naming objects and events for the purpose of management.
- Message protocols for transferring management information.
- Protocol operations (PDUs) for accessing management information.
- Set of fundamental applications and the view-based access control mechanism.

The main design goals for SNMPv1 included the following:

- Simplicity (the integration of the protocol in network devices has to be easy).
- Robustness (when everything else fails, network management still has to be possible).
- Low overhead.
- Minimal network resource requirements.

Simplicity also included limiting the complexity of the specification. Thus, the core of SNMPv1 consisted of just three RFCs, ([RFC1155], [RFC1157] and [RFC1213]), refined by some additional definitions ([RFC1212], [RFC1215]). These documents mainly define the *network structure* between managed nodes and managers, a *communication protocol*, a *data encoding method* and a *specification language* for defining information that may be exchanged between systems as well as a *base set of management information* to be supported.

Network Structure

First and foremost, SNMP defines the correlation between network entities that exchange management information. An *agent* provides information about its network node. The *manager* requests data from a number of agents and helps the network administrators accomplish their work. In other words, the agent represents a server and the manager acts as a client. The base relationship is always a 1:n without intermediate elements (Figure 32.2) or a communication between managers. If a network node does not support SNMP, a *proxy* can act as a gateway.

MIB Definition/SMIv1

An SNMP MIB[1] is the database of the agent. All values that can be requested by the manager are accessed through the MIB, which is arranged in a tree-like manner similar to a directory structure of files on a disk.

[1]Some explanation about the term "MIB": the name MIB is used either for all data (the whole tree) that is accessible from an agent or some subtree that is specified by some organization or company.

© 2005 by CRC Press LLC

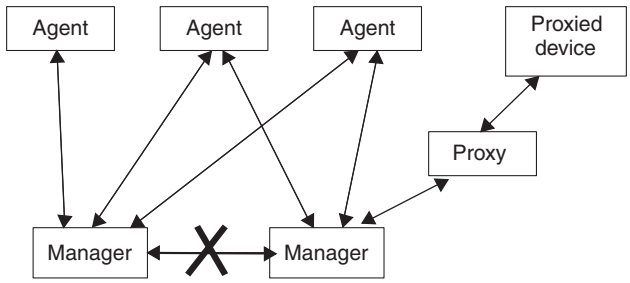

FIGURE 32.2 Manager/agent relationship.

Data is only stored in the leaf elements, never in the intermediated branches. Note that the structure of the MIB is usually fixed — it is constructed by the NW equipment vendor and cannot be added to or modified. The structure and the data provided by a MIB can be seen as a data container; the evaluation of the values depends on the manager application. The huge amount of already defined and supported MIBs can be seen as the most valuable part of SNMP, often defending its existence against alternate network management approaches.

In most cases, MIBs describe simple data containers while complex structures are possible too. One example of a complex MIB structure is the RMON MIB [RFC1271], which defines the interface for a network probe supervising a network on physical and data link layer.

SMI Overview

The Structure of Management Information (SMI, [RFC1155]), is the definition of how managed objects shall be described. By using the SMI, all MIBs are specified in a standardized way. The SMI uses a very small subset of ASN.1 [4] to specify how a MIB has to be defined. Only the following base data types are specified for use with SNMP:

- INTEGER
- OCTET STRING
- OBJECT IDENTIFIER (OID)

Based on these data types, SNMP derives some additional data types like "IpAddress," "Counter," "Gauge," "TimeTicks," etc.

Defining a new MIB module, only the above-mentioned data types can be used. In addition, new types can be derived by defining enumerations and by specification of the value range. Some possibilities are:

- Range for a numeric value: SYNTAX INTEGER (0..65535)
- String of a defined length: SYNTAX OCTET STRING (SIZE (0..255))
- Enumeration of values: SYNTAX INTEGER { enabled(1), disabled(2) }

No complex data types as known by programming languages (structures, objects, unions, etc.) can be defined. Some conventions for the representation of floating-point values, dates, etc., have been established [5].

Using the base data types, only discrete objects and two-dimensional tables can be defined. If the need for more complex structures arises, they have to be mapped to these basic structures. For example, if the MIB designer needs a three-dimensional table, he breaks it apart into several two-dimensional tables thus following the rules of the SMI.

For the specification of the MIB structure and for accessing the values within, a textual representation is used as a human-readable form together with a dotted numeric representation, which is used internally. Both forms are usually combined in the interface of network management tools. Figure 32.3 shows an example.

The ".0" at the end of each line suggests that the accessed object is a discrete object. All discrete objects are accessed by appending a ".0" to the MIB-branch. Appending an INDEX as specified in the table definition accesses the values of a table. This can either be a simple numeric index or even a complex structure like the combination of IP-address and port number appended to the MIB-branch.

© 2005 by CRC Press LLC

Intermediate Objects (OBJECT IDENTIFIER Macro)

For the definition of intermediate MIB branches, an OBJECT IDENTIFIER has to be introduced. This specifies the parent object and the name of a new node in the MIB. Figure 32.4 shows examples for intermediate tree elements taken from MIB-II [RFC1213].

Leaf Objects (OBJECT-TYPE Macro)

The definition of MIB leaf objects is based on the OBJECT-TYPE macro [RFC1212]. Figure 32.5 shows a sample for a discrete object taken from the MIB-II. The object "sysDescr" is a the child of the node "system," under the sub tree "1" and has the following properties:

SYNTAX: The syntax of the object (i.e., the data type) is the type "DisplayString." The value must not be longer than 255 characters.

ACCESS: one of the values *read-only*, *read-write*, *write-only* or *not-accessible*.

STATUS: one of the values *mandatory*, *optional* or *obsolete*. The shown MIB variable is mandatory; thus, the agent must provide it.

DESCRIPTION: a human readable text describing the contents and purpose of the MIB object.

The sample shows the simple structure for the definition of MIB objects. Several conventions have evolved over the years, which increase the complexity of SNMP. These conventions do not have to be followed but make the use more convenient. For more information, see [5]. The sample in Figure 32.5 also reveals that much of the information is in the DESCRIPTION part that is only human readable and not machine-parsable text — one of the criticisms regarding the SMI. The machine-understandable components are very few.

```
Textual form:   Iso.org.dod.internet.mgmt.mib-2.system.sysUptime.0
Dotted decimal: 1.3.6.1.2.1.1.3.0
Combined form:  Iso(1).org(3).dod(6).internet(1).mgmt(2).mib-2(1).system(1).
sysUptime(3).0

    STATUS  mandatory
    DESCRIPTION
        "A textual description of the entity. This value
        should include the full name and version
        identification of the system's hardware type,
        software operating-system, and networking
        software. It is mandatory that this only contain
        printable ASCII characters."
    ::= { system 1 }
```

FIGURE 32.5 SMI sample: discrete object.

© 2005 by CRC Press LLC

Table Definitions

The definition of a table is also based on the OBJECT-TYPE macro but is a little more complex than a discrete object. The table columns are defined exactly the same way as a discrete object. To form the table, a SEQUENCE of the columns must be specified to define an entry of the table together with an INDEX clause. This object in turn is used for another SEQUENCE forming the whole table. Figure 32.6 shows these correlations: the *ifTable* object uses a list of *ifEntry* elements to form the table rows. The *ifEntry* element uses a list of discrete objects to define the columns of the table, specifying that the value of *ifIndex* be used to access a row (the index of the table).

The sample also shows some of the mentioned conventions. For example, all table objects start with the same prefix, the table itself uses the suffix "Table" while the entry has the suffix "Entry."

Trap Definitions

The TRAP-TYPE macro as defined in [RFC1215] is used to specify an SNMP trap. Figure 32.7 shows a sample of a trap definition macro with the following fields:

- The value for the enterprise field of the PDU. This part of the message contains an object identifier with the value of sysObjectID to identify the type of hardware that sent the trap.

```
ifTable OBJECT-TYPE

- Which variables (if any) will be sent as payload of the trap. In the sample, the interface index "ifIndex" will be sent along with the trap.
- A DESCRIPTION clause with human readable text describing the trap.
- The optional REFERENCE clause used for cross-references between traps is not used in the shown definition.

Protocol Operations

SNMPv1 provides just a minimal number of protocol operations. It is a simple request–response scheme between manager and agent. All requests are encoded by the rule of basic encoding rules (BER [6]).

UDP was selected as transport protocol because of low overhead, low bandwidth consumption and high probability to work in faulty networks. Although some of these design issues were revisited and found to be futile later, UDP is still the transport protocol of choice (Figure 32.8).

The simplicity aspect of SNMPv1 was addressed by the low number of different protocol operations supported by the protocol (Figure 32.9). By issuing GET and SET requests, a manager reads or writes variables from/to the agent. Each request can contain either one variable or a collection of variables. The GETNEXT PDU is similar to the GET request but the agent has to send the next variable that can be found in the MIB tree according to the lexigraphical order. That method is an elegant way to traverse whole MIB subtrees without deeper knowledge about their structure issuing GETNEXT requests in a loop. It must be mentioned that a GETNEXT request can contain any subtree, while a GET/SET operation always has to fully qualify a MIB variable. All the listed requests are answered by a GETRESPONSE PDU.

Finally, the agent can send an asynchronous notification to the manager using the TRAP PDU (e.g., if an error occurred). Six predefined traps like *coldStart* (indication the agent reinitializing itself) or *linkDown* (failure in one of the communication links) were specified by [RFC1157]. In addition, every agent can define new ones.

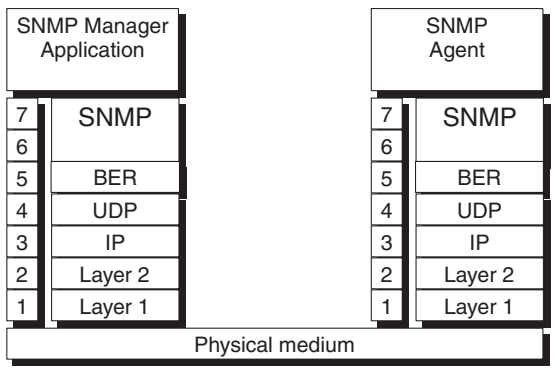

FIGURE 32.8 SNMP protocol stack.

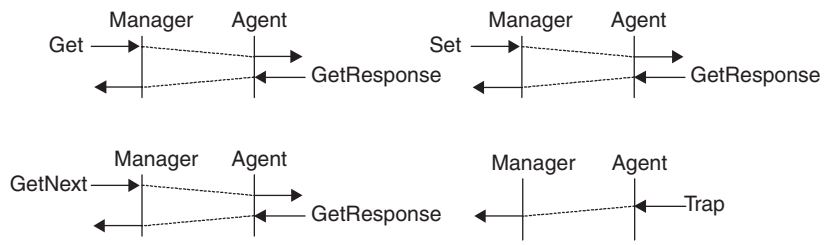

FIGURE 32.9 SNMPv1 protocol operations.

© 2005 by CRC Press LLC

The SNMP message format (Figure 32.10) consists of three parts: the *version information* for SNMPv1 has to be set to the value "0." The *community string* is used for a minimal authentication scheme (See Security Section). The *data* part depends on the PDU type.

All requests except the TRAP PDU share the same structure. The PDU *type* field is used to distinguish the different request types. The *request ID* gives the manager application a possibility for the identification of specific PDUs that he sends. This value is placed inside the PDU by the manager and inserted without change in the same field of the GETRESPONSE PDU by the agent (Figure 32.11). The fields *ErrorStatus* and *ErrorIndex* are filled by the agent to indicate problems answering the request. For the other request types, these values have to be 0. The *VarBind* list of the message is the payload of the PDU and will be described later.

The TRAP message has a special PDU structure (Figure 32.12). It also starts with a *type* field, followed by the *Enterprise* and *Agent Address* fields containing an object ID (OID) identifying the vendor of the equipment that sends the trap and the network address of the device. The *Generic* and *Specific* fields identify why the trap was sent. The *TimeStamp* contains the time since startup of the agent, while the *VarBind* list can contain additional information about the trap and its cause.

One of the intentions at the design time of SNMPv1 was a mechanism called "trap directed polling," where an agent sends a trap to indicate a problem to the manager, which in turn starts to poll the agent for further information. Instead, simple polling approaches are mostly used in reality.

The VarBind fields of all PDU types always contain the payload of the messages. Each VarBind consists of any number of variable bindings. The format is shown in Figure 32.13.

The maximum number of varbinds that can be transported in one request is not specified in SNMP but can be implementation specific for each agent. The only assumption adopted by [RFC1157] was that each agent must be capable of handling a PDU with a size of 484 bytes. It can be expected that most available agents exceed this size by far.

MIB-II

The first standardized set of MIB variables was defined by [RFC1213]. This extensive MIB contains general information about the managed system, its interfaces and protocols. Its content is focused on layers 1–3 information of the monitored device. All information is stored under the MIB subtree

```
Iso(1).org(3).dod(6).internet(1).mgmt.mib-2
```

FIGURE 32.10 SNMPv1 message format.

Group	Mandatory	Description
System	Yes	General information about the network element (e.g. up-time, system location, ...)
interfaces	Yes	Interface specific data (e.g.: operative status, number of bad packets, ...)
At	n.a.	Deprecated part of the MIB
ip, icmp	Both	Network layer information (IP and ICMP protocols)
tcp, udp	If protocol is supported by the device	Transport layer information (UDP and TCP protocols)
Egp	If protocol is supported by the device	Exterior gateway protocol data
transmission	n.a.	Used as a "placeholder" for future MIB about lower network layers (e.g.: Ethernet MIB, Token Ring, FDDI, ...)
Snmp	Yes	Data about the SNMP stack

FIGURE 32.14 MIB-II groups.

The MIB-II is divided into the groups listed in Figure 32.14. Most of these groups are mandatory for devices supporting SNMP — at least if the device supports the mentioned protocols. But the existence of SNMP implies by itself the support of IP, UDP and SNMP. As can be seen by the above list, nearly all groups should be found at any SNMP-enabled device, if the device vendor does not decide to ignore this RFC requirement.

Due to the broad support of the MIB-II by device vendors, each and every management solution should be able to cope with the data provided. The correlation of different values (e.g., correlation of sent packets with discarded packets over a certain amount of time) can help the management staff in tracking down network problems [7, 8].

Security

The community string contained in every PDU is the "security approach" of SNMPv1. But since it is not encrypted and is rather sent as plain text together with the remaining PDU, it can be easily detected by a network sniffer. The only useful function of this field is to give different views of a MIB in a closed environment.

More intrinsic approaches for security have been addressed in SNMPv2 and v3.

Conclusion

SNMPv1 is an easy-to-understand protocol with a broad hardware and software base. Several different solutions either for management applications or for agent implementations do exist. The resource requirements are quite low making the implementation of an SNMP agent feasible even in primitive devices. The SMI provides a formal description of the agent interface that can be used by manager applications. Several standard MIB definitions already exist, together with a countless number of vendor specific MIBs.

SNMPv1 must be criticized for the bad security concept and the waste of bandwidth caused by the PDU format and the polling mechanism that is mostly used.

32.4 SNMP v2

In April 1993, after considerable work by the Network Working Group, the specification of the Simple Network Management Protocol Version 2 (SNMPv2) was released in [RFC1441] to [RFC1452]. Some of these specifications were later marked as historic, while others, like the security model, were reviewed and extended by new specifications [RFC1901] to [RFC1910] released in January 1996.

© 2005 by CRC Press LLC

While SNMPv1 was intended as a quick solution handling a customer's most pressing problems, SNMPv2 should improve its predecessor, especially in the areas of security, capabilities, MIB definition and clarity of the protocol definition. To achieve these goals, new PDUs were defined, the SMI was extended to SMIv2 and several security models were introduced. Unfortunately, indicated by the huge amount of RFCs involved, all these extensions made the specification by far more complex, too.

While the schemes underlying SNMPv1 and SNMPv2 are more or less the same, the two protocols are not compatible. To provide compatibility, agents as well as manager applications have to be bilingual. For easy migration, [RFC1452] defines all steps to convert an SNMPv1 entity to an SNMPv2 entity.

Network Structure

While SNMPv1 defined a clear relationship between a manager and a number of agents, this definition was weakened in SNMPv2, now speaking of "entities." Each entity can take both the roles of a manager and an agent, making even dual role functions possible. Which role is supported by an entity can be distinguished by the supported protocol operations.

An *agent* can generate TRAP and RESPONSE PDUs and must process GET, GETNEXT, GETBULK and SET requests. A *manager* can generate GET, GETNEXT, GETBULK, SET, INFORM and RESPONSE PDUs, while it must process RESPONSE, TRAP and INFORM requests [8, p353].

Protocol Operations

While SNMPv1 is completely based on UDP as a transport protocol, SNMPv2 supports different transport protocol mappings like Novell IPX, AppleTalk, etc [RFC1449].

The overall message format remained the same, but details like the possible states for the field "Error Status" (13 additional error codes providing a better distinction between error conditions) were extended. Also, two new PDUs were introduced: GETBULK for optimized retrieval of larger amounts of data and INFORM for manager-to-manager communications (Figure 32.15).

GETBULK-Request

The GETBULK-Request is a more general form of GETNEXT. It can be used to retrieve table data easier and with less protocol overhead (Figure 32.16).

Using the GETNEXT operation, the lexigraphical successor for each element in the VarBind list is sent back to the requesting application by the RESPONSE message. For each requested element, exactly one element is returned. If the requested data is organized in a table, this method imposes considerable overhead.

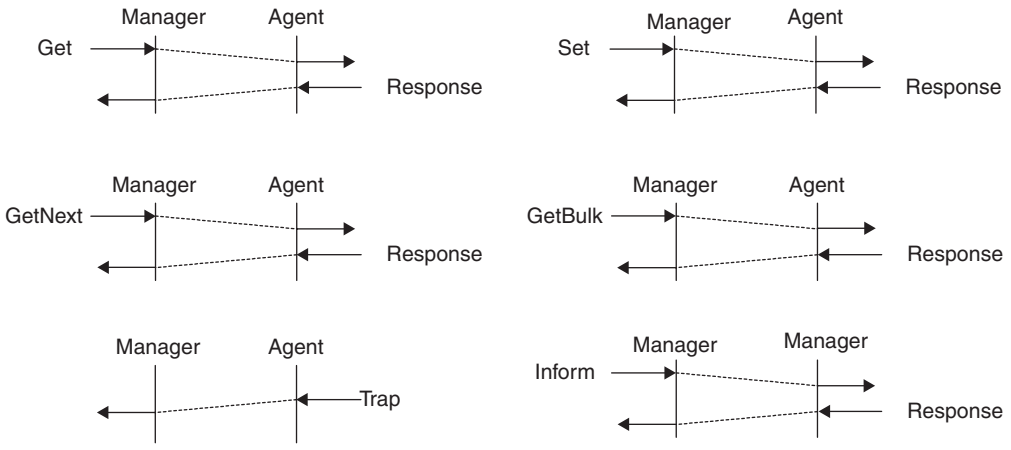

FIGURE 32.15 SNMPv2 PDUs.

© 2005 by CRC Press LLC

PDU Type	Request ID	Nonrepeaters	Max. repetition	VarBind list

FIGURE 32.16 Format of GetBulk PDU.

The GETBULK-Request contains two counters together with the VarBind list: the field *Nonrepeaters* specifies the number of elements in the Varbind list that shall be treated like elements of a GETNEXT request. The first elements up to *Nonrepeaters* each return one field in the RESPONSE PDU. For the remainder of the Varbind list, the *Max. repetition field* specifies the number of GETNEXT requests that shall be issued on each of these elements.

For example, for a Varbind list with six elements, the field *Nonrepeaters* set to 2 and *Max. repetition* set to 3, the response will contain 14 elements: two elements for the *Nonrepeaters* section and three times 4 consecutive elements for the *Max. repetition* part.

Using the GETBULK a manager can retrieve as many variables (e.g., from a large table) as will fit in a RESPONSE without knowing the exact OIDs of all the variables. Tests have shown that the use of this type of request can speed up the performance of an application significantly. In addition, due to the basic similarity to the GETNEXT operation, the extensions for an existing agent implementation are naturally not large.

TRAP PDU

Several improvements were applied to the TRAP PDU, while the number of traps in the management information base for SNMPv2 did not extend the SNMPv1 definitions [RFC1450]. The structure of the TRAP PDU was redefined in SNMPv2. Its format now is identical to all other SNMP PDUs. Furthermore, it is specified that the first elements of the Varbind list have to contain certain values [RFC1448]:

- OID1 … has to contain the actual value of the sysUpTime MIB variable.
- OID2 … has to contain the value of snmpTrapOid.0. This is an OID uniquely identifying each trap.

All other elements of the VarBind list depend on the TRAP definition. See that the SNMPv1 method of using two fields (PDU parts "Generic" and "Specific") to identify a trap was replaced by the use of a unique object identifier (OID2). This approach reduces the problem of different agents on different types of hardware using the same values for trap identification.

INFORM Request

The INFORM Request is intended for communications between two entities in the role of a management application. While this PDU is sometimes referred to as a "confirmed trap," it shall be mentioned that it is not intended for use by agents but rather for manager–manager interaction. It is used in situations where one manager has delegated some responsibility to another manager and wishes to be notified about specific conditions. Like the Trap PDU, the first two Varbind fields are predefined [RFC1448]:

- OID1 … has to contain the actual value of the sysUpTime.0 MIB variable.
- OID2 … has to contain the value of snmpTrapOid.0 (the authoritative identification of the event type).

SMIv2

The definition of the structure of management information SMI was substantially extended to SMIv2. Again, ASN.1 was used as the base for the formal description notation, but new data types were introduced and a large number of macro definitions were established.

The new data types are Bit String, Counter64, NsapAddress and Uinteger32. Some of the data types of SMIv1 were renamed (e.g., Integer to Integer32).

For the definition of MIB modules, the following macro definitions were introduced:

- MODULE-IDENTITY MACRO
- OBJECT-IDENTITY MACRO

© 2005 by CRC Press LLC

- OBJECT-TYPE MACRO
- NOTIFICATION-TYPE
- TEXTUAL CONVENTION
- OBJECT-GROUP
- MODULE-COMPLIANCE
- AGENT-CAPABILITIES.

All these macros will be reviewed in the remainder of this section.

MODULE-IDENTITY MACRO

This macro has to be provided exactly once in every information module. It is used for the description of the MIB, providing contact information, revision history and a general description of the contents of the information module. The sample in Figure 32.17 is taken from [RFC1450] and shows all elements of the macro except the optional REVISION part.

OBJECT-IDENTITY MACRO

This macro is used to assign an OID value to an identifier in the MIB module. It contains the following fields (Figure 32.18):

- STATUS: one of the values *current* or *obsolete*.
- DESCRIPTION: a human readable text describing the contents and purpose of the MIB object.
- REFERENCE: a textual cross-reference to an object assignment in another information module. The field is optional.

The difference between OBJECT-IDENTIFIER and OBJECT-IDENTITY is that the OBJECT-IDENTITY performs a registration of an OID value, thus making the described element of the MIB unique for all time and space. In contrast, an OBJECT-IDENTIFIER is just a reference to a value of the MIB. As

```
snmpMIB MODULE-IDENTITY

a consequence, several OBJECT- IDENTIFIERs can have the same assignment, while no other element may be registered with the same OID if an OBJECT-IDENTITY already exists [5]. A MIB compiler must check for and prevent these duplicate registrations while no restrictions are imposed on several OBJECT-IDENTIFIER value assignments to the same OID value.

OBJECT-TYPE MACRO

The OBJECT-TYPE macro was redefined in SMIv2. It now contains the following fields:

- SYNTAX: the objects data type.
- MAX-ACCESS: one of the values *read-only*, *read-write*, *read-create* or *not-accessible* (this field replaces the former ACCESS-part).
- STATUS: one of the values *current*, *deprecated*, *obsolete.*
- DESCRIPTION: a human readable text describing the contents and purpose of the MIB object.
- REFERENCE: a textual cross-reference to an object in another information module.
- INDEX/AUGMENTS: used for indexing tables.
- DEFVAL: defines a default value for the object.

The fields REFERENCE, INDEX/AUGMENTS and DEFVAL are optional fields and do not have to be present. The usage of the OBJECT-TYPE macro follows the same rules as SMIv1 (see Figure 32.19).

NOTIFICATION-TYPE MACRO

This macro is used for the definition of Traps and confirmed events (INFORM request) (see Figure 32.20). It has the following fields:

- OBJECTS: a list of objects transported together with the notification sent. The field is optional.
- STATUS: one of the values *current*, *deprecated* or *obsolete*.
- DESCRIPTION: a human readable text describing the contents and purpose of the notification.
- REFERENCE: contains a cross-reference to another notification defined in some other information module. The field is optional.

```
snmpStatsPackets OBJECT-TYPE

    DESCRIPTION
        "A linkUp trap signifies that the SNMPv2 entity,
        acting in an agent role, recognizes that one of
        the communication links represented in its
        configuration has come up."
    ::= { snmpTraps 4 }
```

FIGURE 32.20 NOTIFICATION-TYPE macro sample.

© 2005 by CRC Press LLC

TEXTUAL CONVENTION MACRO

This macro is used to define new data types (See Figure 32.21). It provides more details than the type definition of SMIv1. The macro includes the following fields:

- DISPLAY-HINT: gives a hint for INTEGER or OCTET STRING types and how the value of the corresponding MIB variable shall be displayed. The field is optional.
- STATUS: one of the values *current*, *deprecated* or *obsolete.*
- DESCRIPTION: a human readable text describing the contents and purpose of the notification.
- REFERENCE: contains a cross-reference to a related item in another information module. The field is optional.
- SYNTAX: defines the syntax of the new data type.

Comparing this structure to the definition using SMIv1, the improved description quality becomes obvious (See Figure 32.21 compared to Figure 32.22).

Conformance Statement Macros

To provide a possibility for the definition of the lower limit of an actual implementation to the MIB designers, [RFC1444] introduced several conformance statement macros. The OBJECT-GROUP macro is used to define a collection of related object type definitions. It helps the MIB author to explain the logical grouping of object types showing their correspondence to subsystems. Each MIB object with MAX-ACCESS other than "not-accessible" must be a member of at least one OBJECT-GROUP. The MODULE-COMPLIANCE statement defines requirements for an agent implementation (e.g., which groups are mandatory), while the AGENT-CAPABILITIES can be used by an agent designer to specify implementation characteristics. This macro lists groups, objects and events defined in the imported module that are supported by the implementation. Usually, it is used in a MIB module with no statements other than IMPORT and MODULE-IDENTITY.

MIBs

Together with the protocol specification of SNMPv2, several new MIB modules were released: the management information base for SNMPv2, the party MIB and the manager-to-manager MIB. Other MIBs have later been added to these initial specifications (e.g., MIB modules for token ring, token bus, OSPF, BGP, RIP, Ethernet, FDDI, etc.).

In addition, the Internet-sub tree obtained two new successor elements:

- Security: Internet(5) and
- SnmpV2: Internet(6).

MIB for SNMPv2

This MIB is defined in [RFC1450] and extends the MIB-II from SNMPv1 by the following groups:

- Statistic groups for SNMPv2: SNMPv2-specific statistics.
- Statistic groups for SNMPv1: SNMPv1-specific statistics.
- Object resources group: contains all objects that can be dynamically configured in an agent.
- Trap group: a table of all objects that can send an SNMPv2 trap PDU.
- Set group: used to coordinate SET requests of different manager applications.

Party MIB (Now Obsolete)

This MIB should help network administrators to define individual access rights to certain users ([RFC1447]). For each party, a certain area of the MIB tree (a MIB view) can be defined. A specific station then only has access to this MIB view (see also the next section). This MIB was later marked as historic.

Manager-to-Manager MIB (Now Obsolete)

[RFC1451] defines the objects of the manager-to-manager MIB. This MIB was introduced to address one of the weak points of SNMPv1, namely the strict distinction of entities acting in the manager or agent role. Now each entity can act either as a manager, as an agent or in a dual role. This MIB should help to coordinate the work of multiple management stations. It was later marked as historic.

Security/SNMPv2 Versions

The main weakness of SNMPv1 was the lack of an appropriate security model. During the development of SNMPv2, different approaches to address security were proposed [9]. Later, all presented approaches except SNMPv2c became obsolete and were changed to "historical" state.

SNMPv2p

This version called "party-based SNMP" was introduced together with SNMPv2. The model is based on the concept of an SNMP party that comprises a protocol entity at a logical network location together with a security context (authentication and/or privacy protocols). Each implementation using SNMPv2p has to implement the Party MIB.

Authentication of entities is achieved by using MD5 algorithm. A 16-byte fingerprint ensures that a message is unchanged and the originator is known. For privacy, the use of DES [10] encryption was proposed. In addition, each PDU has to contain a timestamp to recognize retransmission of a message. The following combinations of authentication an encryption can be used, allowing scaling for different applications:

- No authentication and no privacy.
- MD5 authentication and no privacy.
- MD5 authentication and DES privacy.

One of the problems of this approach was the export restriction of MD5 and DES for outside the USA at the time the model was introduced. Another setback was the complex handling of the parties of this model. Due to these problems, the approach was later set to historic and replaced by SNMPv2u and SNMPv2c.

SNMPv2u

In SNMPv2u, a *user paradigm* is used. Each user has attributes assigned, regarding which type of authentication and/or privacy protocol shall be used if any. In addition, keys for both areas are defined. All these attributes must be known to both the sender and receiver of the message.

Like SNMPv2p, this approach uses MD5 and DES for authentication and privacy with some modifications (e.g., in the party model, the MD5 key is appended after the digest of the message is computed; in SNMPv2u, it is inserted before computing the digest value).

© 2005 by CRC Press LLC

SNMPv2*

This version was never published as an RFC. It combined the best features of SNMPv2p and SNMPv2u. Little documentation exists about this approach.

SNMPv2c

SNMPv2c uses all the enhanced protocol features of SNMPv2 without any of the security models. Instead, it uses the community string paradigm known from SNMPv1. It is defined by [RFC1901]. This version is still experimental but widely used since it is easy to implement and to use.

Conclusion

SNMPv2 was a big step forward. It extended the previous version SNMPv1 in nearly all areas. But these extensions also increased the complexity of each implementation significantly in addition to the base payload required for encryption and authentication if these features are used. The improved SMIv2 provides a good base for a concise definition of MIB modules. While not all macros might be used to the same extent by MIB designers, others will alleviate problems where MIB contents were inaccurate before.

32.5 SNMP V3

The specification of SNMPv2 substantially extended the definitions of SNMPv1 in nearly all areas. The next step was no revolution but a stepwise refinement of SNMPv2. It was released in 1999 by [RFC2570] to [RFC2580]. Citing [RFC2570], SNMPv3 "…can be thought of as SNMPv2 with additional security and administration capabilities."

The base structure again remained similar to the previous SNMP versions. Adaptations only concerned the structure of the documents that were better modularized to allow easier extensions and replacements by future versions and a more detailed description of the architecture. The only areas with larger changes were security and administration.

Architecture

While previous SNMP versions just identified the roles that an entity can accomplish, an important part of the SNMPv3 architecture covers the description of the entities. Each entity consists of an SNMP engine and some associated applications (Figure 32.23).

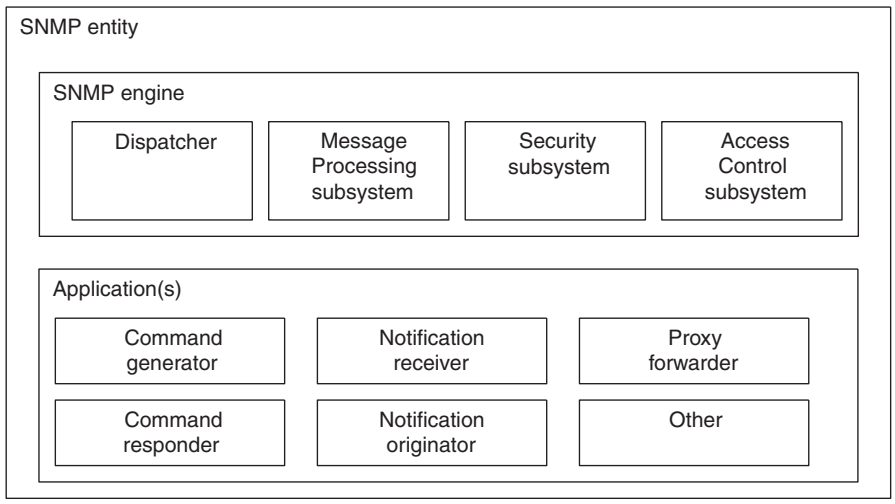

FIGURE 32.23 SNMPv3 entity [RFC2571].

© 2005 by CRC Press LLC

The *Dispatcher* of the SNMP engine is responsible for sending and receiving messages. Depending on the version number in the PDU, each message is passed to the appropriate *Message Processing* subsystem. This subsystem encompasses message handlers for different versions of SNMP. It prepares messages that shall be sent and extracts data from received messages (Figure 32.24).

The *Security subsystem* (Figure 32.25) provides authentication of messages and encrypting/decrypting of messages for privacy. Typical security models would support the community-based security model of SNMPv1 and SNMPv2c or the user-based security model.

The *Access Control subsystem* (Figure 32.25) determines if the access to a managed object shall be allowed or not. At the moment, only one model — the View-based access control model (VACM) — is defined.

In the context of SNMPv3, the term "*application*" is used to describe parts of an SNMP entity. Applications use the functions provided by the SNMP engine to accomplish their tasks. In addition, abstract service interfaces were defined to clarify the interfaces between the various subsystems. They should not constrain the developer but should provide a hint about real-life implementations.

Several types of applications are already defined, including:

- Command generators: generate SNMP commands to collect or set management data.
- Command responders: provide access to management data.
- Notification originators: initiate traps or inform messages.
- Notification receivers: receive and process traps or inform messages.
- Proxy forwarders: forward messages between entities.

An SNMP entity acting in the role of a manager or an agent typically consists of the parts listed by Figure 32.26.

SMI

SMIv2 was updated by [RFC2578] to [RFC2580]. Changes to the former specifications were minimal. Extensions to the older versions only included some new textual conventions. While even the structure of all documents almost remained the same, some effort was spent toward reviewing and clarifying the specifications.

FIGURE 32.26 Elements of SNMP entities.

Protocol changes

No new PDU types were introduced by SNMPv3 but the message format was changed. The format of the PDUs now consists of the following three parts:

- Header: this part contains fields like the version identifier (set to value 3), the maximum message size the sender supports or the identification of the security model used.
- Security parameters: this area depends on the security model used. The data is directly passed to the corresponding Security Model.
- Data: this part is either encrypted or plain text. It contains context information and a valid SNMPv2c PDU.

SNMPv3 messages therefore can be also be described as a message wrapper around SNMPv2 PDUs.

Conclusion

SNMPv3 clarified and extended its predecessors significantly while keeping the overall structure of SNMP the same. Especially, the area of security was consolidated after the different solutions that were proposed and dropped during the evolution of SNMPv2. In addition, the modular approach to the description of an SNMP entity helped in building modular solutions. The future will show if SNMPv3 can completely replace the previous versions.

32.6 Conclusion

All presented SNMP versions provide a good approach for building network management solutions. Significant strengths are found in areas where status information is requested or small amounts of information like switching commands are sent to a network node, while areas like configuration management are still not sufficiently solved. Independent of brand and type, nearly all network equipment on the market today with any form of management interface provides an SNMP agent to access the equipment. Over the years, alternate solutions like WEB-based management were proposed and implemented but none could find the broad acceptance of SNMP.

While the basic structure of SNMPv1 is quite easy to understand, the complexity of the later versions increased considerably. Due to this fact, SNMPv1 solutions are still quite common. Especially, if security is of no concern, for example, in a closed environment and if the new message types are not needed, this version might prove to be an easy solution for network management.

Technical University of Berlin

33.1 Introduction

Client configuration in large networks requires large effort by administrators if the clients need to be manually configured one by one. The Dynamic Host Configuration Protocol (DHCP) [3] provides a common framework to store network- and client-specific options on a central server and to assign network addresses to clients. It consists of two components: a mechanism for stateful allocation of network addresses to hosts and a protocol for delivering host-specific configuration from a DHCP server to a client. Both functionalities can be used together or separately.

DHCP is based on a client–server architecture where requests are issued by a client and answered by one or more servers (anycast). The servers offer network addresses from a pool of addresses in an automatic, dynamic, or manual allocation scheme depending on the server configuration. While being extremely flexible for configuration, DHCP is nonetheless designed to smoothly interoperate with manually configured, nonparticipating hosts who are configured with an address from the server-managed address pool. The operation of DHCP does not require a client to have any preconfigured network-related data, and furthermore the operation of DHCP is transparent to all other hosts in the same network. Thus, under normal circumstances, a network manager should not have to enter any configuration

© 2005 by CRC Press LLC

parameters at the clients. A client that obtained its parameters via DHCP should be able to exchange packets with any other host in the Internet.

As a protocol for basic network configuration, the network address configuration part of DHCP has to fulfill some requirements:

- DHCP has to guarantee that any specific network address is used by at most one client at a time.
- A server should retain DHCP client configuration across a client reboot. Whenever possible, a DHCP client should be assigned the same configuration parameters (e.g., network address) in response to each request.
- DHCP client configuration should be retained across server reboots, and, whenever possible, a DHCP client should be assigned the same configuration parameters despite restarts of the DHCP server.
- It should support the automated assignment of configuration parameters to new clients to avoid manual configuration for new clients.
- It has to support permanent allocation of configuration parameters to specific clients in order to interoperate with older Bootstrap Protocol (BOOTP) [2, 4] clients.
- The DHCP server should not necessarily have to be placed in the same subnet as its clients.

The DHCP evolved from the BOOTP protocol. For this reason, interoperation with BOOTP relay agents and the necessary service for BOOTP clients is required for DHCP. This is achieved by using a compatible message format and the same vendor extension options [1, 12] as defined for BOOTP.

33.2 Protocol Basics

We start with a description of the messages used to exchange DHCP protocol data units (PDU) between server and clients. The set of messages is summarized in Table 33.1. The common message format for BOOTP and DHCP is defined in RFC 951 [2]. A message consists of a header of fixed elements with a total of 236 bytes in length, shown in Figure 33.1. The fields referenced in this figure are explained in Table 33.2. It is followed by a variable length list of options (Figure 33.2) starting with a magic cookie of four octets ('99.130.83.99') followed by the "DHCP message type" and always terminated by the "end" option. The magic cookie helps distinguishing between BOOTP messages and DHCP messages. Messages sent from a client to a server are tagged as a BOOTREQUEST in the `op`-field, while messages from a server to a client are tagged as

TABLE 33.1 DHCP Messages [3]

Message	Use
DHCPDISCOVER	Client broadcast to locate available servers.
DHCPOFFER	Server to client in response to DHCPDISCOVER with offer of configuration parameters.
DHCPREQUEST	Client message to servers either (a) requesting offered parameters from one server and implicitly declining offers from all others, (b) confirming correctness of previously allocated address after, for example, system reboot, or (c) extending the lease on a particular network address.
DHCPACK	Server to client with configuration parameters, including committed network address.
DHCPNAK	Server to client indicating client's notion of network address is incorrect (e.g., client has moved to new subnet) or client's lease has expired
DHCPDECLINE	Client to server indicating network address is already in use.
DHCPRELEASE	Client to server relinquishing network address and canceling remaining lease.
DHCPINFORM	Client to server, asking only for local configuration parameters; client already has externally configured network address.

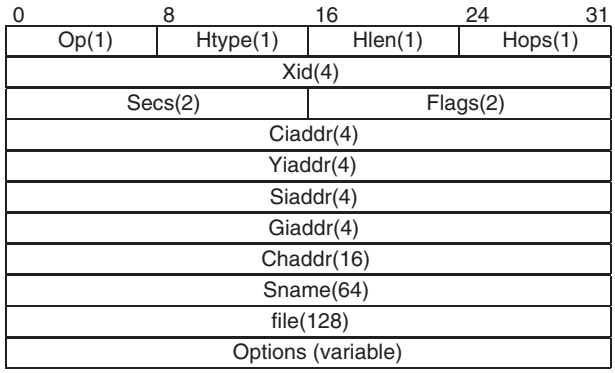

FIGURE 33.1 PDU of DHCP messages.

TABLE 33.2 Description of Fields in a DHCP Message [3]

Field	Octets	Description
op	1	Message op code / message type. 1 = BOOTREQUEST, 2 = BOOTREPLY
htype	1	Hardware address type, see ARP section in "Assigned Numbers" RFC; e.g., "1" = 10mb ethernet.
hlen	1	Hardware address length (e.g., "6" for 10mb ethernet).
hops	1	Client sets to zero, optionally used by relay agents when booting via a relay agent.
xid	4	Transaction ID, a random number chosen by the client, used by the client and server to associate messages and responses between a client and a server.
secs	2	Filled in by client, seconds elapsed since client began address acquisition or renewal process.
flags	2	Flags (e.g., broadcast flag).
ciaddr	4	Client IP address; only filled in if client is in BOUND, RENEW, or REBINDING state and can respond to ARP requests.
yiaddr	4	'your' (client) IP address.
siaddr	4	IP address of next server to use in bootstrap; returned in DHCPOFFER, DHCPACK by server.
giaddr	4	Relay agent IP address, used in booting via a relay agent.
chaddr	16	Client hardware address.
sname	64	Optional server host name, null terminated string.
file	128	Boot file name, null terminated string; "generic" name or null in DHCPDISCOVER, fully qualified directory-path name in DHCPOFFER.
options	var	Optional parameters field. See the options documents for a list of defined options.

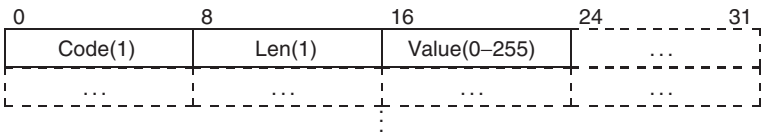

FIGURE 33.2 Format of options in the options area (and the respective option file).

a BOOTREPLY message. These flags identify the allowed options within the DHCP message. An option value can be of arbitrary data type, but limited in size to 255 octets. Longer option sizes (e.g., path names, route descriptions) are conveyed by concatenating the values of options with the same code in the same order as they appear in the message. For interoperability reasons, multi-octet quantities are represented in network byte order.

A DHCP packet is further encapsulated as a UDP packet allowing for sizes up to 65,535 bytes. However, since the minimum guaranteed maximum IP datagram size that can be handled by an arbitrary host is 576 octets, larger message sizes have to be negotiated using the "maximum DHCP message size"

© 2005 by CRC Press LLC

option. IP fragmentation cannot be used here since the IP protocol stack is not supposed to be completely operational at boot time. Usually, this negotiation is initiated by the client as is all message exchange between client and server.[1]

DHCP servers listen for DHCP and BOOTP messages on port 67. They send replies to the client's port 68. The advantage of using different ports for server and clients is that only servers receive the broadcast messages issued by clients. In the other direction, most messages sent from a server to a client use a unicast address, except in those cases where a server issues a DHCPNACK message informing that a requested IP address could not be allocated to a client (which then clearly has no valid IP address). A second reason is that the client explicitly requests a server broadcast in its request messages (using the `broadcast` bit in the flags field). A reason for this could be the client's inability to process unicast IP messages before having an IP address configured. More specifically, whenever the following conditions hold: (a) the `broadcast` bit is set in a request message, (b) the client is in the same subnet, and (c) the client does not provide a valid IP address (`ciaddr` is zero), then DHCPOFFER and DHCPACK messages are broadcasted to the client using the IP broadcast address 0xffffffff (255.255.255.255) and the MAC broadcast address.

The purpose of the `xid` field is to let the client match its request packets with received response packets. The client should choose this id such that it is not identical to the id chosen by another client, although there is no mechanism to guarantee uniqueness. Nevertheless, no problems should result from such a conflict as a client is further identified either with the "client identifier" or by its hardware address `chaddr`.

Address Discovery

The following description shows the messages exchanged to allow a client to obtain a network address. Due to routing restrictions, broadcast messages are not forwarded over (sub-) network boundaries. Without the support of special BOOTP relay agents (see Section 33.4), DHCP servers need to be placed within the same broadcast domain as their clients. The address discovery process allows for having several servers serving the same subnet with the same set of addresses. However, in the case of multiple servers, it has to be guaranteed by the system administrator that the relevant data (address pool, network configuration information) are consistent across the servers, since the DHCP protocol itself provides no mechanism to ensure this consistency.

The message exchange is usually the following (as shown as a timeline diagram in Figure 33.3 and as a state diagram in Figure 33.4):

1. A client initiates an address discovery by broadcasting a DHCPDISCOVER message on its local subnet. The request is sent using a Medium Access Control (MAC)-layer broadcast with the client's MAC address as the source address. The UDP/IP packet has its IP source address set to 0.0.0.0 and a broadcast destination address (255.255.255.255). Enclosed in the DHCPDISCOVER messages the client provides certain options such as a proposed lease time, a maximum message size, and its previously allocated address.
2. Each of the available servers may respond with a DHCPOFFER message. This message contains an available network address (`yiaddr`) and may contain con-figuration options for the network (such as default router, network mask, name server, Domain Name System (DNS) domain name, etc.). Typically, the offering server should check the availability of the proposed address prior to sending the DHCPOFFER message by probing with an Internet Control Message Protocol (ICMP) echo request.
3. The client can collect several DHCPOFFER messages or already answer the first one. In the latter case, all further DHCPOFFER messages must be discarded. Before accepting an offered network address with a DHCPREQUEST broadcast message, the client should by himself probe for availability of the

[1]An exception is the extension of the DHCP protocol with the DHCPFORCERENEW message type shown in point 2 of Section 33.2

© 2005 by CRC Press LLC

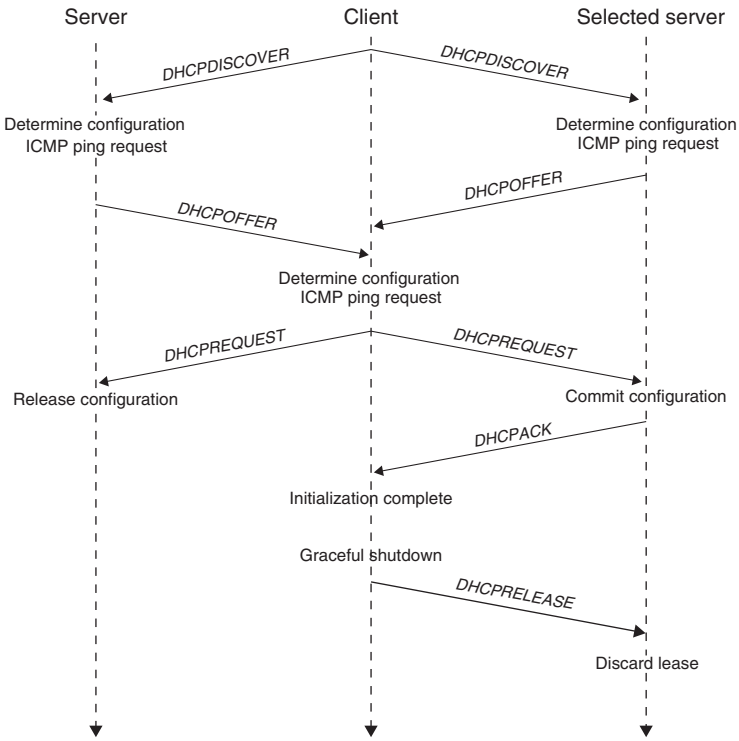

FIGURE 33.3 Timeline diagram of a DHCP address configuration.

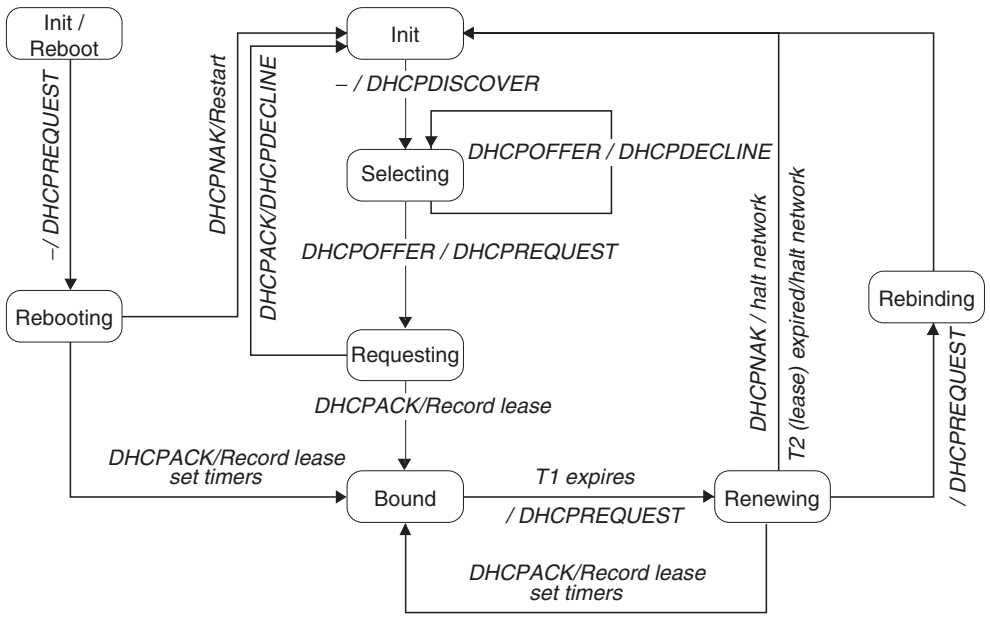

FIGURE 33.4 State chart of the DHCP address configuration.

© 2005 by CRC Press LLC

network address by sending an Address Resolution Protocol (ARP) request message. In order to make it possible to run several DHCP servers for a network, the client's answer has to fulfill a number of constraints:

- the message header's `secs` field must have the same value as the initial DHCPDISCOVER message. This ensures that servers can recognize requests that have been successfully served by other servers and release their own offers to the respective DHCPDISCOVER message.
- the requested IP address must be set to the value of the `yiaddr` field, that is, the selected and available network address.

4. All servers that initially received a DHCPDISCOVER message will likely also receive the DHCPREQUEST message broadcasted from the client. Those servers that are not selected by the DHCPREQUEST command release the offers given to the client. The selected server (as given in the "server identifier option") commits the new binding to persistent storage. A DHCPACK message is used to acknowledge the address to the client and to transmit additional configuration parameters.
   If the server is not able to fulfill the client's request, it sends a DHCPNACK message. There are not many reasons why such a request may fail. Especially, the server should not check an address given in a DHCPREQUEST because the address may already be in use by the requesting client. A request most probably fails if the server does not reserve a network address between the check and DHCPREQUEST message and, therefore, offers the same address to several clients.
5. On receiving a DHCPACK message, the client may again probe the given address, for instance, by issuing an ARP request. If it receives an answer, the client notifies the server by sending an DHCPDECLINE message and restarts the configuration process afterwards.
   If the probe remains unanswered, the client finishes its address configuration by noting the duration of the lease.
   After receiving the DHCPACK message, the client is said to have obtained a lease. This lease is equipped with a permitted lifetime, which the server has given in the DHCPOFFER message (secs field). Before expiry of the lifetime, the client has to renew the lease, as described below.
6. Optionally, the client can relinquish the leased address by sending a DHCPRELEASE message to its server. This is not required, but in networks where addresses are a scarce resource it is useful to relinquish an address, for instance, if the client is shut down. The lease is uniquely identified by the client network address and either the value of the "client identifier option" or the value of the `chaddr` field.

Usually, clients remember their address in a persistent storage. If after a reboot, an old address can be found in the storage or when the client tries to renew its lease, it may use a shortened reservation scheme. The client skips the DHCPDISCOVER message and immediately sends a DHCPREQUEST message containing the remembered network address. There are two reasons why a server might reject a client's request for a given address:

- the requested address is already assigned to another client according to the server's configuration table (this case is different from the case of an initial DHCPDISCOVER message: the server is unable to determine in response to a DHCPREQUEST message if a requested address is already in use by some other system, because the client may already respond to ICMP echo request messages), or
- the requested address is not valid for the network that the client is currently connected to, which is often given for mobile devices such as laptops.

In either case, the server sends a DHCPNACK message. If the server and client are in the same subnet, this message is sent to the broadcast address, as the client may not have a valid address to receive unicast messages. Otherwise, the server has to send the message via unicast to the BOOTP relay agent, as detailed in Section 33.4.

Even if the client receives a DHCPACK message, it has to probe whether the address is already used by another system that does not act as a DHCP client. When receiving an answer to its probe, the client informs the server by sending a DHCPDECLINE message.

In both the cases, a DHCPNACK message or a negative probe result (some answer received), the full DHCP address configuration has to be restarted.

© 2005 by CRC Press LLC

Pushing Reconfiguration Requests

Usually, the DHCP architecture is completely driven by requests initiated from a client. In environments where configuration settings for clients are subject to change at unpredictable times, short lease times can be used to keep the clients up-to-date, at the expense of unnecessarily increased traffic load. In RFC 3203 [5], a new DHCP message type is defined: the DHCPFORCERENEW message. This message is sent to a client as a unicast message, which is possible, as the server keeps track of all clients with valid leases. Upon receipt of the unicast DHCPFORCERENEW message, the client will change its state to the RENEWING state (see Figure 33.4), and will then try to renew its lease according to the shortened DHCP procedures. If the server wants to assign a new IP address to the client, it will reply to the DHCPREQUEST message with a DHCPNACK message. The client will then go back to the init state and broadcast a DHCPDISCOVER message. The server can now assign a new IP address to the client by replying with a DHCPOFFER message. If the DHCPFORCERENEW message is lost, the DHCP server will not receive a DHCPREQUEST message from the client. It retransmits the DHCPFORCERENEW message using a backoff algorithm with an exponentially growing delay as retransmissions fail. The amount of retransmissions is usually limited since the client may have left the network due to power off or movement.

For manually configured devices, a DHCPFORCERENEW message initiates a new DHCPINFORM message to the server.

As with all IP network connections, there are no precautions to avoid session interruptions for clients whose network address is forced to change during a session.

Interpretation of Time

A time data type is needed to specify lease times. Usually, the time is synchronized between computers in a network (e.g., by using the Network Time Protocol [6]). However, since a client enters a network immediately after rebooting, it does not necessarily have a correct absolute time. Therefore, the lease is expressed as a relative time. Later on, the client may update its system time using a time server address provided by the DHCP exchange. The two octet-sized `sec`-fields in the DHCPOFFER message allow to define lease times up to approximately 18 h, which should be enough for the purpose of DHCP. Still, it is assumed that the drift between both the client's and the server's clock is small. Servers avoid running out their leases database before the clients by sending a lease time to the client, which is less than the one they are storing in their database. The client itself needs to maintain various times. For each request issued, the client has to store its issuing time. Additionally, the client keeps track of the lease times: some time before expiry, the client tries to renew the lease with the granting DHCP server (this time is given by the "Renewal (T1) Time Value" option) . If this is not successful and the lease eventually expires, the client has to start the full configuration procedure with a DHCPDISCOVER message. This procedure is started at a time indicated by the "Rebinding (T2) Time Value" option in the servers DHCPOFFER message.

Failure Recovery

Various situations exist where a server might fail to respond to client requests. DHCP is designed to provide any kind of answer in a reasonable amount of time. Failure recovery is the responsibility of the client. For each request, the client sets a timer. On timer expiry, the request is retransmitted a limited number of times. The timeout value depends on the underlying Internet network type with a lower bound of about 3 sec up to a maximum of 64 sec. The exact timeout values are randomized to avoid unwanted synchronization of several clients. After 60 sec without a valid reply, the client gives up and notifies its user.

To protect the client against server failures for initial configurations or lease renewals, the following rules apply:

1. As long as the client has a valid lease for an address, that is, the lease time for this address has not yet elapsed, and there is no other system using the address, the client can use the address until the lease time has elapsed.

2. If a client does not have a configured address, the system may choose stateless autoconfiguration. Specifically, the client picks one address from the range 169.254.0.0/24 and probes this address

© 2005 by CRC Press LLC

with an ARP request. If nobody answers, the client configures this address; otherwise, it tries another one. The address range 169.254.0.0/24 is reserved for autoconfigured networks. An autoconfigured client can only communicate with other autoconfigured clients, since routers do not forward their packets without special measures. For systems supporting the stateless address configuration RFC 2563 obligingly regulates that the "autoconfigure" option has to be included in a DHCPDISCOVER message. The server can indicate in its answer that autoconfiguration addresses are not supported in this subnet (option `DoNotAutoConfigure` set to 0). After receiving this information, the client may notify its user. The client has to respect this option in that it must not configure an autoconfigured address.

Requesting Configuration Information

As we have seen in the beginning, the DHCP protocol is used to fulfill two tasks: network address configuration and provision of additional local configuration information. Both parts may, but do not need to be separated from each other. A manually configured client may request additional configuration information using the DHCP protocol. The special DHCPINFORM broadcast message serves this purpose. It is answered with a unicast DHCPACK message from one or more servers to the client. This answer contains the relevant parameters. In case of multiple servers, the system administrator has to ensure the consistency of the delivered information. The server does not check the client's address for availability and existing bindings of the address (although it should check for consistency!). Furthermore, when formatting the response message, the server fills all address-lease-related fields (e.g., the `yiaddr` field) with zero values.

A client can request specific parameters in its DHCPDISCOVER or DHCPREQUEST message. This is achieved by using the option "Parameter Request List" (code 55) consisting of the lists' length and a list of options the client requests. The response should at least contain all options requested by the client and the order of options should be retained by the server. Additionally, the client should include the maximum DHCP message size it is going to accept. Depending on this size, the server can either send the options completely in a DHCP message, or needs to provide a file, which has to be transferred via the TFTP protocol [9] between the server and client. This file has the same structure as the options part of the DHCP message with the exception that no further indirection to another file is allowed. The use of a file is signaled by setting two flags in the `options` field indicating that the `file` and `sname` field are valid.[2]

The DHCP implementations offer several further options.

Table 33.3 exemplarily lists the basic vendor extensions that are valid for BOOTP and DHCP. The allocation of new options is strictly regulated according to RFC 2489. The rules given there ensure that:

- allocation of new option numbers is coordinated from a single authority,
- new options are reviewed for technical correctness and appropriateness, and
- documentation for new options is complete and published.

33.3 Address Allocation

DHCP supports different modes of address allocation, *automatic*, *dynamic,* and *manual* allocation. Manual allocation is necessary for BOOTP clients that do not have knowledge about lease times. Instead, BOOTP clients assume that an assigned address remains valid forever. Thus, configuration is done in the server by creating a table of assignments from the client's hardware address (as a Reverse Address Resolution Protocol (RARP) replacement) or a unique identifier (which remains fixed even if the network

[2]However, the "option overload" option may alternatively indicate that these two fields are used to transport additional options.

TABLE 33.3 Vendor Extensions [RFC 2132]

Value	Name	Description	Size octets	Octets per element
0	Pad Option	Just padding	1	
255	End Option	Indicates end of options	1	
1	Subnet Mask	Should be before router option	4	
2	Time Offset	positive offset: east of meridian offset, negative offset: west of zero meridian		
3	Router Option	List of IP addresses on the client's subnet given in order of preference	≥ 4	4
4	Time Server Option	List of time servers	≥ 4	4
5	Name Server Option	IEN 116 name servers	≥ 4	4
6	Domain Name Server Option	list of DNS servers	≥ 4	4
7	Log Server Option	list of MIT-LCS UDP log servers	≥ 4	4
8	Cookie Server Option	RFC 865 cookie server	≥ 4	4
9	LPR Server Option	list of RFC 1179 line printer servers	≥ 4	4
10	Impress Server Option	list of Imagen Impress servers	≥ 4	4
11	Resource Location Server Option	RFC 887 Resource Location Servers	≥ 4	4
12	Host Name Option	hostname with or without domain name	≥1	
13	Boot File Size Option	length of default boot image for client in 512-octet blocks, specified in unsigned 16-bit integer. Maximum image size is, therefore, 32 Mbytes	2	
14	Merit Dump File	where to dump core image in case of a client crash	≥ 1	
15	Doain Name	the domain name to use when resolving hostnames via DNS	≥ 1	
16	Swap Server	the clients swap server	4	
17	Root Path	pathname to the clients root disk	≥ 1	
18	Extensions Path	A file containing vendor- specific options with unconstrained size and retrievable by Trivial File Transfer Protocol (TFTP); references to tag 18 in this file are ignored	≥ 1	

interface card is changed) to an IP address. In case of automatic allocation, the server assigns addresses from a given pool of addresses with infinite lease times to the clients. It requires that there be as many addresses available as clients may request address. The dynamic allocation mode differs from the automatic mode in that addresses are given to clients for a limited period of time. This is the default mode of DHCP and is used for situations where several systems exist in a network, but only a limited number of them are in operation at the same time.

Multi-homed Servers

When a DHCP server is equipped with interfaces for different networks (multi-homed), it is able to serve all those networks with addresses. It then needs to keep different configurations matching the respective networks and needs to maintain possibly different server identities ("server identifier option") for the different subnetworks in order to be reachable for clients. The server has to accept packets destined to one of its addresses on any interface. Usually, the server selects the network information based on the network interface on which a request was received.

© 2005 by CRC Press LLC

User Groups

Vendor-specific options are a container to provide special information. They are selected by using the "vendor option," which the client can set in a DHCPDISCOVER message. One of these options is the "user class option" as defined in RFC 3004 [10]. It allows the client to select a specific class it belongs to. Based on the class, a selection of options and a particular address range can be chosen by the server. It allows, for instance, to connect certain users to a specific printer or to provide class-specific routes such as routes secured by a Virtual Private Network (VPN). The selection, however, is completely based on the values provided by the client. In a common configuration, there is no way to check if the client is authorized to provide the values or to receive the requested configuration data, although the use of the "authentication option" provides some control.

Behavior for Multiple Servers

DHCP supports that many servers handle a single network. By delivering certain messages as broadcast messages, an explicit synchronization between the servers is not necessary. Still, not all servers have the same rights. This is mainly seen in that only authorized servers are allowed to reject addresses with a DHCPNACK message, which are not in the group of their offered addresses. Apart from this, a client that already has a network address firstly contacts the server that initially assigned the address. Only if this server fails to answer are all other servers contacted by a broadcast message.

33.4 Bypassing Routers: BOOTP Relay Agents

With the help of BOOTP relay agents [2, Section 8], a server can also serve networks to which it is not directly connected.

Figure 33.5 shows a typical application scenario for a BOOTP relay agent. A relay agent can be colocated to the router, respectively, the Network Access Server (NAS), but might as well be located on a separate system.

Mode of Operation

BOOTP relay agents listen on the well-known client port `bootpc` (67) and server port `bootps` (68). Client broadcasts received on the server port are converted to unicast messages and forwarded to the (well-known) DHCP server. Specifically, the relay agent fills the `giaddr` field with its own IP address. This causes the DHCP server to direct its BOOTREPLY answer message to the relay agent's IP address (unicast) instead of the client's MAC address. On receiving a BOOTREPLY message, the relay agent either broadcasts the message (after suitable modification) on the clients network or sends it as a unicast message to the client's MAC address (the client might still lack a valid IP address). With this mechanism, DHCPNACK messages can even be delivered to clients that try to reuse an invalid address, which cannot be

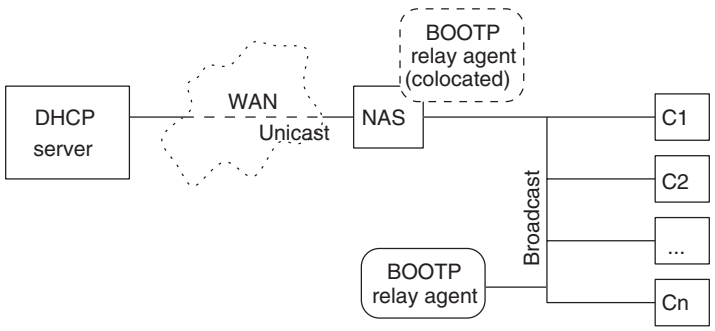

FIGURE 33.5 BOOTP relay agent configuration.

© 2005 by CRC Press LLC

routed within the current network. For the relay agent, it does not make a difference whether it forwards BOOTP or DHCP messages.

Subnet Selection

Usually, a server deduces the network a client belongs to from the interface on which it receives a request. In case of relayed requests, this information is deduced from the `giaddr` field, which usually provides enough information to select the correct network (namely, the IP address of the relay agent within the client's network). However, if this network uses nonroutable private addresses [8], the `giaddr` field should still contain a routable IP address. It is required that the relay agent has a globally routable IP address, which it fills into the `giaddr` field. In this case, the server's automatic selection process must be overridden by using the "subnet selection option" [11]. This option takes precedence over the automatic selection and causes the DHCP server to deduce the network the client is in from the value of the `giaddr` field instead of the incoming interface.

Relay Agent Information

A typical application example of BOOTP relay agents are NASs, which provide public access to the Internet using dial-up lines. The BOOTP agent is often colocated with the NAS and forwards requests coming from the clients (via modem). For proper allocation of IP addresses and configuration information, it is often necessary to let the DHCP server know not only the identity of the client but also the identification of the incoming line. Since there are no standard fields for this in the DHCP packet format, the relay agent is allowed to add a special "Relay agent information option" [7], which contains this information and which allows the (stateless) relay agent to associate the replies of the DHCP server with its request and therefore to the correct incoming line. In addition, this information allows to restrict the BOOTP replies to the single line where the client is reachable instead of broadcasting the packets to all outgoing links. The relay agent removes the "Relay agent information option" before forwarding the BOOTP replies to the client. Since in this situation the relay agent modifies the DHCP packets, it has to be trusted.

33.5 Security Considerations

The DHCP protocol in its basic form is inherently insecure against insider-driven threats even if the network is protected against attacks from outside by a firewall. In a DHCP environment, access rights to a server can only be enforced based on the unique identifier or the hardware address provided by the clients itself. Such values can easily be spoofed, allowing the attacker to gain access to the information provided by the server. Conversely, a rogue DHCP server could spoof replies. The client will not be able to recognize that it is not connected to the regular DHCP server of the network and may be a victim of Denial of Service (DoS) or man-in-the-middle attacks.

The "authentication option" defined in RFC 3118 has been added to prevent these faults. It allows to add replay detection information and authentication information to each DHCP packet. The authentication information is based on the generation of a MAC created, for instance, with an MD5 hash function. This Hashed Message Authentication Code (HMAC) is then signed with a private key of the client or with a shared key. Certain options and fields (such as the `giaddr` field and the "relay agent information") cannot be included in the authenticated part of the packet as they may be purposely inserted or changed by the relay agent during client–server conversation. During message validation, these fields must be set to zero and any further associated options must be ignored. There is currently no mechanism for securing the additional information inserted by BOOTP relay agents. The relay agent is assumed to be trustworthy.

The use of the authentication option necessitates an out-of-band distribution of keys to the clients. In order to make clients distinguishable, each client should have its own unique key. Servers should be able

© 2005 by CRC Press LLC

to obtain the necessary client keys in a secure manner. However, scalability problems may arise if the number of clients is high and the client population changes often (nomadic users).

The "authentication option" adds additional overhead to servers and clients, and servers need to commit additional state information to nonvolatile memory such as the information about security associations (which IP address is bound to which key-owner). However, as compared to the threats an open DHCP environment is exposed to, it is well worth the overhead.

33.6 Related Mechanisms

Internet hosts often request informations from servers identified by human readable names instead of IP addresses. If such a server obtains its IP address via DHCP, then this address might change from time to time. In this case, the *dynamic DNS* approach provides a mapping between host names and network addresses. In dynamic DNS, special DNS servers accept frequent updates for "their" hosts and answer queries with very short live times. It makes sense to let the DHCP server perform the address update with the dynamic DNS server automatically. Thus, the DNS table contains only those addresses that are currently assigned and in use, and the clients can be addressed by human-readable names.

33.7 Conclusion

DHCP is a framework that allows to configure clients in large networks without needing to edit configuration data at the client. Instead, all configuration data are stored at a central server and distributed to the clients. This eases network management substantially, since all data are stored in one station and can be kept consistent. By its ability to operate several servers in parallel and in distant networks, DHCP offers a robust solution for the distribution of configuration information. Due to these advantages, the DHCP framework is in widespread use.

Nomenclature

ARP	Address Resolution Protocol
BOOTP	Bootstrap Protocol
DHCP	Dynamic Host Configuration Protocol
DNS	Domain Name System
DoS	Denial of Service
HMAC	Hashed Message Authentication Code
ICMP	Internet Control Message Protocol
MAC	Medium Access Control
NAS	Network Access Server
RARP	Reverse Address Resolution Protocol
TFTP	Trivial File Transfer Protocol
VPN	Virtual Private Network

34.1 Introduction

In order to provide useful services or to allow people to perform tasks more conveniently, computer systems are attached to networks and get interconnected. This resulted in the worldwide collection of local and wide-area networks known as the Internet. Unfortunately, the extended access possibilities also entail increased security risks as it opens additional avenues for an attacker. For a closed, local system, the attacker was required to be physically present at the network in order to perform unauthorized actions. In the networked case, each host that can send packets to the victim can be potentially utilized. As certain services (such as web or name servers) need to be publicly available, each machine on the Internet might be the originator of malicious activity. This fact makes attacks very likely to happen on a regularly basis.

The following text attempts to give a systematic overview of security requirements of Internet-based systems and potential means to satisfy them. We define properties of a secure system and provide a classification of potential threats to them. We also introduce mechanisms to defend against attacks that attempt to violate desired properties. The most widely used means to secure application data against tampering and eavesdropping, the Secure Sockets Layer (SSL) and its successor, the Transport Layer Security (TLS) protocol, are discussed. Finally, we briefly describe popular application programs that can act as building blocks for securing custom applications.

Before one can evaluate attacks against a system and decide on appropriate mechanisms against them, it is necessary to specify a *security policy* [21]. A security policy defines the desired properties for each part of a secure computer system. It is a decision that has to take into account the value of the assets that should be protected, the expected threats, and the cost of proper protection mechanisms. A security policy that is sufficient for the data of a normal user at home may not be sufficient for bank applications, as these systems are obviously a more likely target and have to protect more valuable resources. Although

© 2005 by CRC Press LLC

often neglected, the formulation of an adequate security policy is a prerequisite before one can identify threats and appropriate mechanisms to tackle them.

34.2 Security Attacks and Security Properties

For the following discussion, we assume that the function of a system that is the target of an attack is to provide information. In general, there is a flow of data from a source (e.g., host, file, memory) to a destination (e.g., remote host, other file, user) over a communication channel (e.g., wire, data bus). The task of the security system is to restrict access to this information to only those parties (persons or processes) that are authorized to have access according to the security policy in use. In the case of an automation system that is remotely connected to the Internet, the information flow is from/to a control application that manages sensors and actuators via communication lines of the public Internet and the network of the automation system (e.g., a field-bus).

The normal information flow and several categories of attacks that target it are shown in Figure 34.1 and explained below (according to [20]).

1. *Interruption*: An asset of the system gets destroyed or becomes unavailable. This attack targets the source or the communication channel and prevents information from reaching its intended target (e.g., cut the wire, overload the link so that the information gets dropped because of congestion). Attacks in this category attempt to perform a kind of *denial-of-service(DOS).*
2. *Interception*: An unauthorized party gains access to the information by eavesdropping into the communication channel (e.g., wiretapping).
3. *Modification*: The information is not only intercepted, but modified by an unauthorized party while in transit from the source to the destination. By tampering with the information, it is actively altered (e.g., modifying message content).
4. *Fabrication*: An attacker inserts counterfeit objects into the system without having the sender doing anything. When a previously intercepted object is inserted, this processes is called *replaying.* When the attacker pretends to be the legitimate source and inserts his desired information, the attack is called *masquerading* (e.g., replay an authentication message, add records to a file).

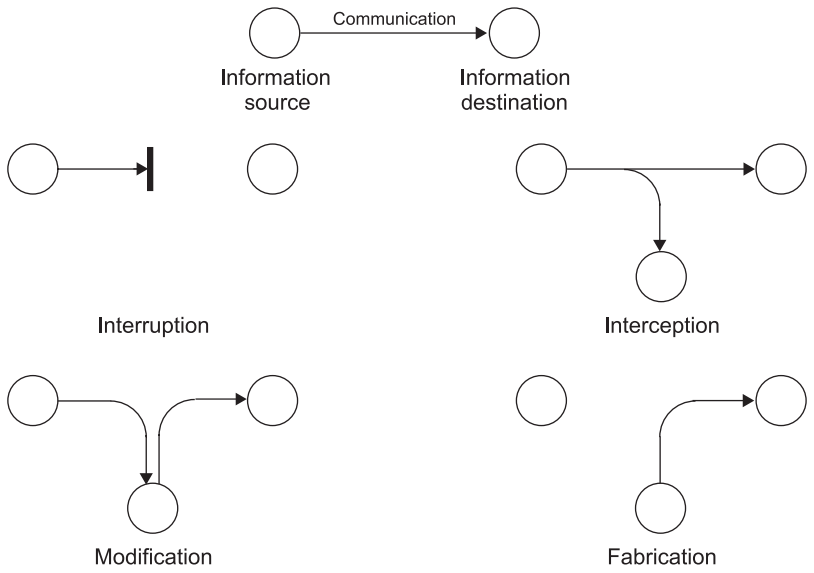

FIGURE 34.1 Security attacks.

© 2005 by CRC Press LLC

The four classes of attacks listed above violate different security properties of the computer system. A security property describes a desired feature of a system with regard to a certain type of attack. A common classification following [5, 11] is listed below.

Confidentiality: This property covers the protection of transmitted data against its release to nonauthorized parties. In addition to the protection of the content itself, the information flow should also be resistant against traffic analysis. Traffic analysis is used to gather information other than the transmitted values themselves from the data flow (e.g., timing data, frequency of messages).

Authentication: Authentication is concerned with making sure that the information is authentic. A system implementing the authentication property assures the recipient that the data are from the source that it claims to be. The system must make sure that no third party can masquerade successfully as another source.

Nonrepudiation: This property describes the feature that prevents either the sender or receiver from denying a transmitted message. When a message has been transferred, the sender can prove that it has been received. Similarly, the receiver can prove that the message has actually been sent.

Availability: Availability characterizes a system whose resources are always ready to be used. Whenever information needs to be transmitted, the communication channel is available and the receiver can cope with the incoming data. This property makes sure that attacks cannot prevent resources from being used for their intended purpose.

Integrity: Integrity protects transmitted information against modifications. This property assures that a single message reaches the receiver as it has left the sender, but integrity also extends to a stream of messages. It means that no messages are lost, duplicated, or reordered and it makes sure that messages cannot be replayed. As destruction is also covered under this property, all data must arrive at the receiver. Integrity is not only important as a security property but also as a property for network protocols. Message integrity must also be ensured in case of random faults, and not just in the case of malicious modifications.

34.3 Security Mechanisms

Different security mechanisms can be used to enforce the security properties defined in a given security policy. Depending on the anticipated attacks, different means have to be applied to satisfy the desired properties. We divide these measures against attacks into three different classes: attack prevention, attack avoidance, and attack detection.

Attack Prevention

Attack prevention is a class of security mechanisms that contains ways of preventing or defending against certain attacks before they can actually reach and affect the target. An important element in this category is access control, a mechanism that can be applied at different levels such as the operating system, the network, or the application layer.

Access control [21] limits and regulates the access to critical resources. This is done by identifying or authenticating the party that requests a resource and checking its permissions against the rights specified for the demanded object. It is assumed that an attacker is not legitimately permitted to use the target object and is therefore denied access to the resource. As access is a prerequisite for an attack, any possible interference is prevented.

The most common form of access control used in multi-user computer systems are access control lists for resources that are based on the user identity of the process that attempts to use them. The identity of a user is determined by an initial authentication process that usually requires a name and a password. The login process retrieves the stored copy of the password corresponding to the user name and compares it with the presented one. When both match, the system grants the user the appropriate user credentials. When a resource should be accessed, the system looks up the user and group in the access control list and grants or denies access as appropriate. An example of this kind of access control is a secure web server. A secure web server delivers certain resources only to clients that have authenticated themselves and that possess sufficient credentials for the desired resource. The authentication process is usually handled by

© 2005 by CRC Press LLC

the web client such as the `Microsoft Internet Explorer`, or `Mozilla` by prompting the user for his name and password.

The most important access control system at the network layer is a firewall [4]. The idea of a firewall is based on the separation of a trusted inside network of computers under single administrative control from a potential hostile outside network. The firewall is a central choke point that allows enforcement of access control for services that may run at the inside or outside. The firewall prevents attacks from the outside against the machines in the inside network by denying connection attempts from unauthorized parties located outside. In addition, a firewall may also be utilized to prevent users behind the firewall from using certain services that are outside (e.g., surfing web sites containing pornographic material).

For certain installations, a single firewall is not suitable. Networks that consist of several server machines that need to be publicly accessible and workstations that should be completely protected against connections from the outside would benefit from a separation between these two groups. When an attacker compromises a server machine behind a single firewall, all other machines can be attacked from this new base without restrictions. To prevent this, one can use two firewalls and the concept of a *demilitarized zone (DMZ)* [4] in between as shown in Figure 34.2.

In this setup, one firewall separates the outside network from a segment (DMZ) with the server machines, while a second one separates this area from the rest of the network. The second firewall can be configured in a way that denies all incoming connection attempts. Whenever an intruder compromises a server, he is now unable to immediately attack a workstation located in the inside network.

The following design goals for firewalls are identified in [4]:

1. All traffic from inside to outside, and *vice versa,* must pass through the firewall. This is achieved by physically blocking all access to the internal network except via the firewall.
2. Only authorized traffic, as defined by the local security policy, will be allowed to pass.
3. The firewall itself should be immune to penetration. This implies the use of a trusted system with a secure operating system. A trusted, secure operating system is often purpose-built, has heightened security features, and only provides the minimal functionality necessary to run the desired applications.

These goals can be reached by using a number of general techniques for controlling access. The most common is called *service control* and determines Internet services that can be accessed. Traffic on the Internet is currently filtered on the basis of IP addresses and TCP/UDP port numbers. In addition, there may be proxy software that receives and interprets each service request before passing it on. *Direction control* is a simple mechanism to control the direction in which particular service requests may be initiated and permitted to flow through. *User control* grants access to a service based on user credentials similar to the technique used in a multiuser operating system. Controlling external users requires secure authentication over the network (e.g., such as provided in IPSec [9]). A more declarative approach in contrast to the operational variants mentioned above is *behavior control.* This technique determines how particular services are used. It may be utilized to filter e-mail to eliminate spam or to allow external access to only part of the local web pages.

A summary of capabilities and limitations of firewalls is given in [20]. The following benefits can be expected:

- A firewall defines a single choke point that keeps unauthorized users out of the protected network. The use of such a point also simplifies security management.
- It provides a location for monitoring security-related events. Audits, logs, and alarms can be implemented on the firewall directly. In addition, it forms a convenient platform for some nonsecurity-related functions such as address translation and network management.

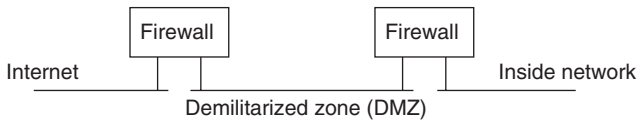

FIGURE 34.2 Demilitarized zone.

© 2005 by CRC Press LLC

- A firewall may serve as a platform to implement a virtual private network (e.g., by using IPSec).

The list below enumerates the limits of the firewall access control mechanism.

- A firewall cannot protect against attacks that bypass it, for example, via a direct dial-up link from the protected network to an Internet Service Provider (ISP). It also does not protect against internal threats from an inside hacker or an insider cooperating with an outside attacker.
- A firewall does not help when attacks are against targets whose access has to be permitted.
- It cannot protect against the transfer of virus-infected programs or files. It would be impossible, in practice, for the firewall to scan all incoming files and e-mails for viruses.

Firewalls can be divided into two main categories. A *Packet-Filtering Router,* or short packet filter, is an extended router that applies certain rules to the packets that are forwarded. Usually, traffic in each direction (in- and outgoing) is checked against a rule set, which determines whether a packet is permitted to continue or should be dropped. The packet filter rules operate on the header fields used by the underlying communication protocols, for the Internet almost always IP, TCP, and UDP. Packet filters have the advantage that they are cheap as they can often be built on existing hardware. In addition, they offer a good performance for high traffic loads. An example for a packet filter is the `iptables` package, which is implemented as part of the `Linux` 2.4 routing software.

A different approach is followed by an *Application-Level Gateway,* also called proxy server. This type of firewall does not forward packets on the network layer but acts as a relay on the application level. The user contacts the gateway, which in turn opens a connection to the intended target (on behalf of the user). A gateway completely separates the inside and outside networks at the network level and only provides a certain set of application services. This allows authentication of the user who requests a connection and session-oriented scanning of the exchanged traffic up to the application-level data. This feature makes application gateways more secure than packet filters and offers a broader range of log facilities. On the downside, the overhead of such a setup may cause performance problems under heavy load.

Attack Avoidance

Security mechanisms in this category assume that an intruder may access the desired resource but the information is modified in a way that makes it unusable for the attacker. The information is preprocessed at the sender before it is transmitted over the communication channel and postprocessed at the receiver. While the information is transported over the communication channel, it resists attacks by being nearly useless for an intruder. One notable exception are attacks against the availability of the information as an attacker could still interrupt the message. During the processing step at the receiver, modifications or errors that might have previously occurred can be detected (usually because the information cannot be correctly reconstructed). When no modification has taken place, the information at the receiver is identical to the one at the sender before the preprocessing step.

The most important member in this category is cryptography, which is defined as the science of keeping messages secure [16]. It allows the sender to transform information into a random data stream from the point of view of an attacker but to have it recovered by an authorized receiver (see Figure 34.3).

The original message is called *plain text* (sometimes clear text). The process of converting it through the application of some transformation rules into a format that hides its substance is called *encryption.* The corresponding disguised message is denoted *cipher text* and the operation of turning it back into clear text is called *decryption.* It is important to notice that the conversion from plain to cipher text has to be loss-less in order to be able to recover the original message at the receiver under all circumstances.

The transformation rules are described by a cryptographic algorithm. The function of this algorithm is based on two main principles: *substitution* and *transposition.* In the case of substitution, each element of the plain text (e.g., bit, block) is mapped into another element of the used alphabet. Transposition describes the process where elements of the plain text are rearranged. Most systems involve multiple steps (called rounds) of transposition and substitution to be more resistant against cryptanalysis. Cryptanalysis is the science of breaking the cipher, that is, discovering the substance of the message behind its disguise.

© 2005 by CRC Press LLC

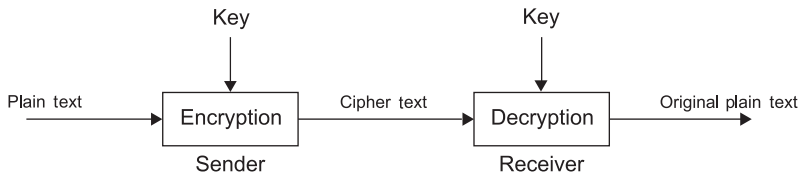

FIGURE 34.3 Encryption and decryption.

When the transformation rules process the input elements one at a time, the mechanism is called a *stream cipher;* in case of operating on fixed-sized input blocks, it is called a *block cipher.*

If the security of an algorithm is based on keeping the way how the algorithm works (i.e., the transformation rules) secret, it is called a restricted algorithm. Those algorithms are no longer of any interest today because they do not allow standardization or public quality control. In addition, when a large group of users is involved, such an approach cannot be used. A single person leaving the group makes it necessary for everyone else to change the algorithm.

Modern cryptosystems solve this problem by basing the ability of the receiver to recover encrypted information on the fact that he possesses a secret piece of information (usually called the *key).* Both encryption and decryption functions have to use a key and they are heavily dependent on it. When the security of the cryptosystem is completely based on the security of the key, the algorithm itself may be revealed. Although the security does not rely on the fact that the algorithm is unknown, the cryptographic function itself and the used key together with its length must be chosen with care. A common assumption is that the attacker has the fastest commercially available hardware at his disposal in his attempt to break the cipher text.

The most common attack, called *known plain text attack,* is executed by obtaining cipher text together with its corresponding plain text. The encryption algorithm must be so complex that even if the code breaker is equipped with plenty of such pairs and powerful machines, it is infeasible for him to retrieve the key. An attack is infeasible when the cost of breaking the cipher exceeds the value of the information or the time it takes to break it exceeds the lifespan of the information.

Given pairs of corresponding cipher and plain text, it is obvious that a simple key guessing algorithm will succeed after some time. The approach of successively trying different key values until the correct one is found is called *brute force* attack because no information about the algorithm is utilized whatsoever. In order to be useful, it is a necessary condition for an encryption algorithm that brute force attacks are infeasible.

Depending on the keys that are used, one can distinguish two major cryptographic approaches — public and secret key cryptosystems.

Secret Key Cryptography

This is the kind of cryptography that has been used for the transmission of secret information for centuries, long before the advent of computers. These algorithms require that the sender and the receiver agree on a key before communication is started.

It is common for this variant (which is also called single key or symmetric encryption) that a single secret key is shared between the sender and the receiver. It needs to be communicated in a secure way before the actual encrypted communication can start and has to remain secret as long as the information is to remain secret. Encryption is achieved by applying an agreed function to the plain text using the secret key. Decryption is performed by applying the inverse function using the same key.

The classic example of a secret key block cipher that is widely deployed today is the Data Encryption Standard (DES) [6]. DES was developed in 1977 by IBM and was adopted as a standard by the US government for administrative and business use. Recently, it has been replaced by the Advanced Encryption Standard (AES — Rijndael) [1]. It is a block cipher that operates on 64-bit plain text blocks and utilizes a key with 56-bits length. The algorithm uses 16 rounds that are key dependent. During each round, 48 key bits are selected and combined with the block that is encrypted. Then, the resulting block is piped

© 2005 by CRC Press LLC

through a substitution and a permutation phase (which use known values and are independent of the key) to make cryptanalysis harder.

Although there is no known weakness of the DES algorithm itself, its security has been much debated. The small key length makes brute force attacks possible and several cases have occurred where DES-protected information has been cracked. A suggested improvement called 3DES uses three rounds of the simple DES with three different keys. This extends the key length to 168 bits while still resting on the very secure DES base.

A well-known stream cipher that has been debated recently is RC4 [14], which has been developed by RSA. It is used to secure the transmission in wireless networks that follow the IEEE 802.11 standard and forms the core of the WEP (wired equivalent protection) mechanism. Although the cipher itself has not been broken, current implementations are flawed and reduce the security of RC4 down to a level where the used key can be recovered by statistical analysis within a few hours.

Public Key Cryptography

Since the advent of public key cryptography, the knowledge of the key that is used to encrypt a plain text also allowed the inverse process, the decryption of the cipher text. In 1976, this paradigm of cryptography was changed by Diffie and Hellman [7] when they described their public key approach. Public key cryptography utilizes two different keys, one called the *public key,* and the other called the *private key.* The public key is used to encrypt a message, while the corresponding private key is used to do the opposite. Their innovation was the fact that it is infeasible to retrieve the private key given the public key. This makes it possible to remove the weakness of secure key transmission from the sender to the receiver. The receiver can simply generate his public/private key pair and announce the public key without fear. Anyone can obtain this key and use it to encrypt messages that only the receiver with his private key is able to decrypt.

Mathematically, the process is based on the *trap door* of *one-way* functions. A one-way function is a function that is easy to compute but very hard to inverse. This means that given x, it is easy to determine $f(x)$ but given $f(x)$ it is hard to obtain x. Hard is defined as computationally infeasible in the context of cryptographically strong one-way functions. Although it is obvious that some functions are easier to compute than their inverse (e.g., square of a value in contrast to its square root), there is no mathematical proof or definition of one-way functions. There are a number of problems that are considered difficult enough to act as one-way functions but it is more an agreement among crypto analysts than a rigorously defined set (e.g., factorization of large numbers). A one-way function is not directly usable for cryptography, but it becomes so when a trap door exists. A trap door is a mechanism that allows one to easily calculate x from $f(x)$ when an additional information y is provided.

A common misunderstanding about public key cryptography is thinking that it makes secret key systems obsolete, either because it is more secure or because it does not have the problem of secretly exchanging keys. As the security of a cryptosystem depends on the length of the used key and the utilized transformation rules, there is no automatic advantage of one approach over the other. Although the key exchange problem is elegantly solved with a public key, the process itself is very slow and has its own problems. Secret key systems are usually a factor of 1000 (see [16] for exact numbers) faster than their public key counterparts. Therefore, most communication is stilled secured using secret key systems and public key systems are only utilized for exchanging the secret key for later communication. This hybrid approach is the common design to benefit from the high speed of conventional cryptography (which is often implemented directly in hardware) and from a secure key exchange.

A problem in public key systems is the authenticity of the public key. An attacker may offer the sender his own public key and pretend that it origins from the legitimate receiver. The sender then uses the faked public key to perform his encryption and the attacker can simply decrypt the message using his private key. In order to thwart an attacker that attempts to substitute his public key for the victim's one, *certificates* are used. A certificate combines user information with the user's public key and the digital signature of a trusted third party that guarantees that the key belongs to the mentioned person. The trusted third party is usually called a *certification authority (CA).* The certificate of a CA itself is usually verified by a higher-level CA that confirms that the CA's certificate is genuine and contains its public key. The chain of

© 2005 by CRC Press LLC

third parties that verify their respective lower-level CAs has to end at a certain point, which is called the root CA. A user that wants to verify the authenticity of a public key and all involved CAs needs to obtain the self-signed certificate of the root CA via an external channel. Web browsers (e.g., `Netscape Navigator, Internet Explorer`) usually ship with a number of certificates of globally known root CAs. A framework that implements the distribution of certificates is called a public key infrastructure (PKI). An important protocol for key management is X.509 [23]. Another important issue is revocation, the invalidation of a certificate when the key has been compromised.

The best-known public key algorithm and textbook classic is RSA [15], named after its inventors Rivest, Shamir, and Adleman at MIT. It is a block cipher that is still utilized for the majority of current systems, although the key length has been increased over recent years. This has put a heavier processing load on applications, a burden that has ramifications especially for sites doing electronic commerce. A competitive approach that promises similar security as RSA using far smaller key lengths is elliptic curve cryptography. However, as these systems are new and have not been subject to sustained cryptanalysis, the confidence level in them is not yet as high as in RSA.

Authentication and Digital Signatures

An interesting and important feature of public key cryptography is its possible use for authentication. In addition to making the information unusable for attackers, a sender may utilize cryptography to prove his identity to the receiver. This feature is realized by *digital signatures.* A digital signature must have similar properties as a normal handwritten signature. It should be hard to forge and it has to be bound to a certain document. In addition, one has to make sure that a valid signature cannot be used by an attacker to replay the same (or different) messages at a later time.

A way to realize such a digital signature is by using the sender's private key to encrypt a message. When the receiver is capable of successfully decrypting the cipher text with the sender's public key, he can be sure that the message is authentic. This approach obviously requires a cryptosystem that allows encryption with the private key, but many (such as RSA) offer this option. It is easy for a receiver to verify that a message has been successfully decrypted when the plain text is in a human readable format. For binary data, a checksum or similar integrity checking footer can be added to verify a successful decryption. Replay attacks are prevented by adding a time-stamp to the message (e.g., `Kerberos` [10] uses time-stamps to prevent that messages to the ticket granting service are replayed).

Usually, the storage and processing overhead for encrypting a whole document is too high to be practical. This is solved by one-way hash functions. These are functions that map the content of a message onto a short value (called *message digest).* Similar to one-way functions, it is difficult to create a message when given only the hash value itself. Instead of encrypting the whole message, it is enough to simply encrypt the message digest and send it together with the original message. The receiver can then apply the known hash function (e.g., MD5 [13]) to the document and compare it to the decrypted digest. When both values match, the messages is authentic.

Attack and Intrusion Detection

Attack detection assumes that an attacker can obtain access to his desired targets and is successful in violating a given security policy. Mechanisms in this class are based on the optimistic assumption that most of the time the information is transferred without interference. When undesired actions occur, attack detection has the task of reporting that something went wrong and then to react in an appropriate way. In addition, it is often desirable to identify the exact type of attack. An important facet of attack detection is recovery. Often, it is enough to just report that malicious activity has been found, but some systems require that the effect of the attack has to be reverted or that an ongoing and discovered attack is stopped. On the one hand, attack detection has the advantage that it operates under the worst-case assumption that the attacker gains access to the communication channel and is able to use or modify the resource. On the other hand, detection is not effective in providing confidentiality of information. When the security policy specifies that interception of

© 2005 by CRC Press LLC

information has a serious security impact, then attack detection is not an applicable mechanism. The most important members of the attack detection class, which have received an increasing amount of attention in the last few years, are intrusion detection systems (aka IDS).

Intrusion Detection [2, 3] is the process of identifying and responding to malicious activities targeted at computing and network resources. This definition introduces the notion of intrusion detection as a process, which involves technology, people, and tools. An IDS basically monitors and collects data from a target system that should be protected, processes and correlates the gathered information, and initiate responses, when evidence for an intrusion is detected. IDS are traditionally classified as anomaly- or signature-based. Signature-based systems act similar to virus scanners and look for known, suspicious patterns in their input data. Anomaly-based systems watch for deviations of actual from expected behavior and classify all "abnormal" activities as malicious.

The advantage of signature-based designs is the fact that they can identify attacks with an acceptable accuracy and tend to produce fewer false alarms (i.e., classifying an action as malicious when in fact it is not) than their anomaly-based cousins. The systems are more intuitive to build and easier to install and configure, especially in large production networks. Because of this, nearly all commercial systems and most deployed installations utilize signature-based detection. Although anomaly-based variants offer the advantage of being able to find prior unknown intrusions, the costs of having to deal with an order of magnitude more false alarms is often prohibitive.

Depending on their source of input data, IDS can be classified as either network- or host-based. Network-based systems collect data from network traffic (e.g., packets by network interfaces in promiscuous mode), while host-based systems monitor events at the operating system level such as system calls or receive input from applications (e.g., via log files). Host-based designs can collect high-quality data directly from the affected system and are not influenced by encrypted network traffic. Nevertheless, they often seriously impact the performance of the machines they are running on. Network-based IDS, on the other hand, can be set up in a nonintrusive manner — often as an appliance box without interfering with the existing infrastructure. In many cases, this makes them the preferred choice.

As many vendors and research centers have developed their own intrusion detection system versions, the IETF has created the intrusion detection working group [8] to coordinate international standardization efforts. The aim is to allow intrusion detection systems to share information and to communicate via well-defined interfaces by proposing a generic architectural description and a message specification and exchange format (IDMEF).

34.4 Secure Network Protocols

After the general concepts and mechanisms of network security have been introduced, the following section concentrates on two actual instances of secure network protocols: the SSL [18] and the TLS [22] protocol.

The idea of secure network protocols is to create an additional layer between the application and the transport/network layer to provide services for a secure end-to-end communication channel.

TCP/IP are almost always used as transport/network layer protocols on the Internet and their task is to provide a reliable end-to-end connection between remote tasks on different machines that intend to communicate. The services on that level are usually directly utilized by application protocols to exchange data, for example, Hypertext Transfer Protocol (HTTP) for web services. Unfortunately, the network layer transmits these data unencrypted, leaving it vulnerable to eavesdropping or tampering attacks. In addition, the authentication mechanisms of TCP/IP are only minimal, thereby allowing a malicious user to hijack connections and redirect traffic to his machine as well as to impersonate legitimate services. These threats are mitigated by secure network protocols that provide privacy and data integrity between two communicating applications by creating an encrypted and authenticated channel.

SSL has emerged as the de-facto standard for secure network protocols. Originally developed by Netscape, its latest version SSL 3.0 is also the base for the standard proposed by the IETF under the name TLS. Both protocols are quite similar and share common ideas, but they unfortunately cannot interoperate. The following discussion will mainly concentrate on SSL and only briefly explain the extensions implemented in TLS.

© 2005 by CRC Press LLC

The SSL protocol [19] usually runs above TCP/IP (although it could use any transport protocol) and below higher-level protocols such as HTTP. It uses TCP/IP on behalf of the higher-level protocols, and in the process allows an SSL-enabled server to authenticate itself to an SSL-enabled client, allows the client to authenticate itself to the server, and allows both machines to establish an encrypted connection. These capabilities address fundamental concerns about communication over the Internet and other TCP/IP networks and give protection against message tampering, eavesdropping, and spoofing.

SSL server authentication allows a user to confirm a server's identity. SSL-enabled client software can use standard techniques of public-key cryptography to check that a server's certificate and public key are valid and have been issued by a CA listed in the client's list of trusted CAs. This confirmation might be important if the user, for example, is sending a credit card number over the network and wants to check the receiving server's identity.

SSL client authentication allows a server to confirm a user's identity. Using the same techniques as those used for server authentication, SSL-enabled server software can check that a client's certificate and public key are valid and have been issued by a CA listed in the server's list of trusted CAs. This confirmation might be important if the server, for example, is a bank sending confidential financial information to a customer and wants to verify the recipient's identity.

An encrypted SSL connection requires all information sent between a client and a server to be encrypted by the sending software and decrypted by the receiving software, thus providing a high degree of confidentiality. Confidentiality is important for both parties to any private transaction. In addition, all data sent over an encrypted SSL connection are protected by a mechanism for detecting tampering — that is, for automatically determining whether the data have been altered in transit.

SSL uses X.509 certificates for authentication, RSA as its public-key cipher, and one of RC4-128, RC2-128, DES, Triple DES, or IDEA as its bulk symmetric cipher. The SSL protocol includes two subprotocols: the SSL Record Protocol and the SSL Handshake Protocol. The SSL Record Protocol simply defines the format used to transmit data. The SSL Handshake Protocol (using the SSL Record Protocol) is utilized to exchange a series of messages between an SSL-enabled server and an SSL-enabled client when they first establish an SSL connection. This exchange of messages is designed to facilitate the following actions.

- Authenticate the server to the client.
- Allow the client and server to select the cryptographic algorithms, or ciphers, that they both support.
- Optionally authenticate the client to the server.
- Use public-key encryption techniques to generate shared secrets.
- Establish an encrypted SSL connection based on the previously exchanged shared secret.

The SSL Handshake Protocol is composed of two phases. Phase 1 deals with the selection of a cipher, the exchange of a secret key, and the authentication of the server. Phase 2 handles client authentication, if requested and finishes the handshaking. After the handshake stage is complete, the data transfer between client and server begins. All messages during handshaking and after, are sent over the SSL Record Protocol layer. Optionally, session identifiers can be used to reestablish a secure connection that has been previously set up.

Figure 34.4 lists in a slightly simplified form the messages that are exchanged between the client C and the server S during a handshake when neither client authentication nor session identifiers are involved. In this figure, `{data}` key means that data have been encrypted with key.

The message exchanges shows that the client first sends a challenge to the server, which responds with an X.509 certificate containing its public key. The client then creates a secret key and uses RSA with the server's public key to encrypt it, sending the result back to the server. Only the server is capable of decrypting that message with its private key and can retrieve the shared, secret key. In order to prove to the client that the secret key has been successfully decrypted, the server encrypts the client's challenge with the secret key and returns it. When the client is able to decrypt this message and successfully retrieves

© 2005 by CRC Press LLC

Message type	Direction	Data transferred
client-hello	C > S	challenge-data and supported ciphers
server-hello	C < S	server-certificate and ciphers both support
client-master-key	C > S	chosen cipher and {secret-key}server-public-key
server-verify	C < S	{challenge-data}secret-key

FIGURE 34.4 SSL handshake message exchange.

the original challenge by using the secret key, it can be certain that the server has access to the private key corresponding to its certificate. From this point on, all communication is encrypted using the chosen cipher and the shared secret key.

TLS uses the same two protocols shown above and a similar handshake mechanism. Nevertheless, the algorithms for calculating message authentication codes (MACs) and secret keys have been modified to make them cryptographically more secure. In addition, the constraints on padding a message up to the next block size have been relaxed for TLS. This leads to an incompatibility between both protocols.

SSL/TLS is widely used to secure web and mail traffic. HTTP as well as the current mail protocols IMAP (Internet Message Access Protocol) and POP3 (post office protocol, version 3) transmit user credential information as well as application data unencrypted. By building them on top of a secure network protocol such as SSL/TLS, they can benefit from secured channels without modifications. The secure communication protocols simply utilize different well-known destination ports (443 for HTTPS, 993 for IMAPS, and 995 for POP3S) than their insecure cousins.

34.5 Secure Applications

A variety of popular tools that allow access to remote hosts (such as telnet, rsh, and rlogin) or that provide means for file transfer (such as rcp or ftp) exchange user credentials and data in plain text. This makes them vulnerable to eavesdropping, tampering, and spoofing attacks. Although the tools mentioned above could have also been built upon SSL/TLS, a different protocol suite called Secure Shell (SSH) [17] has been developed, which follows partial overlapping goals. The SSH Transport and User Authentication protocols have features similar to those of SSL/TLS. However, they are different in the following ways:

- TLS server authentication is optional and the protocol supports fully anonymous operation, in which neither side is authenticated. As such connections are inherently vulnerable to man-in-the-middle attacks, SSH requires server authentication.
- TLS does not provide the range of client authentication options that SSH does — public-key via RSA is the only option.
- Most importantly, TLS does not have the extra features provided by the SSH Connection Protocol.

The SSH Connection Protocol uses the underlying connection, aka secure tunnel, which has been established by the SSH Transport and User Authentication protocols between two hosts. It provides interactive login sessions, remote execution of commands, and forwarded TCP/IP as well as XI1 connections. All these terminal sessions and forwarded connections are realized as different logical channels that may be opened by either side on top of the secure tunnel. Channels are flow-controlled, which means that no data may be sent to a channel until a message is received to indicate that window space is available.

The current version of the SSH protocol is SSH 2. It represents a complete rewrite of SSH 1 and improves some of its structural weaknesses. As it encrypts packets in a different way and has abandoned the notion of server and host keys in favor of host keys only, the protocols are incompatible. For applications built from scratch, SSH 2 should always be the preferred choice.

Using the means of logical channels for interactive login sessions and remote execution, a complete replacement for telnet, rsh, and rlogin could be easily implemented. A popular site that lists open-source

© 2005 by CRC Press LLC

implementations, which are freely available for many different platforms, can be found under [12]. Recently, a secure file transfer (sftp) application has been developed that makes the use of regular FTP-based programs obsolete.

Notice that it is possible to tunnel arbitrary application traffic over a connection that has been previously set up by the SSH protocols. Similar to SSL/TLS, web and mail traffic could be securely transmitted over an SSH connection before reaching the server port at the destination host. The difference is that SSH requires that a secure tunnel is created in advance, which is bound to a certain port at the destination host. The setup of this secure channel, however, requires that the client that is initiating the connection has to log into the server. Usually, this makes it necessary that the user has an account at the destination host. After the tunnel has been established, all traffic sent into by the client gets forwarded to the desired port at the target machine. Obviously, the connection is encrypted. In contrast to this SSL/TLS connects directly to a certain point without prior logging into the destination host. The encryption is set up directly between the client and the service listening at the destination port without a prior redirection via the SSH server.

The technique of tunneling application traffic is often utilized for mail transactions when the mail server does not support SSL/TLS directly (as users have accounts at the mail server anyway), but it is less common for web traffic.

34.6 Summary

This chapter discusses security threats that systems face when they are connected to the Internet.

In order to achieve the security properties that are required by the security policy in use, three different classes of mechanisms can be adopted. The first is attack prevention, which attempts to stop the attacker before it can reach its desired goals. Such techniques fall into the category of access control and firewalls. The second approach aims to make the data unusable for unauthorized persons by applying cryptographic means. Secret key as well as public keys mechanism can be utilized. The third class of mechanisms contains attack detection approaches. They attempt to detect malicious behavior and recover after undesired activity has been identified.

The text also covers secure network protocols and applications. SSL/TLS as well as SSH are introduced and its most common fields of operations are highlighted. These protocols form the base of securing traffic that is sent over the Internet on behalf of a variety of different applications.

Internet Firewalls

35.1 Tasks and Basic Principles of Internet Firewalls
35.2 Firewall-Relevant Internet Services and Protocols
35.3 Terminology and Building Blocks
35.4 Firewall Architectures
35.5 Packet Filtering
35.6 Bastion Hosts and Proxy Servers
35.7 Summary

Günter Schäfer
Technical University of Berlin Germany

Internet Firewalls[1] basically realize access control on the subnetwork level, that is, they control which "kind" of IP packets are allowed to flow into a subnetwork and which kind of packets are allowed to flow out of it, thereby protecting certain parts of a network from the intrusion of "undesirable" data units.

In building construction, the word *firewall* has become the established term for describing the task of protecting certain parts of a building from the spread of fire. Based on this term, the components used for protecting specific subnetworks from potential attack from other parts of the Internet are referred to as *Internet firewalls.* This term may not be totally accurate from a technical standpoint since Internet firewalls, unlike normal firewalls, should not be completely impenetrable (disconnecting the physical network connection would suffice in this case). However, it does convey an intuitive understanding of the necessary task.

35.1 Tasks and Basic Principles of Internet Firewalls

Due to the fact that an Internet firewall should not be completely impenetrable, it can easily be compared to the drawbridge of a medieval castle [ZCC00]. A drawbridge typically had the following functions:

- It forced people to enter a castle at one specific location that could be carefully controlled.
- It prevented attackers from getting close to other defense components of the castle.
- It forced people to exit the castle at one specific location.

For obvious reasons, an Internet firewall is normally installed at the network gateway between a protected trusted subnetwork and an untrustworthy network, which allows it to monitor incoming and outgoing data traffic. An example of this is the point where a corporate local area network is connected to the global Internet (compare Figure 35.1). All systems of a protected subnetwork are normally protected in the same way — that is, from the same undesirable data packets — with access control implemented by an Internet firewall at the subnetwork level.

[1]This chapter is an excerpt from the book "Security in Fixed and Wireless Networks", reprinted with kind permission of John Wiley & Sons.

© 2005 by CRC Press LLC

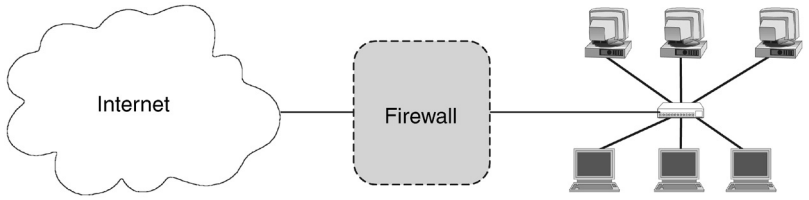

FIGURE 35.1 Firewall placement between a protected network and the Internet.

An Internet firewall therefore provides a central point where access control decisions are made and implemented [Sem96]. It is also an effective means for monitoring the Internet activities of subnetworks and preventing certain security problems from proliferating from one network area to another.

Firewalls can — if at all — provide only limited protection against malicious insiders who are determined to bypass the security strategy of a subnetwork. In particular, a firewall cannot influence any data traffic that is not passing through it. This self-evident fact is often overlooked. An example of this is a modem dial-up access that is set up with a system placed behind the corporate firewall. Furthermore, a firewall cannot protect against totally new attack patterns and also only offers limited protection against the intrusion of software viruses.

A differentiation is made between two diametrically opposed approaches to the basic security strategy that can be implemented by an Internet firewall [WC95]:

The *Default-Deny Strategy* is based on the principle that "Anything that is not explicitly permitted is denied." First an analysis is undertaken to determine which network services users of the protected subnetwork require and how these services can be made available in a secure way. Only those services for which a legitimate need exists and that can be supplied in a secure manner are provided. All other services are blocked through technical means. An example of this approach is permitting the transmission of HTTP traffic to any arbitrary systems and SMTP traffic to an e-mail gateway. All other data traffic would be blocked by the firewall. The advantage of this strategy from the perspective of security is that it also provides limited protection from unknown threats.

The *Default-Permit Strategy* follows an opposite approach, which is, "Anything that is not explicitly forbidden is permitted." With this approach services categorized as high-risk or contravening local security strategies are explicitly blocked through appropriate measures in the firewall. All other services are considered permissible and not blocked by the firewall. For example, such a strategy could mean that traffic from the *Network File System (NFS)* and *X11* protocols are generally blocked and that Telnet connections are only permitted to a specific host. This is the approach most users prefer because it usually gives them more flexibility. However, this strategy can by principle only offer protection from known threats.

As the description of these two approaches indicates, each Internet service blocked or permitted by a firewall always has to be examined specifically. The following section provides a brief overview of popular Internet services and their transport within the framework of the TCP/IP protocol family.

35.2 Firewall-Relevant Internet Services and Protocols

Internet Services: In practice, the following Internet services are of particular importance in the context of Internet firewalls:

- *Electronic mail (e-mail)*, normally implemented with the *Simple Mail Transfer Protocol (SMTP)*.
- *File exchange* on the basis of the *File Transfer Protocol (FTP)*, *Network File System (NFS),* and *NetBIOS* protocols.
- *Remote terminal access* and *remote command execution* through *Telnet, RLogin,* or *Secure Shell (SSH)* protocols.
- *Usenet News,* which is distributed through the *Network News Transfer Protocol (NNTP)*.

© 2005 by CRC Press LLC

- *World Wide Web* on the basis of the *Hypertext Transfer Protocol (HTTP)*.
- *Information about people* that can be called up using the *Finger* protocol.
- *Real-time conferencing systems*, such as *CUseeMe, Microsoft Netmeeting, Netscape Conference*, and the multicast-based *MBone Tools*.
- *Name services*, which are provided in the Internet through the *Domain Name System (DNS)*.
- *Network management* based on the *Simple Network Management Protocol (SMTP)*.
- *Clock synchronization* using the *Network Time Protocol (NTP)*.
- *Graphical window systems*, with *X11* being the most popular protocol in use.
- *Printing services*, based, for example, on the *Line Printing Protocol (LPR)*.

These services are normally realized through client/server programs and the application protocols used between these programs. The data units of the application protocols are usually transported either in the segments of a TCP connection or in the datagramms of the UDP protocol. TCP segments and UDP datagrams are transported in IP packets that in turn are sent in protocol data units of the layer 2 protocols used on the different communication links between source and destination computer (e.g., Ethernet, FDDI, ATM).

The two tuples *(source-IP address, source port)* and *(destination-IP address, destination port)* are used to address individual application processes. A *port* represents a number comprising two octets that explicitly identifies the Service Access Point (SAP) of an application process within an end system.

Figure 35.2 shows the frame format of an IP packet that is transporting a TCP segment.The following protocol fields are of particular importance for Internet firewalls:

Fields of the access protocol ("layer 2 protocol", not shown): The fields of particular interest are those that identify the contained layer 3 protocol (e.g., IP, Appletalk, IPX) and the source addresses of the access protocol (e.g., Ethernet-MAC address).

Fields of the IP protocol: Of special interest here are the source and destination addresses, the field Flags, which also contain one bit to display IP fragments, the protocol identification of the user data contained (e.g., TCP, UDP), and possible options such as the stipulation of the transmission path by the source. However, IP options are seldom used for anything other than attacks.

Fields of the TCP protocol: The fields of particular interest are the source and destination ports that have a limited influence on determining the sending and receiving application since many popular Internet services use well-defined port numbers. In addition, individual bits of the control field have an effect on connection control. An ACK bit is set in all PDUs except in the first connection establishment PDU, which means that an ACK bit that has not been set identifies a connect PDU. An SYN bit is set in all PDUs except in the first two PDUs of a connection. A packet with a set ACK bit and an SYN bit that is not set

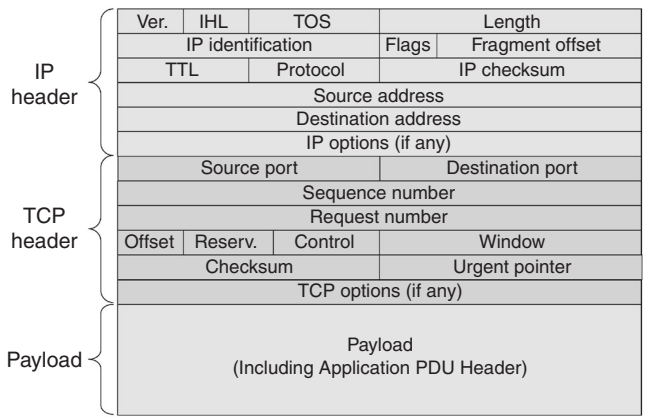

FIGURE 35.2 Frame format of an IP packet with a TCP segment.

© 2005 by CRC Press LLC

therefore identifies the PDU accepting the connection. Lastly, an RST bit permits a connection to be terminated immediately without displaying a further error message and can therefore be used to terminate a connection without providing additional information.

Fields of the application protocol: In some instances, it may also be necessary or meaningful for the Internet firewall to check the protocol fields of an application protocol. However, these vary from application to application and therefore will not be discussed here.

35.3 Terminology and Building Blocks

Internet firewalls are usually made up of certain building blocks that fulfill specific tasks and possess certain characteristics. This section briefly introduces the relevant terminology.

An *Internet firewall* (hereafter also simply referred to as firewall for short) is a component or a group of components that restricts access between a protected network and the Internet or another untrustworthy network. In this context, access refers to the exchange of data packets. Even if the term may appear to be an unusual choice at first glance, it should convey that, from the view of security, access control decisions are made and implemented on the basis of a firewall.

Packet filtering specifies the actions a specific system takes when selectively controlling the flow of data packets from and to a specific network. Packet filtering is an important basic technique for implementing access control at the subnetwork level in packet-oriented networks such as the Internet. The packet filtering process is also referred to as *screening*.

A *Bastion host* is a computer that has special security requirements due to the network configuration that makes it more vulnerable to certain attacks than the other computers in a subnetwork. A bastion host within a firewall often represents the main point of contact between application processes within a protected network and the processes of external hosts.

A computer is identified as a *dual-homed host* if it has at least two network interfaces and is therefore "at home" in two subnetworks.

A *proxy* is a program that deputizes for the client processes of a protected subnetwork and communicates with external server programs. Proxies relay approved requests from internal clients to the actual servers and also forward server responses to the internal clients.

The term *perimeter network* identifies a subnetwork that is inserted between an external and an internal network in order to create an additional security zone. Perimeter networks are often referred to as *demilitarized zones (DMZ)*.

Network Address Translation (NAT) is a technique in which an intermediate system deliberately modifies the address fields in a data packet in order to implement an address conversion between internal and external addresses. For example, with this technique, a large number of systems can be connected to the Internet on the basis of a small number of externally valid addresses (i.e., in the Internet). Although NAT is not actually a security technique, it offers the advantage from a security perspective that the internal addresses will not be known to external attackers. This makes it more difficult for deliberate attacks to be executed to individual internal systems from the outside. With NAT, the "initiative" for specific data streams must basically originate from internal systems, and the application processes of internal systems are not visible from the outside.

35.4 Firewall Architectures

As mentioned above, Internet firewalls can be built from one component or a group of components. As a result, a number of firewall architectures have established themselves over the years. The structures of some of the popular ones will be explained in this section.

The simplest of these architectures consists solely of one packet filter and is illustrated in Figure 35.3. This architecture can be built either with a commercially available workstation computer using two network interfaces or a dedicated router that also incorporates basic packet filter functions. The protection

© 2005 by CRC Press LLC

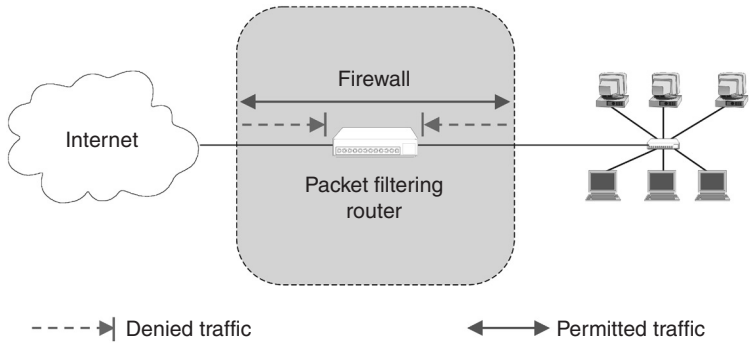

FIGURE 35.3 Architecture of a packet filter firewall.

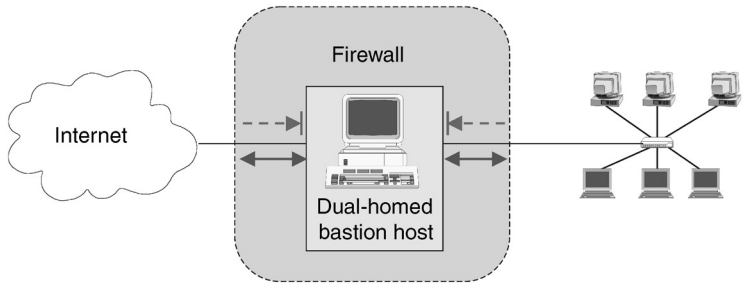

FIGURE 35.4 Dual-homed-host architecture.

function of this architecture is based solely on filtering undesirable data packets between a protected network and the Internet (or other untrustworthy subnetwork). In Figure 35.3 (and in other figures in the rest of this section), a straight arrow shows the "permitted" data traffic and a dotted line shows the "blocked traffic."

Figure 35.4 illustrates the minimally more complex *dual-homed-host architecture.* Although there may be no difference between the hardware configuration of this architecture and a packet filter (if the packet filter is implemented on a workstation computer), the software on the dual-homed host provides additional security functions because its main task is not limited to pure packet filtering.

A dual-homed host provides proxy services to internal and external clients; thus, for security reasons IP packets do not need to be routed directly into and out of the protected subnetwork. The protected network in this case is only attached to the Internet through monitored proxy services. In some cases, the dual-homed host can also handle routing functions for IP packets. However, appropriate packet filter functionality must then also be implemented on the host to prevent the protective effects of the firewall from being lost.

With this architecture, the dual-homed host is the central attack point for potential attackers. Therefore, it should be regarded as a bastion host and protected accordingly (also compare Section 35.6).

The drawback of this architecture is that, depending on the size of the protected subnetwork and the bandwidth of the Internet connection, a dual-homed host can develop into a performance bottleneck.

Figure 35.5 shows a *screened-host architecture,* which spreads the functionality of the packet filter and the proxy server over two components. The packet filter allows permitted traffic to pass between the Internet and the internal bastion host and blocks all direct traffic between other internal computers and the Internet. In some cases, certain traffic streams can also be permitted directly between the internal computers and the Internet; however, this can introduce potential vulnerabilities. The bastion host in turn provides proxy services for communication between internal computers and the Internet.

© 2005 by CRC Press LLC

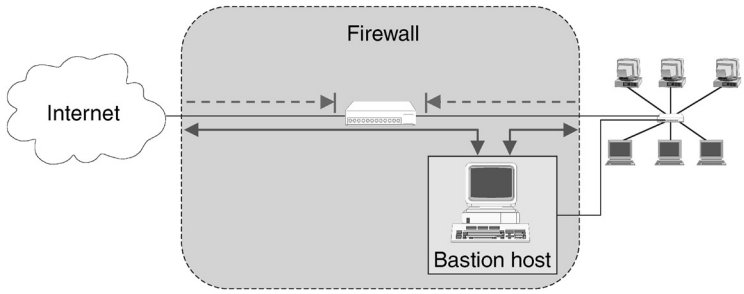

FIGURE 35.5 Screened-host architecture.

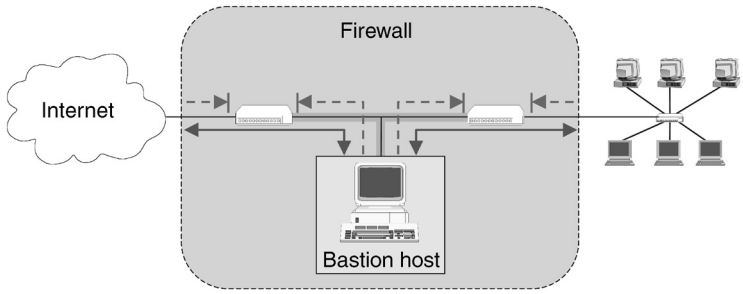

FIGURE 35.6 Screened-subnetwork architecture.

Two main advantages can be gained from separating packet filter functionality and proxy services into two consecutively switched devices:

In terms of security, a bastion host will be better protected from attacks on potentially available services that should not be accessible from outside. Furthermore, compared to proxy services, relatively simple software can be used to implement packet filter functionality, which means that a relatively compact software installation is all that is required on the respective system. This is particularly an advantage because complexity is the "main obstacle" in the construction of secure systems.

Another benefit of this architecture is that it can also provide a performance advantage. When certain data streams (e.g., Internet telephony) are routed directly into an internal network, they do not have to "cross through" the same computer that also provides the proxy services.

In terms of the physical structure of the networking, it should be noted that a bastion host could sometimes also be connected to the same internal subnetwork for which it provides security services. In this case, its relationship with the firewall rather tends to be of a logical nature since it is only conditional on the packet filter rules. It is particularly important to note that a bastion host essentially has special protection needs and therefore should physically be more difficult to access than the systems protected by it (also see Section 35.6). However, this kind of networking presents a security problem even if the bastion host is a physically separate installation: depending on the networking technique used (e.g., Fast-Ethernet-Hub), attackers who are able to compromise a bastion host can then directly sniff the traffic in the internal network.

The *screened-subnetwork architecture* illustrated in Figure 35.6 counters the particular threat of a potentially compromised bastion host by setting up a *demilitarized zone,* also referred to as a *perimeter network.* This zone is created using two packet filters between which one or more bastion hosts is embedded for the purpose of providing proxy services. This zone is also available for the connection of the servers that provide services to external computers, such as WWW and FTP. The main task of the second packet filter is to protect the internal network from the threat of a possibly compromised bastion host.

© 2005 by CRC Press LLC

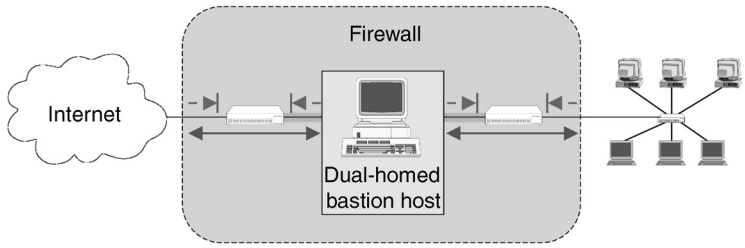

FIGURE 35.7 Split-screened subnetwork architecture.

The *split-screened subnetwork architecture* shown in Figure 35.7 is an even more sophisticated architecture in terms of security. In this architecture, a dual-homed bastion host divides the demilitarized zone into two separate subnetworks. Using proxy services, the bastion host is better able than a simple packet filter to exercise finely granulated control over the data streams. Furthermore, an outer packet filter protects the bastion host from external attackers and an inner packet filter protects the internal subnetwork from the bastion host if it is compromised. The architecture thus provides an "in-depth defense," comparable to that of a knight's castle where attackers normally have to surmount several protective walls before they can penetrate the interior.

35.5 Packet Filtering

As our discussion on the different firewall architectures has shown, the packet filtering function plays a central role in securing individual subnetworks. This section takes a detailed look at the role of packet filtering.

The first question in this context is which protective functions IP packet filtering can provide for access control?

Theoretically, protective measures of any complexity are feasible because all data exchanged between two or more entities in the Internet are ultimately transported in IP packets. In practice, however, the two basic considerations listed below have proven useful in the decision criteria for designing protective measures:

1. Selection operations, which require detailed knowledge about the functioning of higher level protocols or a comprehensive evaluation of the protocol data units transmitted in previous IP packets, are easier to implement as specific proxy services.
2. Simple selection operations that have to be executed quickly and always evaluate individual IP packets can be implemented more efficiently through the use of packet filters.

This kind of *basic packet filtering* uses the following information to make its selection decision:

- Source IP address,
- Destination IP address,
- Transport protocol,
- Source address port,
- Destination address port,
- In some cases, specific protocol fields (e.g., TCPs, ACK-bit, and SYN-bit), and
- Network interface where an IP packet was received.

In addition to these basic functions, *stateful packet filtering* is also sometimes used in selection decisions. This variant, also referred to as *dynamic packet filtering,* ensures that incoming UDP packets are only allowed to pass if they are a response to previously observed outgoing packets.

Lastly, packet filters can also handle basic *protocol checks.* An example is the checking of IP packets that are sent to a DNS port for correct formatting in accordance with the DNS protocol. Another related point

© 2005 by CRC Press LLC

is that packets containing an HTTP-PDU in their data part should definitely not be forwarded to certain IP addresses.

The design of packet filter functions should take into account that the more complex they become, the more resources they require for execution. Therefore, it is always important to consider whether a two-step approach using a simple packet filter and application-specific proxy services would produce a more efficient mechanism for the checking process.

Based on the filtering rules configured in it, a packet filter decides how to proceed with each IP packet it looks at. This involves the following actions:

- Forwarding the packet
- Dropping the packet
- In some cases, logging either an entire packet or parts of it
- Possibly sending an error message to the sender, taking into account that error messages could be helpful to any attackers who are preparing further attacks.

Because packet filters normally attempt to separate a protected subnetwork from a less trustworthy network, an implicit understanding of the traffic direction is required for the specification of filter rules. Therefore, IP packets that are received from a network interface located outside the protected network are referred to as *inbound traffic.* Accordingly, packets that are received from the network interface of a protected subnetwork are considered *outbound traffic.* When packet filter rules are specified, the information identifying which network interface received the IP packet is usually based on one of the three alternatives *"inbound,"* *"outbound,"* or *"either."*

Placeholders (also called "wildcards") can be used to specify source and destination IP addresses: for example, "125.26.*" refers to all IP addresses that begin with the prefix "125.26."

The IP addresses in the following examples are often simply indicated as *"internal"* or *"external"* to keep the discussion neutral in terms of any particular network topology. Often, when the source and destination ports are given, entire ranges are specified, for example, ">1023" for all port numbers higher than 1023.

One basic assumption is that packet filter rules are evaluated in the sequence in which they are specified and that the first rule applicable to a packet determines the action to be taken. Over the years, it has been proven that this method is the easiest one for system administrators to understand and the best one for keeping errors in rule specification to a minimum.

The set of packet filter rules developed below illustrate the concepts described so far and are aimed at ensuring that only e-mail traffic is allowed between a protected subnetwork and the Internet (example according to [ZCC00]).

Internet e-mail is being exchanged between two SMTP servers in TCP connections. The initiative for the exchange originates from the server that is delivering the e-mails. This server establishes a TCP connection to destination port 25 of the receiving SMTP server for this purpose, selecting a number higher than 1023 as the source port. Since incoming as well as outgoing e-mails are allowed, packet filter rules have to be designed for both directions.

Table 35.1 shows the first approach that can be taken. The two rules A and B are used to transmit incoming e-mails and rules C and D fulfill the same task for outgoing e-mails. The last one, rule E, is aimed at denying all other data traffic ("Default-Deny Strategy").

TABLE 35.1 Example of a packet filter specification

Rule	Direction	Src. addr.	Dest. addr.	Protocol	Src.port	Dest. port.	ACK	Action
A	Inbound	External	Internal	TCP		25		Permit
B	Outbound	Internal	External	TCP		>1023		Permit
C	Outbound	Internal	External	TCP		25		Permit
D	Inbound	External	Internal	TCP		>1023		Permit
E	Either	Any	Any	Any		Any		Deny

© 2005 by CRC Press LLC

Rule A allows inbound IP packets that are being sent to destination port 25 and are transporting TCP segments as payload. For the TCP connection to be established and maintained between the two SMTP servers, the corresponding response packets of the server receiving the e-mails must be allowed to pass outside. Rule B therefore allows outbound IP packets to port numbers higher than 1023.

The following examples help to explain the protection function of these rules:

Assume that an IP packet with a forged internal source address is being sent to the protected subnetwork from the outside: since inbound packets are only forwarded if they have external source addresses and internal destination addresses (rules A and D), this kind of attack will be successfully defeated. The same applies to outgoing packets from an internal attacker making use of external source addresses (rules B and C).

This filter specification is also effective at blocking incoming Telnet traffic, because Telnet servers normally wait at port 23 for incoming connections and incoming traffic is only allowed by the packet filter if it is being sent either to port 25 or to a port higher than 1023 (rules A and D). On the basis of rules B and C, the same applies to outgoing Telnet traffic.

However, this ruleset is not totally effective. For example, it does not block either incoming or outgoing X11-Protocol traffic. An X11 server usually waits at port 6000 for incoming connections and the corresponding client programs use destination ports from the set of numbers above 1023. Because of rule B, inbound X11-PDUs can therefore pass the packet filter and, because of rule D, outbound X11-PDUs are not blocked either. This provides potential attackers with an attractive opportunity because the X11-Protocol leaves the door open to various different attacks, for example, reading and manipulation of screen information and of keyboard input.

This problem can be dealt with through the inclusion of the source port in the filter specification. Table 35.2 shows the resulting filter rules. With this ruleset, outbound packets are only permitted to ports higher than 1023 if they originate from source port 25 (rule B). Therefore, PDUs from internal X11-client or X11-server programs are blocked. Similarly, rule D blocks incoming traffic to X11-client or X11-server programs.

In practice, however, one cannot assume that an attacker will not use Port 25 as the source port for an attacking X11-client. In this instance, the packet filter would allow the traffic to pass.

Table 35.3 therefore shows an improved version of the filtering specification that also incorporates the ACK bit of the TCP protocol header and includes rules B and D. Since the ACK bit is assumed to be set in rule B, this rule can no longer be used to open an outgoing connection (the TCP connect-request is

TABLE 35.2 Inclusion of source port in a packet filter ruleset

Rule	Direction	Src. addr.	Dest. addr.	Protocol	Src.port	Dest. port.	ACK	Action
A	Inbound	External	Internal	TCP	>1023	25		Permit
B	Outbound	Internal	External	TCP	25	>1023		Permit
C	Outbound	Internal	External	TCP	>1023	25		Permit
D	Inbound	External	Internal	TCP	25	>1023		Permit
E	Either	Any	Any	Any	Any	Any		Deny

TABLE 35.3 Inclusion of an ACK bit in the packet filter ruleset

Rule	Direction	Src. addr.	Dest. addr.	Protocol	Src.port	Dest. port.	ACK	Action
A	Inbound	External	Internal	TCP	>1023	25	Any	Permit
B	Outbound	Internal	External	TCP	25	>1023	Yes	Permit
C	Outbound	Internal	External	TCP	>1023	25	Any	Permit
D	Inbound	External	Internal	TCP	25	>1023	Yes	Permit
E	Either	Any	Any	Any	Any	Any	Any	Deny

© 2005 by CRC Press LLC

TABLE 35.4 Inclusion of bastion host in packet filter ruleset

Rule	Direction	Src. addr.	Dest. addr.	Protocol	Src.port	Dest. port.	ACK	Action
A	Inbound	External	Bastion	TCP	>1023	25	Any	Permit
B	Outbound	Bastion	External	TCP	25	>1023	Yes	Permit
C	Outbound	Bastion	External	TCP	>1023	25	Any	Permit
D	Inbound	External	Bastion	TCP	25	>1023	Yes	Permit
E	Either	Any	Any	Any	Any	Any	Any	Deny

identified by an ACK bit not set). Similarly, the stipulation of a set ACK bit in Rule D prevents the opening of incoming TCP connections sent to ports with a number higher than 1023.

As a basic guideline, it should be noted that each packet filter rule designed to allow TCP-PDUs for outgoing connections (or the reverse) should request a set ACK bit.

If the firewall contains a bastion host, then the SMTP server should preferably be run on this system (or the SMTP host should be regarded as a bastion host). Incorporating the IP address of the bastion host into the packet filter ruleset can increase the security of the protected subnetwork, because in this instance attacks on the SMTP server program will only affect the bastion host. Table 35.4 shows the resulting packet filter ruleset.

With a screened subnetwork firewall, two packet filters have to be equipped with the appropriate rulesets: one for the traffic between the Internet and the bastion host and one for the traffic between the bastion host and internal subnetwork.

35.6 Bastion Hosts and Proxy Servers

As explained in Section 35.3, the bastion host is the main point of contact between application processes within a protected network and the processes of external systems. Depending on the firewall architecture, it is responsible for the task of packet filtering and/or provides dedicated proxy services for specific applications. As the principal point of contact for the protected network to external systems, a bastion host has a higher exposure to threats than the systems to which it provides security functions.

Even though a dedicated packet filter can be used to reduce these risks, special measures should also be taken to secure the proxy server itself. This section begins by presenting some general observations on securing bastion hosts and concludes by briefly reviewing how proxy services are implemented.

The principles applied to building a "secure" bastion host are ultimately merely extensions to the strategies used for securing any key system in a network. The basic rule is that the system configuration of a bastion host should be kept *as simple as possible.* If there are any services that should not be offered on the bastion host, they should not even be installed on it.

One should also basically anticipate the fact that a bastion host might be compromised. Internal systems therefore should not place more trust in the bastion host than is absolutely necessary. For example, no file systems should be exported to the bastion host, no Login should be enabled from the bastion host to internal systems, etc. If possible, the bastion host should be integrated into the network infrastructure in such a way that it is unable to eavesdrop on data traffic in the internal subnetwork. (This can be done through the use of another packet filter to separate the network or through a network interface that does not support "promiscuous mode," which is necessary for eavesdropping.)

In addition, extensive event logging should take place on the bastion host to ensure early detection of any attacks or successful compromising of the host. Note that a successful attacker should not be able to tamper with event logging at a later time. One possibility is to transfer the event entries over the serial interface to a separate log-computer that does not have a network interface itself.

As long as no important reasons exist to the contrary, the bastion host should be a preferably "unattractive" target for potential attackers. For example, slow computers are less attractive targets and also of less use to an attacker than high-speed systems. At the same time, one has to bear in mind that a bastion

© 2005 by CRC Press LLC

host should not turn into a performance bottleneck for the internal network and sometimes also has to offer resource-intensive services (e.g., Web proxy services). Nonetheless, the potential usefulness of a bastion host to an attacker should be minimal. Therefore, the only software tools that should be installed on it are those that are essential to its operation. Above all, no user accounts should be available on a bastion host. This will prevent anyone from spying on data or executing password attacks.

Lastly, a bastion host should definitely be installed in a secure location where general physical access is not allowed to ensure that the risk of manipulation is kept to a minimum. Its system configuration should be backed up at regular intervals. A routine reinstallation of the system from a security copy can also be considered for the purpose of correcting any possible manipulation that has occurred. However, it is important to be aware that any existing weakness in a system configuration that has already been exploited by an attacker can be used again for gaining access to the system. A reinstallation of the system, therefore, does not reduce the risk of it being compromised.

A bastion host equipped with proxy services can give users of a protected subnetwork the illusion that all systems in this network are able to access Internet — although in reality, it is only the bastion host that has access.

There are two main different types of proxy services:

If a proxy server analyzes the commands of the application protocol and interprets its semantics, it is referred to as an *application-level proxy.*

If, on the other hand, the proxy server is restricted to forwarding application PDUs between client and server, it is called a *circuit-level proxy.*

Possible "candidates" for proxy services include FTP, Telnet, DNS, SMTP, and HTTP. The following situation usually exists when a proxy server is available: the user of the proxy service thinks that his or her system is exchanging data directly with the actual server, and the server is under the illusion that it is exchanging data with the bastion host.

If a proxy service is used, applications-specific data streams have to be rerouted to the proxy server. In each case, the proxy server must be informed of which application server it is to use for the connection. The following four implementation possibilities exist:

Proxy-aware user procedures: An example of this variant is the use of Telnet proxies. Here, the user first registers on the bastion host and then from there establishes a Telnet session to the actual desired server.

Proxy-aware client software: In this case, the client software is responsible for transferring the corresponding data to the proxy server. This approach is used, for example, with proxy-enabled Web browsers where client software only has to be notified once of the name or address of the Web proxy.

Proxy-aware operating system: With this variant, the operating system (using the appropriate configuration data) is responsible for the rerouting and transfers the required parameters to the proxy server.

Proxy-aware router: This variant transfers the task of activating the proxy to an intermediate system, which reroutes connections initiated by internal client computers to a proxy computer, also sending the necessary address data to the computer.

35.7 Summary

Internet firewalls provide access control at the subnetwork level. For this purpose, Internet firewalls are normally installed between a protected subnetwork and a less trustworthy network, such as the public Internet.

At the same time, it should be noted that an Internet firewall is only capable of monitoring those data streams that pass through it and that it basically cannot provide any protection from internal attackers.

Depending on the level of security being sought and the resources available, an Internet firewall can be constructed using either a single or a group of components. Over time, a number of architectures have

© 2005 by CRC Press LLC

evolved as a result, each offering specific security features. In practice, the *packet filter,* the *dual-homed-host,* the *screened-host,* the *screened-subnetwork,* and the *split-screened-subnetwork* architectures are the most popular.

The central elements used by all these architectures are *packet filters,* which make access decisions for each IP packet routed through them, and *proxy servers*, which enable an applications-specific monitoring of data streams. The computing systems with specific functions installed in a firewall are called *bastion hosts*. Because they have a high level of exposure to attackers, bastion hosts must be installed with particular care and should be constantly monitored.

36.1 Introduction

Ad hoc networks are networks that are spontaneously set up, often for a dedicated purpose, and where devices can configure themselves into a connected network. When wireless communication is used, *ad hoc* networks often use multiple wireless communication hops between a message's sender and receiver to overcome the limited range of wireless communication. This relaying of messages is typically done by the participants of the *ad hoc* network themselves, merging the concepts of terminals and network equipment.

Such self-organized *ad hoc* networks make new applications possible, but problems, for example, in the link, routing, and transport layer have to be solved. This chapter gives an overview of these problems and their principal solutions.

36.2 The Case for *Ad Hoc* Networks

Typical communication networks consist of devices connected by wired or wireless communication links where the structure of these links and the communication relationships between these devices are carefully planned and set up: desktop computers are connected to Ethernet switches serving a floor of an office building; these switches are connected to a router, which in turn talks to the Internet backbone. The topology of the entire network is judiciously planned and which device is allowed to communicate how

© 2005 by CRC Press LLC

with which other device is carefully preconfigured; integrating new devices in such a network can be cumbersome.

This inflexibility of traditional communication networks can be an obstacle for many types of applications. In any scenario where devices are dynamically deployed or where the communication relationships between devices change frequently, a preplanned network structure is rather onerous. If only devices could spontaneously communicate with each other on an asneeded basis, new application scenarios would be possible. Some dynamic scenarios are:

- Connecting a laptop to either a home, office, or hotel network without having to reconfigure it.
- Automatically connecting the laptops in a meeting room to enable the meeting participants to share documents.
- Electronic price tags in shopping malls update their displayed price and product information via a wireless interface.
- Vehicles in an automated factory floor communicating with each other and with the machinery they pass by as well as accessing a wired backbone network, regardless of the current vehicle position.
- Cars inform each other about driving hazards ahead.
- Wireless communication for rescue teams in disaster relief operations, for example, fire fighters at a wild fire.
- Rapid deployment of numerous tiny, sensor-equipped devices, for example, temperature sensors, over such a disaster area, communicating with each other and with rescue teams.

To support such application types, the concept of *ad hoc networking* has been developed. This concept describes the construction of a communication network out of participating devices on-the-fly in a simple, dynamic manner with as little human intervention as possible. These networks are intended for a dedicated purpose rather than to serve as a general networking infrastructure.

For some of these scenarios, wireline communication would make sense: a laptop can be plugged into a hotel network using a cable; for most scenarios, however, wireless communication is the medium of choice for an appealing solution. Hence, *ad hoc* networks are usually associated with wireless communication. In a wired *ad hoc* network, the questions to solve are more associated with problems of autoconfiguration and seamless integration with existing restrictions, for example, a company laptop might not be allowed to access the company's internal network from any location. These problems are not the topic of this chapter.

Wireless communication, on the other hand, introduces some difficulties, in particular, the limited communication range. While this is no problem for laptops in a meeting room, firefighters will be spread out over a region too large for an individual device to cover with a single wireless transmission. In traditional wireless communication systems, for example, cellular telephony systems like Global System for Mobile Communication (GSM), this problem is overcome by additionally installing infrastructure components — base stations or access points — that both are capable of wireless communication and are connected to the fixed network. These infrastructure components then handle communication between distant devices. But when fighting a wildfire, such infrastructure is typically not available nor would it be cost-efficient to deploy it on a factory floor. The only possible recourse is hence to use other terminal devices to help in communication between distant terminals: these terminals would volunteer to relay data from one terminal toward its destination; data would travel over several wireless communication hops, making such a network a *wireless multi-hop ad hoc network*.

Such a multi-hop *ad hoc* network can be used as a stand-alone solution — communication among firefighters is a prime example. Or they can be combined with infrastructure devices, forming hybrid networks. An evident goal for such hybrid devices is to extend the reach of an access point by relaying data of a terminal too far away for direct communication via intermediate terminals to/from the access point. This would reduce the number of access points required to cover a given area; it is also particularly useful in environments where many obstacles can impede radio communication despite short distances, for

© 2005 by CRC Press LLC

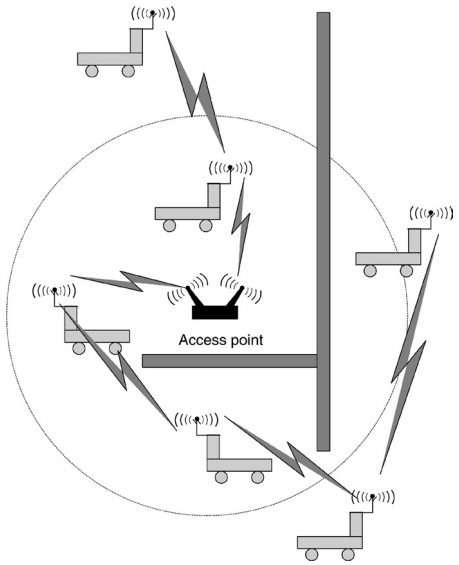

FIGURE 36.1 Typical scenario for hybrid cellular/multi-hop *ad hoc* networks. The dotted circle indicates the maximum range of the access point, and dark rectangles represent obstacles; vehicles are in wireless contact with the access point directly or indirectly.

example, on a factory floor, where an access point would have to communicate "around the corner". One such scenario is illustrated in Figure 36.1.

Using wireless multi-hop *ad hoc* networks in industrial communications carries a number of advantages and disadvantages and a number of challenges that have to be tackled. The biggest advantages are the simple deployment and low cost — no or only little infrastructure is necessary — and the inherent support of mobile devices — partially owing to wireless communication, and also owing to the liberation from coverage restrictions imposed by traditional communication systems.

This ability to support extended mobile scenarios is also the biggest challenge to a Mobile *Ad Hoc* Networks (MANET): when all terminals, including the ones used for relaying data, are free to move about, how to decide where to send data so that it eventually arrives at its destination? Is it possible to give any type of guarantees regarding the connectivity of such an *ad hoc* network as a whole or regarding basic networking metrics like through-put and delay; is it possible to make the communication service rendered by an *ad hoc* network dependable, predictable, and configurable? For some scenarios, additional issues like the energy efficiency of the communication — if the terminals are battery-operated — or processing power required for communication are important as well.

These are the typical problems tackled by wireless mobile *ad hoc* networks research and development. As this is still an active research field, not all of these questions have been completely solved yet. This chapter gives an overview of these problems and some of the currently more popular solutions.

Regarding the physical layer, *ad hoc* networks differ not much from other wireless networks, unless very tight constraints on the processing power are present, for example, in sensor networks where very simple physical layers are used. Other layers differ more substantially. Specifically, the approaches for wireless link layers amenable to support *ad hoc* networks are discussed in Section 36.2. Section 36.3 explains the core problem of mobile *ad hoc* networks, how to find a communication peer despite the changing topology of the network. The following Section 36.4 looks at problems of transport protocols in mobile *ad hoc* networks. Section 36.5 focuses on a specific type of *ad hoc* networks, wireless sensor networks, which are based on tiny devices containing sensors, a simple controller, and a radio modem to form an *ad hoc* network embedded in the physical environment. Finally, Section 36.6 wraps up the chapter by looking at some smaller issues.

© 2005 by CRC Press LLC

This chapter cannot do justice to the entire field of *ad hoc* networks. Some recommendable books on the topic are [8, 12]; but currently many books on wireless communication also include material on *ad hoc* networks that is more detailed than the survey presented here.

36.3 Wireless Link Layers for Mobile *Ad Hoc* Networks

Centralized or Distributed?

The basic tasks of the link layer in general are framing, medium access, local error, and flow control. Not all of them are specific in the wireless case; only the main problems and solutions for the wireless case are briefly summarized here. A link layer for a wireless transmission medium has to contend with additional challenges compared to a wired link layer: the channel quality varies over time, available bandwidth is smaller, the wireless medium usually has broadcast character, and a wireless sender cannot usually sense the medium while it is sending, precluding collision-detection-based mechanisms for medium access.

In an infrastructure-based wireless network where all mobile terminals only communicate with a base stations, a link layer is nevertheless conceptually simple. A straightforward option is to put all medium access and link layer control in such a central base station and use Time Division Multiple Access (TDMA) to assign each terminal a fixed time slot by the base station. This approaches is used, for example, by GSM or HiperLAN/2. A prerequisite for this approach is, however, that every terminal is close enough to the base station to receive synchronization or scheduling commands, for example, when is which terminal allowed to send.

But this proximity requirement to a base station or even the mere need for one is the very property that *ad hoc* networks are intended to overcome; therefore, such centralized link layers are not immediately applicable to *ad hoc* networks. Distributed solutions are required.[1] One such distributed solution is the IEEE 802.11 system, along with its Request To Send (RTS)/Clear To Send (CTS) mechanism to combat the hidden and exposed terminal problems. IEEE 802.11 is based on a Carrier Sense Multiple Access (CSMA) scheme, where a terminal has to check whether the medium is idle before it is allowed to send and has to observe certain times between listening and sending and a given backoff scheme when a busy medium is detected. The goal is to avoid interfering with another ongoing transmission and causing high packet error rates. This turns mere CSMA into a CSMA with Collision Avoidance (CSMA/CA) scheme.

Hidden and Exposed Terminals

While this CSMA/CA scheme is reasonably efficient as long as all terminals are in mutual sending range, it breaks down as soon as this is no longer the case. Consider the scenario in Figure 36.2: terminals A and C both want to send to B but are too far away from each other to receive their respective transmission; they are *hidden* from each other. C would start its own transmission to B when A is already sending and so would destroy A's packet. To solve this hidden terminal problem and avoid the collisions caused by it, a sending terminal A is required to first send, after observing the CSMA regulations, an RTS message to the destination, which answers with a CTS. This CTS is then also observable by C, now knowing that there is an ongoing transmission at B with which C must not interfere.

This solution to the hidden terminal effect is satisfactory but comes at additional overhead for the RTS/CTS messages. Also, it fails in some situations: for example, when B's CTS message collides with the transmission of an additional terminal D's RTS (similar in setup to the one in Figure 36.3). Terminal C would then assume the medium to be still idle and answer the retransmission of D's RTS with a CTS, disturbing the ongoing packet reception at B.

[1]There is some research on how to build *ad hoc* networks out of centralized protocols like HiperLAN/2. The core idea is to dynamically elect controlling terminals out of all mobile terminals and use these controlling terminals for coordination. While such an approach has some advantages regarding the possible Quality-of-Service guarantees, it is quite complicated and not the main track of current research.

© 2005 by CRC Press LLC

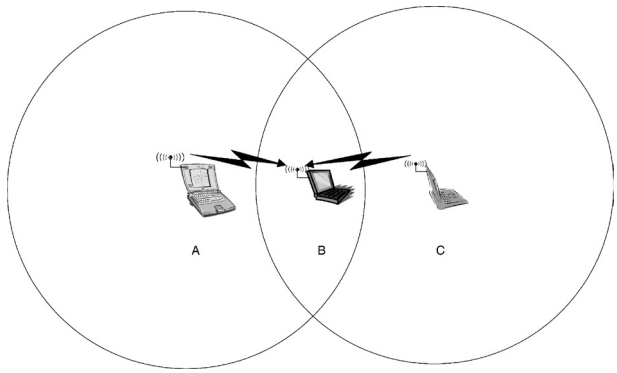

FIGURE 36.2 Hidden terminal scenario.

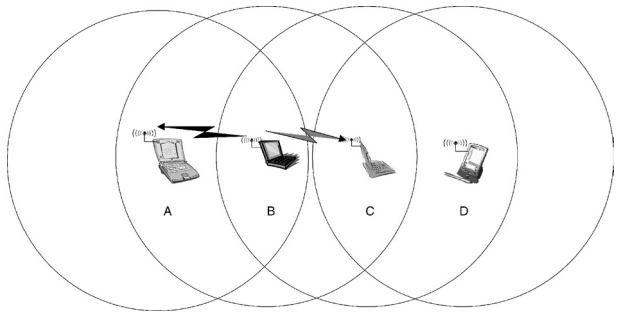

FIGURE 36.3 Exposed terminal scenario.

The *exposed terminal effect* occurs in a similar scenario, shown in Figure 36.3. Suppose terminal B sends to A and C intends to send to D, with C and A again beyond mutual range. As C senses an occupied medium, it defers its transmission according to CSMA/CA rules until the medium is idle again. However, this delay is unnecessary as C's transmission would not interfere with A's reception process. Hence, possible parallelism is wasted.

Shortcomings of Multi-hop *Ad Hoc* Networks

When putting these mechanisms to work in a multi-hop environment, the resulting capacity — measured as the amount of data that reaches its destination per unit time — of the entire network is interesting. Intuitively, one would expect an increase in capacity by the introduction of multi-hopping: an individual transmission covers only shorter distances, allowing multiple transmissions to proceed in parallel, increasing the number of packets delivered per unit time.

As theoretical considerations using a set of idealized assumptions have shown [3], the total capacity of a network does indeed increase with the number of nodes, but only slowly. In fact, the useful throughput per node actually *decreases* as terminals are added to a network. The ultimate limitation is the need to share resources with nearby terminals to communicate over long distances. This result, however, strongly depends on the communication pattern: when terminals only intend to communicate in their vicinity, substantial capacity gains are achievable.

Attempting to apply these theoretical results to a practical multi-hop system reveals some of the major shortcomings of today's protocols. When simulating an *ad hoc* network, a common observation is that the data rate available to each node is indeed only a small fraction of the raw link bandwidth, for example, in a network of 100 terminals each with a 2 Mbit/sec radio transceiver, the available data rate per

© 2005 by CRC Press LLC

terminal is on the order of a few kilobits per second. In [6], LI et al. considered several configurations of terminals, in particular, a linear chain of terminals where the first terminal sends data to the last terminal in line, where only neighboring terminals can communicate and interference extends to terminals two hops away. Using such a simple interference model, a Medium Access Control (MAC) protocol should achieve about one-fourth of the raw link bandwidth as end-to-end goodput by pipelining transmissions through the chain. As simulations show, IEEE 802.11 only converges to about one-seventh of the raw link bandwidth as the chain length increases. The capacity is also quite sensitive to the offered load: any load beyond the sustainable throughput will result in congestion losses as IEEE 802.11 cannot effectively arbitrate medium access. Other investigations have attempted to overcome these problems by applying cleverer distributed scheduling schemes where the medium access of a terminal is made contingent upon some partial knowledge of the load situation at other terminals. An alternative is to look at rate adaptation to solve this problem; but no overall solution exists yet. How to solve this problem is still an open research problem.

Apart from medium access control, the link layer has to solve some other problems, in particular, local retransmissions for erroneous packets and flow control. The retransmission schemes are identical for both traditional and multi-hop wireless networks. The flow control, on the other hand, is actually still an open problem as the lack in efficiency of an appropriate flow and congestion control is one of the reasons for the capacity degradations described in the previous paragraph.

Summary

The IEEE 802.11 approach discussed here is not the only possible one, although it is currently by far the most popular one. A reader interested in some of the history of and research on wireless MAC protocols should have a look at Multiple Access with Collision Avoidance (MACA), MACA with Acknowledgement (MACAW), Floor Acquisition Multiple Access (FAMA), Power-Aware Multi-Access Protocol with Signaling (PAMAS), Dual Busy Tone Multiple Access (DBTMA), and Elimination-Yield Non-Preemptive Priority Multiple Access (EY-NPMA), to name but a few protocols.

In summary, some of the currently available link-layer technologies for wireless networks are in principle suitable for multi-hop *ad hoc* networks. As long as the network is expected to work only under low load, the link layer performance is acceptable. In high load situations, however, the sustainable capacity collapses. Moreover, it is difficult to make any guarantees for such distributed link layers. Some work regarding fairness between terminals has been performed, but this problem is also not completely solved. Strict guarantees on the throughput that a particular flow obtains are difficult to make in a distributed multi-hop system and applications therefore should not rely on such guarantees.

36.4 Network Layer for Mobile *Ad Hoc* Networks

Basic Tasks and Main Problems for *Ad Hoc* Routing

The most basic task of a communication network is to move data from its sender to its intended receiver. In most networks, and in *ad hoc* networks as well, senders and receivers are usually not directly connected to each other. Intermediate terminals have to forward an incoming data packet that is not destined for itself toward the packet's destination. However, when a terminal has more than two neighbors, it has to decide to which neighbor to forward a packet. Providing the necessary information to a terminal to make these forwarding decisions is the *routing problem.*

In conventional, fixed networks, the routing problem has to be solved as well; a popular solution is Dijkstra's shortest path algorithm that minimizes the number of hops a packet has to travel. Minimizing the hop count is also desirable in wireless *ad hoc* networks, but the global view of the network that Dijkstra's algorithm requires is not available. While there are other fixed-network routing algorithms that only rely on local information (e.g., distance vector algorithms), they still cannot cope with the idiosyncrasies of *ad hoc* networks. The main problem is the high volatility of the neighborhood relationships: nodes that move around lose contact with their previous neighbors and find new ones. As a consequence,

© 2005 by CRC Press LLC

routes from a sender to a receiver can change frequently. Hence, routing protocols are required that can *discover* routes quickly and *maintain* them, if necessary, despite changes in the network's topology. Additionally, energy conservation concerns and relatively high errors rates complicate the design of *ad hoc* routing protocols.

Several families of *ad hoc* routing protocols have emerged during the last few years; the number of individual solutions and enhancements is staggering — in fact, routing has been the most active research area in *ad hoc* networks at all so far. More detailed information can be found in several survey and comparison papers, for example, [9]. An additional complication is presented by asymmetric links, when not all terminals have the same transmission power; this is not covered here.

Most of these routing protocols use an abstract view of the network as a graph with dynamically created and destroyed edges, representing the dynamic nature of the links between terminals. How to detect when a link appears or disappears is actually not a simple problem; common mechanisms are the exchange of "hello" messages to test links or by trying to overhear other terminals' activity, for example, receiving an acknowledgment from a hitherto unknown node. Especially for nodes that are on the borderline of reachability with a highly erroneous link between them, it is not clear whether and when to signal the availability of such a link to the routing protocol. Often, conservative choices are made in that only fairly stable links are used to avoid oscillation of topology information and frequent routing updates.

Besides the routing problem itself, two other important problems also pertain strongly to the networking layer: assigning addresses to nodes that do not previously possess unique identifiers and connecting *ad hoc* networks to larger networks like the Internet. These two topics will also be briefly touched upon here.

Ad Hoc Routing Protocols

Two main types of *ad hoc* routing protocols can be distinguished: "table-driven" and "source-initiated on-demand" protocols. Table-driven protocols are more akin to traditional routing protocols in that they keep a routing table in every participating node. This table contains information via which way any other node in the network can be reached. Handling changes in the network topology — new nodes joining or nodes moving around, forming new neighbors — is the challenge for these protocols, especially since the signaling traffic should be kept at a minimum and routing loops should be prevented. As these protocols try to keep routing information up to date upon topology changes, irrespective of whether this information is actually needed, these protocols are classified as *proactive.* Traditional routing protocols follow similar goals in general, but the requirements in the *ad hoc* case are much tighter. Examples for table-driven protocols are Destination Sequenced Distance Vector (DSDV), Cluster Switch Gateway Routing (CSGR), or Wireless Routing Protocol (WRP).

Source-initiated on-demand protocols adopt a different approach. Instead of attempting to always keep routing tables to all possible destinations up to date, they only become active when a packet is to be sent somewhere and no routing information is available — they are *reactive* rather than proactive. While this economizes on signaling traffic, it introduces delay for determining a route when the first packet to a destination is to be sent; similarly, when a route breaks and a new route has to be found, delay occurs. Additionally, as long as a route exists, it is a challenge for these protocols to capitalize on new, shorter routes becoming available. The classic example is Dynamic Source Routing (DSR); *Ad Hoc* On-Demand Distance Vector Routing (AODV) is currently very popular. Another example is Temporally Ordered Routing Algorithm (TORA), which combines some proactive and reactive components.

A third possibility for an *ad hoc* routing protocol is to not only consider the abstract network topology but to additionally make use of external information. One example for such information would be the location of terminals. As location knowledge is important for several types of context-dependent applications, this information can also be exploited for routing purposes. The basic idea of such *location-aided routing* is to use the sender's and destination's position to choose from the possible next hop terminals one that is closest to the destination. Location information is very useful to easily obtain a packet in the

© 2005 by CRC Press LLC

destination's vicinity; however, to actually reach the destination, usually some other *ad hoc* routing protocol is also required (e.g., owing to the limited precision of location information). Also, location-aided routing has to overcome specific problems like dead ends. A popular example is the Location-Aided Routing (LAR) protocol; an overview can be found in [7].

Address Configuration

The dynamic nature of *ad hoc* networks results in some more fundamental problems other than just routing and forwarding: it is not clear as to how to assign addresses to terminals. In the Internet, addresses are assigned either statically or dynamically to reflect the topology of the network, enabling aggregated routing tables. While *ad hoc* routing protocols do not require such a structured address space, addresses still have to be unique. In the simplest case, all nodes have a built-in unique identifier, for example, a MAC id. For some *ad hoc* networks, however, this is not a justifiable assumption (see Section 36.5).

Hence, a mechanism is required that automatically configures the addresses of nodes joining an *ad hoc* network so that no address is assigned twice. A particular challenge here is to handle the case of merging two partitions into one larger *ad hoc* network and to resolve the inevitable address conflicts arising from the independent operation of two sundered partitions.

Several approaches exist in the literature, for example, Duplicate Address Detection (DAD) or weak DAD along with some extensions for large-scale *ad hoc* networks. One approach, Distributed Dynamic Host Configuration (DDHC), is capable of even handling merging partitions: a joining terminal contacts another terminal that is already part of the *ad hoc* network and that negotiates a new address on behalf of the new terminal with the rest of the network. Partitioning is handled by using a partition identifier; when two partitions merge, address tables are exchanged between partitions and for conflicting address, one of the nodes has to newly join the *ad hoc* network.

Gatewaying to the Internet

In many application scenarios, an isolated *ad hoc* network would only be of limited use. Rather, a terminal within an *ad hoc* network usually also desires to communicate with the Internet at large. To do so, some of the terminals in the *ad hoc* network need to be in contact with the fixed network and act as a gateway between *ad hoc* and fixed network; such a gateway could, for example, be an access point in a wireless LAN. *Ad hoc* routing protocols can route packets to the gateway; but the question is how to integrate an *ad hoc*-connected node in the Internet.

The Internet's basic method for supporting mobile terminals with varying points of connection is the Mobile IP protocol. An *ad hoc*-connected terminal should be integrated into Mobile IP; more precisely, the *ad hoc* routing protocol and Mobile IP's agent system have to be coordinated. One proposal for integrating AODV and Mobile IP is describedin [11]. MIPMANET is an alternative approach that uses the *ad hoc* routing to tunnel any Internet-destined data to an Mobile IP foreign agent, which is located on the gateway node.

When connecting *ad hoc* networks to the Internet, a important special case is that the *ad hoc* network moves in its entirety from one gateway to the next — think of a person with a Personal Area Network (PAN) moving around. Here, the amount of signaling traffic should be minimized. This is currently ongoing research work.

Summary

Forwarding and routing have long been the research focus in *ad hoc* networks. The dynamic nature of a mobile *ad hoc* network makes routing an interesting challenge, for which a number of stable solutions exist. However, as there is no optimal routing protocol, the scenario requirements do determine the best choice. Additional problems, like address configuration and gatewaying *ad hoc* networks to the Internet, are also solved at least conceptually.

36.5 Transport in Wireless *Ad Hoc* Networks

Reliable Transport over Wireless Links

The task of transport protocols is to abstract away the details of a communication network and to provide a simple-to-use service interface to an application programmer, an interface that does not consider the structure of the network any longer but that allows the programmer to concentrate on the communication on the application level. The service provided by the transport layer is therefore oriented toward the endpoints of communication; it is the first *end-to-end* communication layer.

The simplest end-to-end service is just to take a packet the application wants to send and transport it to the peer endpoint — without attempting to repair errors in the network or worrying about overloading the network or the receiver (congestion and flow control). Such a service is provided by the User Datagram Protocol (UDP) in the Internet. Putting a UDP-like service on top of an *ad hoc* network is no challenge as the promises made are very small.

A more interesting case is reliable service with flow and congestion control, for example, in the manner of the Transport Control Protocol (TCP): a wireless network will produce packet losses, and the service provided by the routing layer is also quite different from a fixed Internet as routes are likely to change, resulting in quite unpredictable round-trip delays. For TCP, both effects challenge its basic assumptions that the network as such is in principle stable and pretty much reliable, and that the only reason for a network to lose packets is congestive overload. Under this assumption, the obvious reaction to a lost packet (e.g., detected by a timeout) is to reduce the load offered to the network in order to reduce congestion.

In a wireless network, however, a packet loss can be due to bad link quality or mobility-induced rerouting and not to congestion. Then, reducing offered load, that is, delaying the retransmission, is counterproductive; the lost packet should rather be repeated quickly. Overcoming this TCP deficiency has been tackled by many research efforts; the challenge is to maintain TCP's end-to-end semantics as best as possible. Some of the resulting approaches work in the end systems (e.g., TCP Westwood), some rely on support from entities within the network, for example, an access point that connects wired and wireless communication to each other; an overview is given in [2].

Some of this research was performed with mostly older radio hardware and pretty poor link-layer performance in mind and for scenarios where a large fixed network is connected via a single wireless last hop to a mobile terminal. With reliable link layers that perform local retransmissions, some of these problems go away; but on the downside, the round-trip time variance is increased. This fools TCP's round-trip time estimation, resulting in somewhat similar problems.

In either case, the case of a single wireless hop combined with a fixed network is not the most relevant case here. What happens when TCP is faced with a multi-hop wireless network?

TCP and Multi-hop Wireless Networks

When running TCP over a wireless multi-hop network, the problems of the error-prone wireless channel combine with additional complications introduced by the multi-hop nature and, possibly, by terminal mobility and ensuing route changes and re-routing delays.

As already discussed in Section 36.2, current wireless link layers cannot efficiently deal with multi-hop wireless networks. When a reliable end-to-end transport protocol like TCP is added, performance degrades further — even if terminals do not move around and routes are stable. One problem is that data packets and TCP acknowledgments conflict with each other, trying to travel over the same route in opposite directions. A second problem can appear by an interaction of TCP with the backoff timers deployed in the MAC protocol. As a consequence, several TCP connections sharing such a multi-hop route are unable to efficiently share the available bandwidth among each other, but one connection can capture the route for seconds or even minutes. Different wireless MAC protocols are more or less susceptible to these problems, but the problem is present for most of them.

© 2005 by CRC Press LLC

TCP's behavior over multi-hop networks becomes even more complicated when terminals additionally become mobile and routes are likely to break. With many *ad hoc* routing protocols, TCP packets or acknowledgments stuck in a now dead end route are likely to be silently discarded; may be the breaking of the route is signaled to the original sender. Two things now occur in parallel: a route repair will take place, searching for a new route between the sender and destination, and TCP will eventually time out and resend packets again. This timing out and resending of packets evidently degrades throughput. If route repair takes a long time, TCP will back off its timers, taking a potentially very long time until even the resending of packets is attempted again — by which time the terminals might already have moved around so much that the just repaired route is already useless. While the details of this process depend on the used routing protocol, mobility will in general decrease the useful throughput that TCP can realize.

Possible Improvements

When attempting to improve TCP performance over multi-hop networks, the basic problem is similar to the wireless last hop scenario: TCP has no information about the actual reason why it observes variations in packet delivery rate and round-trip time; hence, it cannot distinguish between congestion- and mobility-caused problems.

An obvious approach is to provide this information to TCP. This idea is well known even from fixed networks, where routers can provide explicit notifications about imminent or existing congestion to a TCP sender. For an *ad hoc* network, the relevant information is the failure of a (possibly remote) link, which is already provided by many routing protocols. Using such information can result in significant performance improvements. Similarly, such feedback information is used in the TCP-feedback scheme to explicitly freeze TCP timers until a route repair message arrives in order to avoid that TCP mistakenly reduces its congestion window size. The newer TCP-BuS approach uses similar messages, but just stops sending during route repair and extends timer values explicitly (instead of just stopping all timers).

Summary

Using TCP over a wireless multi-hop *ad hoc* network is challenging due to both the nature of the erroneous wireless link itself and the interaction of TCP with wireless MAC and *ad hoc* routing protocols. Errors on the wireless link can, to a certain degree, be handled by reliable link layers; TCP and MAC layer interactions require a careful choice of MAC mechanisms and timer values. Routing protocols and TCP should be modified to explicitly exchange information about route status and on-going route repairs. With these extensions to standard protocols, TCP in *ad hoc* networks becomes a viable concept, but here also considerable research is still required.

36.6 Sensor Networks

Applications for Sensor Networks

In recent years, miniaturization and low-power circuit design have made a new technological vision possible: bring down the cost, size, and power consumption of a device capable of wireless communication, minimal computation, and sensing to a level where such devices can be mass-deployed and embedded into our physical environment. Typical sensing tasks for such a device could be temperature, light, vibration, sound, radiation, etc. The hoped-for size would be a few cubic millimeters, the target price range less than one US$, including radio front end, microcontroller, power supply, and the actual sensor. All these components together in a single device form a so-called *sensor node.*

Joining some or even many of these sensor nodes together forms a new type of an *ad hoc* network, a *wireless sensor network.* Even large-scale sensor networks can be handled by applying *ad hoc* networking technologies. The sensor nodes will configure themselves into a connected network, determining which sensor node is responsible for which task: merely sensing the environment or also forwarding data between different nodes? For a large number of nodes, manual configuration is next to impossible.

© 2005 by CRC Press LLC

Based on such a technological vision, new types of applications become possible. Applications include environmental control such as fire fighting or marine ground floor erosion but also installing sensors on bridges or buildings to understand earthquake vibration patterns; surveillance tasks of many kinds like intruder surveillance in premises; deeply embedding sensing into machinery where wired sensors would not be feasible, for example, because wiring would be too costly, could not reach the deeply embedded points, limits flexibility, represents a maintenance problem, or disallows mobility of devices; tagging mobile items like containers or goods in a factory floor automation system or smart price tags for foods that can communicate with the fridge, etc. The possibilities abound — sensor networks could potentially become a disruptive technology when the basic size and cost problems are solved.

Wireless sensor networks have recently received considerable of attention in the research literature; a good recent survey paper is [1].

Main Challenges

While wireless sensor networks share many similarities with *ad hoc* networks, there are also several important differences. These differences result from both technological structure of sensor nodes and from the intended application scenarios. The most important ones are:

Because sensor nodes have to be small and cheap, the processing and storage capacity of a node is very limited. Also, the radio front ends have to very simple,disallowing high bandwidth or complicated transmission schemes. This fits with intended application scenarios, where only occasionally small amounts of data are to be expected from a simple sensor, on the order of a few kbits/sec at most.

Energy is even more at a premium than in mobile *ad hoc* networks — it is just not acceptable to frequently change batteries of hundreds or thousands of deeply embedded devices; rather, applications demand lifetimes of months or better years on a very small battery. Hence, the entire construction of sensor networks is highly energy efficiency driven, also incorporating technologies like energy scavenging.

Sensor nodes might not necessarily have a unique address (e.g., a MAC identifier). What is more, the individual identity of such a sensor node is not even particularly important; rather, the *data* are.

As data are important, so is the location where data are sensed. For example, in a wildfire detection scenario, it is useless to know that temperature has exceeded a threshold without knowing where this happened.

Given the large numbers of sensor nodes in a sensor network, the simplest possible deployment is crucial — for a wildfire, sensor nodes should just be dropped from an airplane.

Interfacing a sensor network in a meaningful form to an outside network like the Internet is also important.

New Approaches in Sensor Networks

These challenges require some new approaches for communication in sensor networks. Some of the more important issues are outlined here.

Energy-efficient communication protocols: Already in *ad hoc* protocols, the issue of energy-efficient MAC, routing, and transport protocols has come up. In a sensor network, it is possible and useful to take the hardware and physical layer peculiarities as the driving force of protocol and algorithm design. On the other hand, the application characteristics in sensor networks are very different from traditional networks, which also affects the design of communication protocols.

An additional perspective to consider is the low data rates that are generated by a sensor node. For a MAC layer, this means that most of the time should be spent in a sleep mode as even just sensing the channel for an incoming transmission is quite energy-intensive. The most elegant solution would be a so-called wake-up radio, where only a primitive receiver is used that can detect the presence of a signal but is unable to actually decode it. Upon signal detection, the wake-up receiver would power up the more complicated and more power-hungry main receiver to perform the actual reception.

Using more conventional receiver architectures, CSMA schemes can be designed to support such low data rates. Alternatively, sleeping cycles between neighboring nodes could be synchronized (somewhat

© 2005 by CRC Press LLC

akin to TDMA schemes) as, for example, proposed in the S-MAC protocol; a combined TDMA/FDMA approach with similar goals is described in [10].

Also, on higher layers, in particular routing, energy efficiency is a driving force. For example, when selecting the route to be taken between source and destination, it stands to reason to choose nodes that currently have a high-energy supply. Work in this area abounds and is summarized in survey papers (e.g., [1]).

Data-centric communication: More specific to sensor networks is a change in paradigm. The interaction patterns are likely to differ from traditional networks: there will be a large amount of short request/reply-type communication, possibly with periodic replies initiated by a single request ("provide sensor reading every one second for the next five minutes"); "file-transfer"-like communications will not take place. Moreover, it should be possible to address the data, not the individual nodes; requests like "Is the temperature anywhere larger than 100° C?" or "Give me the temperature in the living room" are desirable communication primitives. Bearing in mind the required energy efficiency, specific communication protocols are necessary.

These requirements make the communication data-centric rather than node-centric like in traditional networks. One possible programming paradigm to support such data-centric communication is publish/subscribe: a node could publish its *interests* [5] in certain types of events (e.g., a temperature threshold is exceeded). This interest is distributed in the network, and sensor nodes with matching data can subscribe to these interests, providing the relevant information. One option how to implement this programming paradigm is the "directed diffusion" approach, where paths in the network are reinforced implicitly by data traveling toward the interested party. However, setting up such interest structures is a comparatively expensive undertaking; hence, the invested energy must be amortized over many replies.

Data-centric protocols can also be implemented in forms other than directed diffusion, for example, the rumor routing approach can be regarded as one such possibility.

Determining location: For many sensor applications, each sensor needs to know its own location to support correct application semantics or to leverage location information to support protocol operation like routing. This location information must be generated with very simple means: neither is it feasible to explicitly provide the location to a sensor during installation (think of deployment from an aircraft) nor is expensive and bulky location equipment like Global Positioning System (GPS) acceptable. Hence, the location of sensor nodes must be determined by the sensor network itself.

Without any sensor node having access to an absolute location, evidently only location in a relative coordinate system can be determined. Alternatively, a few of the sensor nodes could know their absolute position; these nodes can be used to translate such a relative coordinate system into an absolute one. In either case, the relative location of sensor nodes has to be determined. The basic options here are to use the signal attenuation between a sender and a receiver, which can serve as a rough indicator of distance; the time when signals arrives or the offset in time of two different signal times generated at the same time (e.g., a sender could transmit both a radio and an ultrasonic impulse and the receiver measures the time difference of their arrival), or information about the direction from which signals are received. Each of these options has pros and cons; the differential method using two types of signals tends to have the best accuracy but also requires the largest hardware overhead.

Irrespective of what method to estimate distance and angles between sensor nodes is used, this information will always be inaccurate. Algorithms are required that take this information and compute a most likely estimate for the true locations of all sensor nodes. Several such algorithms exist, but no final solution is available here as all algorithms suffer from different kinds of trade-offs.

A good overview paper on this topic is [4].

Trading off communication and computation — Aggregation: Unlike common sensor systems so far, a wireless sensor network can perform computation inside the network. Compared with wireless communication, computation (on usual hardware platforms) is relatively cheap in power consumption. An evident consideration is therefore how to best trade off communication against some additional computation in the network.

One obvious possibility is to suppress duplicate information to be forwarded to the same receiver. More generally, more or less arbitrary aggregation functions can be usefully computed in sensor

© 2005 by CRC Press LLC

networks, for example, averaging or counting functions. Such aggregation is even more useful since the reading of any one individual sensor is usually not of utmost importance or might not even be very reliable as sensor nodes, to be cheap, can only rely on low-quality sensors. More typically, a user would be interested in obtaining an overview of a large area and the "average" situation could be more relevant. How to best choose protocols and aggregation functions, in particular in the presence of node and link failures and the need to be energy-efficient, is still an active research area.

Summary

Wireless sensor networks can be regarded as a specific form of *ad hoc* networks. The stringent miniaturization and cost requirements make economic usage of energy and computational power an even bigger issue than in normal *ad hoc* networks. Moreover, specific applications require a rethinking of some of the basic paradigms with which communication protocols are engineered.

As wireless sensor networks are still a young research field, much activity is still on-going to solve many open issues. As some of the underlying hardware problems, especially with respect to the energy supply and miniaturization, are not yet completely solved, wireless sensor networks are at the time of this writing not yet ready for practical deployment. Nevertheless, these problems could be resolved in the near future.

Perhaps the most pressing conceptual problem is the handling of mobility. In a sensor network, three types of mobility can be distinguished: the sensor nodes themselves can move; an observed phenomenom can move, for example, an intruder in a surveillance application, and the requester of information from a sensor network. None of these mobility types is satisfactorily handled by today's sensor network protocols; the current research results here are still just a first step.

36.7 Further Issues in *Ad Hoc* Networks

Besides the main problems for *ad hoc* networks discussed in the previous sections, there are some additional issues that deserve brief mentioning.

Service discovery: Finding a node that offers a specific service rather than finding a specific node directly can be a handy faculty to solve several problems. For example, when trying to connect an *ad hoc* network to a fixed network, the *ad hoc* routing protocol has to first discover which node(s) offer the service of forwarding a packet onto the fixed network. General service discovery approaches are, in principle, applicable to *ad hoc* networks as well, but are likely to suffer performance degradation. Some initial work on integrating service discovery protocols into *ad hoc* routing protocols exists, but is not yet completed.

Frequency assignment: A key technique in cellular systems is the spatial reuse of spectrum: a given frequency band is used within a cell, neighboring cells use different bands, and a frequency is reused in cells sufficiently far away. This way, terminals/cells do not interfere with each other and multiple transmissions can occur in parallel.

In *ad hoc* networks discussed so far, only a single frequency band is in use, making simultaneous transmissions and hence an efficient forwarding impossible. Using multiple frequencies also in an *ad hoc* network to enable spatial reuse would help to overcome this problem. However, the problem here is more complicated than in cellular networks as terminals would have to listen on one frequency band and to transmit on another one. This requires careful orchestration of switching between frequencies and choosing the times of sending and receiving.

Clearly, a fixed assignment of frequencies to areas is not a good fit with *ad hoc* networks. Rather, a distributed way of choosing frequencies is necessary; the specific challenge is to ensure that a terminal receives at the right moment on the right frequency. There are several "multi-channel" link layers for *ad hoc* networks that try to solve this problem. Alternative approaches do not try to solve the frequency assignment on a per-link basis, but group terminals together in clusters and perform frequency assignments on the basis of such clusters of terminals (of course, membership in such a cluster is dynamic if terminals move around).

© 2005 by CRC Press LLC

In practice, dynamic frequency assignment is not widely deployed. Even for conventional wireless LAN systems, automatic frequency selection is not common practice; the frequency has to be selected manually for each access point.

Multicasting in ad hoc networks: So far, only unicast communication has been considered: a source sending data to a sink. Sometimes, a source intends to deliver data to all reachable terminals (broadcasting) or to an explicitly determined group of terminals (multicasting). An example for broadcasting has already appeared in Section 36.5 on sensor networks, when one terminal distributes its interest in a set of data to all other nodes. Such a broadcast can easily be implemented by flooding: every terminal repeats a received packet (but makes sure that it is only repeated once).

Multicasting is a bigger challenge and several options exist (the classification here follows [12]). Only those terminals repeat a packet that are on a shortest path from the sender to any one of the destinations (for multiple shortest paths, choose the smallest subset of repeaters such that each destination is served). This is equivalent to constructing a tree for this multicast that is rooted in the sender. Constructing such trees can be complicated, depending on the precise requirements; also, maintaining separate trees for each multicast group can result in scalability problems.

An alternative is not to source these trees individually in each sender, but to use only a single tree for all multicast groups. As this tree is rooted at a designated node in the network core (not necessarily in a sender), these approaches are called *core-based tree.* The advantage is the reduced maintenance overhead; the main disadvantages are the introduction of a single point of failure — the core node — and a concentration of traffic on the shared links around the core node. In this sense, these approaches are not ideal for *ad hoc* networks. A popular example is an AODV extension supporting multicast.

Multicasting can also be implemented without trees. An alternative distribution structure is to "overlay" a mesh over the *ad hoc* network and forward data along the mesh lines. The main difference to a tree and both advantage and disadvantage is the existence of multiple paths in such a mesh. It introduces resilience to faults, but also the danger of routing loops.

In sensor networks, also convergecast is relevant: collecting data from multiple senders in a single receiver. Convergecast is usually combined with aggregation of data and is discussed in Section 36.5.

Security: Security for and in *ad hoc* networks is of course faced with the common tasks of security in communication networks. But now, the network infrastructure itself can no longer be trusted and new, additional security problems appear. For example, a node could claim that it forwards all routing signaling messages correctly, but actually acts as a "black hole." Moreover, it becomes necessary to provide and police incentives for nodes to play fair: a node that makes use of other nodes forwarding data on its behalf but never reciprocates should perhaps be excluded from the *ad hoc* network. It becomes necessary to protect against malice and selfishness in the network itself. Zhou and Haas [13] give an overview of some security problems in *ad hoc* networks.

Quality of service: A wireless mobile *ad hoc* network, by its very structure, is a collection of uncertainties: the wireless channel is error-prone, medium access is stochastic or deterministic only with high overhead, routing is constantly endangered by terminals moving around, etc. All these peculiarities make it difficult to provide Quality of Service in its stringent interpretation. Even guarantees on simple connectivity is a difficult problem. Nevertheless, more modest approaches to Quality of Service are, of course, possible even in *ad hoc* networks, such as service differentiation between classes. Moreover, hybrid approaches are conceivable where Quality-of-Service-sensitive data are transported via a cellular infrastructure as far as possible, but best-effort traffic can use *ad hoc* mechanisms, taking advantage of increased capacity and energy efficiency.

These limitations have to be weighted against the advantages of *ad hoc* networks in general. Whether the service rendered by an *ad hoc* network is of sufficient quality largely depends on the application that is to be supported.

Implementations: When trying to build *ad hoc* networks, common communication hardware can be used. IEEE 802.11 systems are by nature of the protocol suited for use in *ad hoc* networks (with the many caveats already mentioned); Bluetooth devices can also be coerced into working as *ad hoc* networks (called "scatternets"), although the master/slave structure of Bluetooth is not really amenable for this purpose.

© 2005 by CRC Press LLC

With respect to practically available protocol implementations, a lot depends on the operating system to be used. For Microsoft Windows, especially Windows CE, only a limited number of implementations are available. The lion's share of academic implementation and experimental work is done using Linux, for which consequently many implementations are available as public domain software. Commercially implemented solutions are not relevant at this time.

For sensor networks, special-purpose operating systems from academic institutions, for example, TinyOS, are currently most relevant.

36.8 Conclusions

Ad hoc and sensor networks open the door to new types of applications. The spontaneous, *ad hoc* deployment of mobile terminals, the self-configuration of the network as a whole are considerable advantages. These networks can be built using readily available communication equipment; implementations for most of the necessary protocols are available at least as a prototype.

These prototypes rest on a large amount of theoretical research. Much understanding regarding the dynamics of *ad hoc* networks in different circumstances has already been gained. This work shows that *ad hoc* networks can be expected to work fine as long as the requirements on them are modest: the load should be low and Quality of Service requirements should not be too tight.

Nonetheless, these investigations also show that there is still quite a bit of counterproductive interaction between protocol layers that is difficult to understand and to forecast. Final solutions for *ad hoc* networking protocols that work perfectly in all conceivable circumstances are not yet available; the application scenario's requirements — the load or mobility to be supported, acceptable delays, and outage ratios — still determine the choice of, for example, link layer, routing, or transport protocols to be used in an *ad hoc* network. Moreover, there is still only limited experience with *ad hoc* networks outside of research laboratories available. In particular, experience with large-scale deployments is still rather limited.

Ad hoc and sensor networking will be a substantial part of networking in the future. It is starting today with limited application fields, and it will expand more and more as the remaining conceptual problems are being solved.

37.1 Introduction

In packet-switched networks, the lower layers (data link layer, medium access control layer, and physical layer) have to solve some fundamental tasks in order to facilitate successful communication. The lower layers are concerned with communication between neighbored stations, as compared to the layers above (networking layer, transport layer), which are concerned with end-to-end communications over multiple intermediate stations.

The lower layers therefore communicate over *physical channels* and are thus most strongly influenced by physical channel properties (bandwidth, channel errors, etc.), which in turn affect their design. The importance of the lower layers for industrial communication systems is related to the often found requirement for giving *hard real-time and reliability guarantees*: if the lower layers could not guarantee successful delivery of a packet/frame within a prescribed amount of time, this cannot be compensated by any actions of the upper layers. Therefore, a wide variety of mechanisms has been developed to implement these guarantees and to deal with harmful physical channel properties like transmission errors.

In virtually all data communication networks used in industrial applications, the transmission is *packet-based,* that is, the user data is segmented into a number of distinct *packets* or *frames* and these frames are transmitted over the channel. Therefore, the following fundamental problems have to be solved:

What constitutes packet and how are the bounds of a packet specified? How does the receiver detect packets and the data contained in a packet? To this end, *framing and synchronization schemes* are needed, discussed in Section 37.2.

© 2005 by CRC Press LLC

When to transmit a packet? If multiple stations want to transmit their packets over a common channel, appropriate rules are needed to share the channel and to let each station determine when it may send its packets. This problem is tackled by *medium access control* (MAC) protocols, discussed in Section 37.3.

How to cope with channel errors? The topic of *error control* is briefly touched in Section 37.4.

Which packet to transmit next? This is the problem of *packet scheduling.*

How to protect the receiver against too much data sent by the transmitter? This is the problem of *flow control.*

This chapter surveys framing and synchronization, MAC protocols and error control in some detail in the following sections. Some references discussing packet scheduling algorithms are [57, 59–61, 58, Chapter 9]. Flow control algorithms are explained in [20].

37.2 Framing and Synchronization

The problem of synchronization is related to the transmission of information units (packets, frames) between a sending and a receiving entity. In computer systems, information is usually stored and processed in a binary digital form (bits). A *packet* is formed from a group of bits and shall be transmitted to the receiver. The receiver must be able to uniquely determine the start and end of a packet as well as the bits within the packet.

The transmission of information over short distances, for instance, inside the computer, can be done with parallel transmission. Here, a number (say, 64) of parallel copper wires transport all bits of a 64-bit data word at the same time. In most cases, one additional wire transmits the common reference clock. Whenever the transmitter has applied the correct voltage (representing a "0" or "1" bit) on all wires, it signals this by sending a sampling pulse on the clock wire toward the receiver. Conversely, on receiving a pulse on the clock wire, the receiver samples the voltage levels on all data wires and converts them back to bits by comparing them with a threshold.

This kind of transmission is fast and simple, but cannot span large distances, because the cabling cost becomes prohibitive. Therefore, the data words have to be *serialized* and transmitted bit-by-bit on a single wire.[1]

Bit Synchronization

The spacing of bits generated by the transmitter depends on its local clock. The receiver needs this clock information to sample the incoming signal at appropriate points in time. Unfortunately, the transmitters and receivers clocks are not synchronized, and the synchronization information has to be recovered from the data signal; the receiver has to *synchronize* with the transmitter. This process is called *bit synchronization.* The aim is to let the receiver sample the received signal in the middle of the bit period in order to be robust against the impairments of the physical layer, like bandwidth limitation and signal distortions. Bit synchronization is called *asynchronous* if the clocks are synchronized only for one data word and have to be resynchronized for the next word. One common mechanism used for this uses one *start bit* preceding the data word and one or more *stop bits* concluding it. The Universal Asynchronous Receiver/Transmitter (UART) specification defines one additional parity bit that is added to the 8 data bits, leading to the transmission of 11 bits in total for every 8 data bits [3]. The upper row in Figure 37.2 illustrates this.

For longer streams of information bits, it is necessary to synchronize the receiver clock continuously. The Digital Phase-Locked Loop (DPLL) is an electrical circuit that controls a local clock and adjusts it to the received clock that is extracted from the incoming signal [20]. To recover the clock from the signal, sufficiently frequent changes of signal levels are needed. Otherwise, if the wire shows the same signal level for a long time (as may happen for the *Non-Return to Zero* (NRZ) coding method, where bits are directly

[1]The term wire is actually used here as a synonym for a transmission channel. Therefore, it could also be a wireless or ISDN channel.

© 2005 by CRC Press LLC

mapped to voltage levels), the receiver clock could drift away from the transmitter clock. The Manchester encoding that is shown in the second row of Figure 37.1 ensures that there is at least one signal change per bit. Every logical "1" is represented by a signal change from one to zero, while a logical "0" shows the opposite signal change. The internal clock of the DPLL samples the incoming signal with a much higher frequency, for instance, 16 times per bit. For a logical "0" bit that is arriving exactly in time, the DPLL receives a sample pattern of 0000000011111111. If the transition between the "0" and "1" samples is not

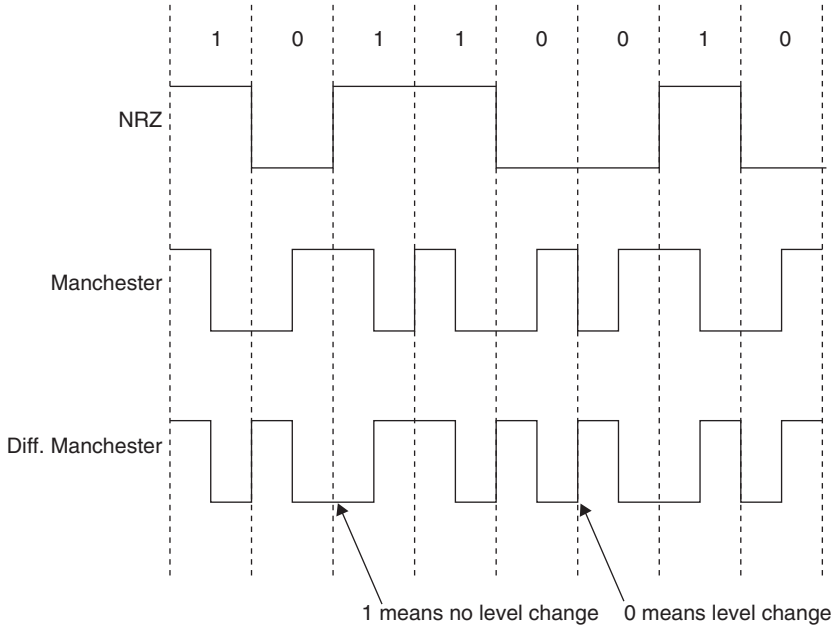

FIGURE 37.1 NRZ, Manchester, and differential Manchester codes.

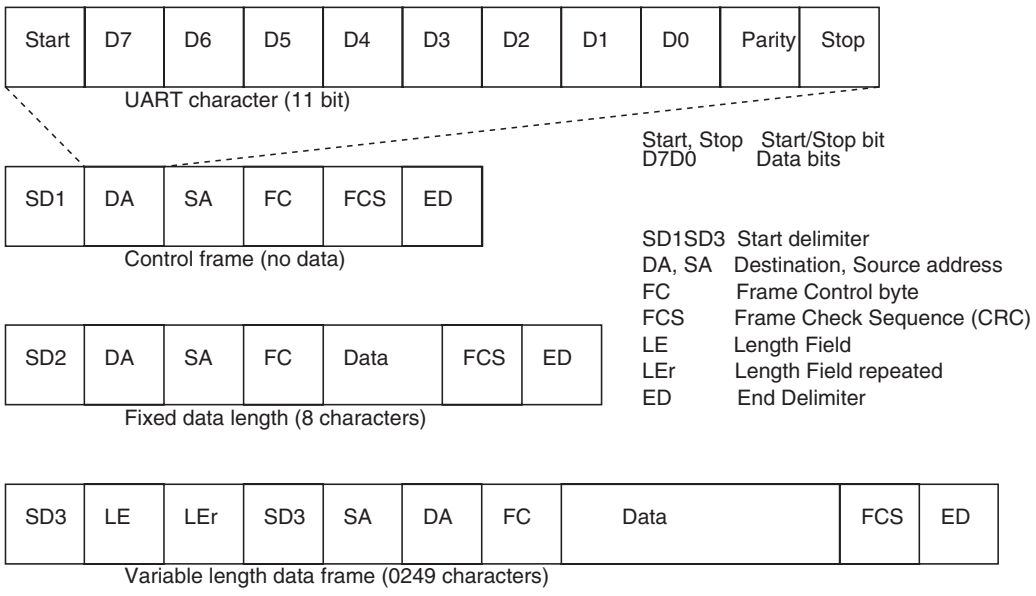

FIGURE 37.2 DIN 19245 Profibus: character and selected frame formats.

© 2005 by CRC Press LLC

exactly in the middle of the bit, but rather left or right of it, the local clock has to be re-adjusted to run faster or slower, respectively. In the classical IEEE 802.3 Ethernet, the bits are Manchester encoded [2]. To allow the DPLL of the receiver to synchronize to the received bit stream, a 64-bit long *preamble* is transmitted ahead of each frame. This preamble consists of alternating "0" and "1" bits that result in a square wave of 5 MHz. A start of frame delimiter of two consecutive "1" bits marks the end of the preamble and the beginning of the data frame.

Frame Synchronization

It is of interest for the receiver to know if the received information was (a) complete and (b) correct. Section 37.4 treats the latter problem in some more detail. To decide about the first problem, the receiver needs to know where a packet starts and ends. The question that arises immediately is that of marking the start and the end of a frame. There are several ways to accomplish this. In real-world protocols, one often finds combinations of them. In the following, the most important will be discussed briefly:

Time Gaps

The most straightforward way to distinguish between frames is to leave certain gaps of silence between them. However, specifically if the medium is shared between several stations, all of them have to obey these time gaps. As it will be seen in CSMA Protocols section, several MAC protocols rely on minimum time gaps to determine if the medium is accessible.

While time gaps are a simple way to detect the start of a frame it should be possible to detect the end of it, too. Using time gaps, the end of the previous packet can be detected only after a period of silence. Even if the receiver detects a silent medium, it cannot be sure if this is the result of a successful transmission or a link or node failure. Therefore, other ways have to be explored.

Code Violations

A bit is usually encoded by a certain signal pattern (e.g., a change in voltage or current levels) that is, of course, different for a "0" and "1" bit. A signal pattern that represents neither of the allowed values can be taken as a marker for the start of a frame. An example for this is the IEEE 802.5 token ring protocol [23], which uses the differential Manchester encoding (see Figure 37.1 and [23]). Here, two special symbols "J" for a so-called positive code violation and "K" for a negative one appear. In contrast to the bit definitions in the encoding, these special symbols do not show a transition in the middle of the bit. Special 8-bit long characters that mark the beginning and end of the frame are constructed from these symbols.

Start/End Flags

Some protocols use special *flags* to indicate the frame boundaries. A sequence of 01111110, that is, six "1" bits in a sequence, marks the beginning and the end of each frame. Of course, since the payload that is being transmitted can be an arbitrary sequence of bits, it is possible that the flag is contained in the payload. To avoid the misinterpretation of a piece of payload data as being the end of a frame, the sender has to make sure that it only transmits the flag pattern if it is meant as a flag. Any flag-like data have to be altered in a consistent way to allow the receiver to recover the original payload. This can be done using *bit* or *byte(character) stuffing* techniques.

Bit stuffing, as it is done in High-level Data Link Control (HDLC) [20], means for the sender to insert a zero bit after each sequence of 5 consecutive "1" bits. The receiver checks if the sixth bit that follows the five ones is a zero or one bit. If it detects a zero, it removes it from the sequence of bits. If it detects a "1," it can be sure that this is a frame boundary. Unfortunately, it might happen that a transmission error modifies the data sequence 01111100 into 01111110 and thus creates a flag prematurily. Therefore, additional mechanisms like time gaps are needed to remove the following bits and detect the actual end of the frame.

Byte stuffing as in Point-to-Point Protocol (PPP) uses the same flag pattern, but relies on a byte-oriented transmission medium [5, 6]. Thus, the flag can be written as a hexadecimal value 0x7E. Every unintentional appearance of the flag pattern is replaced by two characters, 0x7D 0x5E. This way the flag character disappears, but the 0x7D (also called *escape character)* also has to be replaced, if it is found in

© 2005 by CRC Press LLC

the user data. To this end, 0x7D is replaced by 0x7D 0x5D. The receiver, after detecting the escape character in the byte stream, discards this byte and performs an XOR operation of 0x20 with the following byte to recover the original payload.

In both cases, more data are being transmitted than it would be necessary without bit or byte stuffing techniques. To make things worse, the amount of overhead that has to be added depends on the contents of the payload. A malicious user might effectively double the data rate (with byte stuffing) or increase it by around 20% (with bit stuffing) by transmitting a continuous stream of flags. To avoid this, several measures can be taken. One is to *scramble* the user data before it is put into data frames [4].

Another possibility is the so-called consistent overhead byte stuffing (COBS), proposed in [1]. Here, the stream of data bytes is scanned in advance for appearing flags. The sequence of data bytes is then cut into chunks of at most 254 bytes *not* containing the flag. Thus, every flag that appears in the flow is replaced by one byte representing the number of nonflag data bytes following it. This way, no additional data are to be transmitted as long as there is at least one flag every 255 data bytes. Otherwise, one byte is inserted every 254 bytes, indicating a full-length chunk.

Length Field

To avoid the processing overhead that comes with bit or character stuffing, it is possible to reserve a field in the header of the frame that indicates the length of the whole frame. Having read this field, the receiver knows in advance how many characters or bytes will arrive. No end delimiter is needed anymore. Either a continuous transmission of packets followed by idle symbols or the usual combination of preamble and start delimiter is needed to correctly determine which of the header fields carries the length information.

Being potentially the best solution concerning transmission overhead, the length field mechanism suffers from erroneous transmission media. If the packet length information is lost or corrupted, then it is difficult to find it again. Therefore, it has to be protected separately using error-correcting codes or redundant transmission. Additional mechanisms (e.g., time gaps) should be used to find the end of a frame even when the length field is erroneous.

Example: Bit and Frame Synchronization in the Profibus

As an example to illustrate the mechanisms introduced above, let us look at the lower layers of the DIN 19245 PROcess FIeld BUS (Profibus) [42]. This standard defines a field bus system for industrial applications. The lowest layer, the *physical layer,* is based on the RS-485 electrical interface. A shielded twisted pair or fiber cable may be used as a transmission medium. The UART converts every byte into 11-bit transmission characters by adding start, parity, and stop bits. Thus, asynchronous bit synchronization is used on the lowest layer of the Profibus, no matter which transmission medium is being used.

The second layer is called Fieldbus Data Link (FDL). It defines the frame format as it can be seen in Figure 37.2. Start and end delimiters are used in every frame, but different SDx (SD1–SD4; the latter is not shown in the figure) define different frame types. Thus, a receiver knows after reading an SD1 that a control frame of fixed length will arrive. In addition, time gaps of 33 bit times have to be left between the frames. After receiving an SD3, the receiver interprets the next byte as LE (length field) and checks this against the redundant transmission of LE in the third byte, thereby decreasing the probability of undetected errors in the length field. Using the combination of time gaps and the redundant transmission of the length field, a character stuffing to replace all possible start and end delimiters in the payload becomes unnecessary.

37.3 Medium Access Control Protocols

All *medium access control* or *MAC* protocols try to solve the same problem: to let a number of stations share a common resource (namely, the transmission medium) in an efficient manner and such that some desired performance objectives are met. They are a vital part of local area network (LAN) and metropolitan area network (MAN) technologies, which typically connect a small to moderate number of users in a small geographical area such that a user can communicate with other users.

© 2005 by CRC Press LLC

With respect to the OSI reference model, the MAC layer does not form a protocol layer of its own, but is a sublayer of either the physical layer or the data link layer [35]. However, in the following, we will consider the MAC as being a layer of its own, since it has a distinguished task. The importance of the MAC layer is reflected by the fact that many MAC protocol standards exist, for example, the IEEE 802.x standards. Its most fundamental task is to determine for each station attached to a common broadcast medium when it is allowed to access the medium, that is, to send data or control frame to it. To this end, each station executes a separate instance of a MAC protocol.

The operation and behavior of a MAC protocol are heavily influenced by the properties of the underlying physical layer and the design goals. Specifically for hard real-time communications, the MAC layer is a key component: if the delays on the MAC layer are not strictly bounded, the upper layers cannot compensate this. A large number of MAC protocols have been developed during the last three decades. The following references are landmark papers or survey articles covering the most important protocols: [7, 8, 26, 27, 37, 43, 38, 19, 32, 33, 39, 40, 15]. Furthermore, MAC protocols are covered in many textbooks on computer networking, for example, [35, 12, 20]. In this survey, we restrict to those classes of protocols that are important for industrial applications and have found some deployment in factory plants, either as stand-alone protocols or as building blocks of more complex protocols.

Requirements and Quality of Service Measures

There are a number of (sometimes conflicting) requirements for MAC protocols, some of which are specific for industrial applications with hard real-time and reliability constraints.

There are two main *delay-oriented measures*: the *medium access delay* and the *transmission delay.* The medium access delay is the time between the arrival of a frame and the time its transmission starts. This time is affected by the operational overhead of the MAC itself, like collisions, MAC control frames, backoff and waiting times, etc. The transmission delay denotes the time between frame arrival and its successful reception at its intended receiver. Clearly, the medium access delay is a fraction of the transmission delay. For industrial applications with hard real-time requirements, both delays must be upper-bounded. In addition, a desirable property is to have low medium access delays in case of low network loads.

A key requirement for industrial applications is the support for *priorities:* important frames (e.g., alarms, periodic process data) should be transmitted before unimportant ones. This requirement can be posed *locally* or *globally*: in the local case, each station decides independently as to which of its frames is transmitted next. There is no guarantee that station *A*'s important frames are not blocked by another station *B*'s unimportant frames. In the global case, the protocol identifies the most important frame of all stations to be transmitted next.

The need to share bandwidth between stations constitutes another important class of desired MAC properties. A frequently posed requirement is *fairness*: stations should get their "fair share" of the bandwidth, which, for example, can be defined as the minimum of a stations load and the overall bandwidth divided by the number of stations. It is also often required that a station receives a *minimum bandwidth,* like for the transmission of periodic process data of fixed size.

With respect to *throughput* clearly, it is important to keep the MAC overhead low. This concerns the frame formats, the number and frequency of MAC control frames, and efficiency losses due to the operation of the MAC protocol. An example for efficiency losses is when the protocol allows collisions: the bandwidth spent for collided packets is lost, since typically the collided frames are useless and must be retransmitted, which is costly in terms of bandwidth. A MAC protocol is said to be *stable* if an increase in the overall load does not lead to a decrease in throughput.

Depending on the application area, other constraints can be important as well. For simple field devices, the MAC implementation should have a low complexity and be simple enough to be implemented in hardware. For mobile stations using wireless media, the energy consumption is a major concern; the MAC should contain different power-saving mechanisms. For wireless transmission media, the MAC should contain additional mechanisms to adapt to the instantaneous error behavior of the wireless channel; possible control knobs are the transmit power, error correcting codes, the bit rate, etc.

Design Factors

The most important factors influencing the design of MAC protocols are the medium properties/medium topology and the available feedback from the medium.

We can broadly distinguish between *guided media* and *unguided media.* In guided media, the signals originating from frame transmissions propagate within specified geographical bounds, typically within copper or fiber cables. If the medium is properly shielded, then beyond these bounds the communications are invisible, and two cables can be placed close to each other without mutual interference. In contrast, in unguided media (with radio-frequency or infrared wireless media being the prime example), the wave propagation is visible in the whole geographical vicinity of the transmitter, and ongoing transmissions can be received at any point close enough to the transmitter. Therefore, two different networks overlayed within the same geographical region can influence each other.

Guided media networks can show a number of topologies. We discuss a few examples. In a *ring topology* (see Figure 37.3) each station has a point-to-point-link to two neighbors, such that the stations form a ring. In a *bus topology* like the one shown in Figure 37.4, the stations are connected to a common bus, and all stations see the same signals. Hence, the bus is a *broadcast medium.* In the *star topology* illustrated in Figure 37.5, all stations only have a physical connection to a central device, the *star coupler,* which repeats and optionally amplifies the signals coming from one line to all the other lines. A network with a star topology also provides a broadcast medium, where each station can hear all transmissions. When using wireless transmission media, the distance between stations might be too large to allow all stations to receive all transmissions. Therefore, the network is often only partially connected or has a *partial mesh structure,* shown in Figure 37.6. Additional mechanisms have to be employed to implement *multi-hop transmission.*

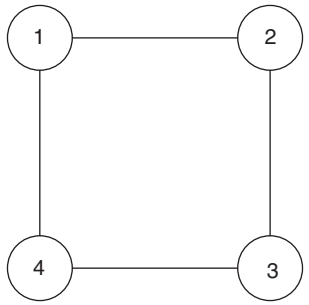

FIGURE 37.3 Ring topology.

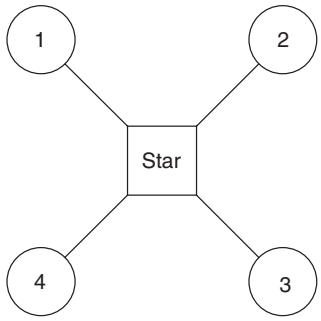

FIGURE 37.5 Star topology.

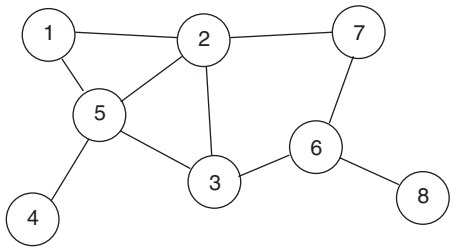

FIGURE 37.6 Partial mesh topology.

An important property of a physical channel is the available feedback. Specifically, some kinds of media allow a station to read back data from the channel while transmitting. This can be done to detect faulty transceivers (like in the PROFIBUS protocol [42]), collisions (like in the Ethernet protocol), or parallel ongoing transmissions of higher priority (like in the CAN protocol). This feature is typically not found in wireless channels. Here, it is not possible to send and receive simultaneously on the same channel.

Random Access Protocols

In random access (RA) protocols, the stations are uncoordinated and the protocols operate in a fully distributed manner. RA protocols often incorporate a random element, for example, by exploiting random packet arrival times, setting timers to random values, etc. The lack of central coordination and of fixed resource assignment allows to share a channel potentially between an infinite number of stations, while fixed assignment and polling protocols support only a finite number of stations. However, the randomness can make it impossible to give deterministic guarantees on medium access delays and transmission delays. There are many RA protocols, which are not only used on their own but also as building blocks of more complex protocols.

ALOHA and Slotted ALOHA

A classical protocol is ALOHA [7], where a station sends a newly arriving data frame immediately without inquiring the status of the transmission medium. Hence, frames from multiple stations can overlap in time (collisions), which may make them unrecognizable. In *slotted ALOHA,* all stations are synchronized to a common time reference and the time is divided into fixed-sized *slots.* In slotted ALOHA, newly arriving frames are sent at the beginning of the next time slot. In both cases, the transmitter starts a timer after frame transmission. The receiver has to send an immediate acknowledgement frame upon successful reception of the data frame. When the transmitter receives the ack, it stops the timer and considers the frame as successfully transmitted. If the timer expires, the transmitter randomly selects a *backoff time,* which has to expire before it attempts to transmit the frame again. The backoff time is chosen randomly to avoid synchronization of colliding stations. This protocol has two advantages: it is extremely simple and it offers short delays

© 2005 by CRC Press LLC

in case of a low network load. However, the protocol does not support priorities and with increasing network load the collision rate increases and the transmission delays grow as well. In addition, ALOHA is not *stable:* above a certain threshold load, an increase in the overall load leads to a *decrease* in overall throughput. The maximum normalized throughput of pure ALOHA is $1/2e \approx 18.4\%$ under Poisson arrivals and an infinite number of stations. The maximum throughput can be doubled with slotted ALOHA. A critical parameter in ALOHA is the backoff time, which is typically chosen from a certain time interval *(backoff window).* A collision can be interpreted as a sign of congestion. If after the backoff time another collision occurs, the next backoff time should be chosen from a larger backoff window to reduce the pressure on the channel. A popular rule for the evolution of the backoff window is the *truncated binary exponential backoff scheme,* where the backoff window size is doubled after each collision, up to a certain threshold, after which the window stays constant. After successful transmission, the backoff window is restored to its original value.

CSMA Protocols

In carrier sense multiple access (CSMA), the stations act more careful than in ALOHA: before transmitting a frame they listen on the medium (carrier sensing) to see whether it is busy or free [39, 36]. If the medium is free (many protocols require it to be contiguously free for some minimum amount of time), the station transmits its frame. If the medium is busy, the station defers transmission. The steps following this distinguish the protocols.

In *nonpersistent CSMA,* the station simply defers for a random time (backoff time) without listening to the medium during this time. All other protocols discussed next wait until the end of the ongoing transmission before starting further activities.

In p-persistent CSMA ($0 < p < 1$), the time after the preceding transmission ends is divided into time slots. A station listens to the medium at the beginning of a slot. If the medium is free, the station starts transmitting its frame with a probability p and with probability $1 - p$ it waits until the next slot. In 1-persistent CSMA, the station transmits immediately without further actions. Both approaches still have the risk of collisions, if two or more stations decide to transmit (1-persistent CSMA) or choose the same slot (p-persistent CSMA). The problem is as follows: if one station A senses the medium idle and starts transmission at time τ_0, another station B would notice this earliest at some later time $\tau_0 + \tau$, due to the propagation delay. If B performs carrier sensing at a time between τ_0 and $\tau_0 + \tau$, it senses the medium idle and starts transmission, which results in a collision. Therefore, the collision probability depends on the propagation delay and thus on the maximum geographical distance between stations. As in ALOHA, in pure CSMA protocols the recognition of collisions needs acknowledgement frames.

Although the throughput of CSMA-based protocols is much better than that of ALOHA (ongoing transmissions can be completed without disturbance), the number of collisions and their duration limit the throughput. Collision detection and collision avoidance techniques can be used to relax these problems. These are discussed in the following sections.

Specifically for wireless media, the task of carrier sensing is not without problems, since it is the transmitter who senses the medium ultimately because he wants to know the state of the medium at the intended receiver (collisions are only important at the receiver). However, due to path loss [30, Chapter 4] the signal experiences attenuation with increasing distance. If a minimum signal strength is required, the *hidden terminal problem* occurs (please refer to Figure 37.7): consider three stations A, B, and C with transmission radii as indicated by the circles. Stations A and C are in the range of B, but A is not in the range of C and *vice versa*. If C starts to transmit to B, A cannot detect this by its carrier-sensing mechanism and considers the medium to be free. Hence, A also starts frame transmission and a collision occurs at B.

For wireless media, there is a second scenario where carrier sensing leads to false predictions about the channel state at the receiver: the so-called *exposed terminal scenario,* depicted in Figure 37.8. The four stations A, B, C, and D are placed such that the pairs A/B, B/C, and C/D can hear each other, and all remaining combinations cannot. Consider the situation where B transmits to A, and one short moment later C wants to transmit to D. Station C performs carrier sensing and senses the medium as being busy, due to B's transmission. As a result, C postpones its transmission. However, C could safely transmit its frame to D, without disturbing B's transmission to A. This leads to a loss of efficiency.

© 2005 by CRC Press LLC

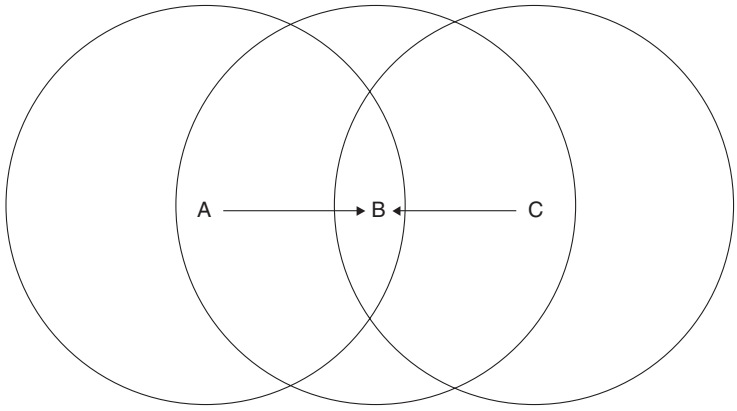

FIGURE 37.7 Hidden terminal scenario.

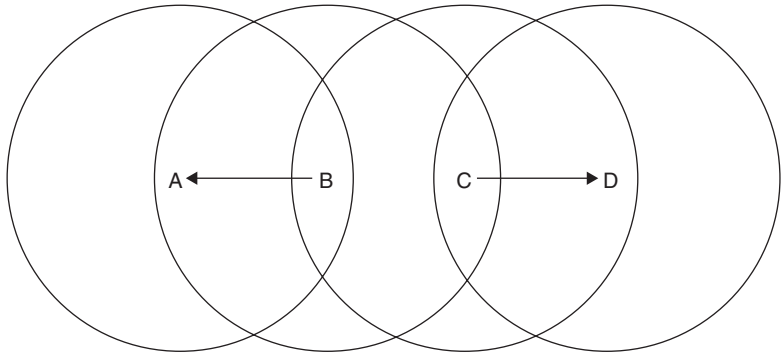

FIGURE 37.8 Exposed terminal scenario.

Two approaches to solve these problems are busy tone solutions [40] and the RTS/CTS protocol, as applied in the IEEE 802.11 wireless LAN medium access control (MAC) protocol [28]. In the busy tone approach, the receiver transmits a busy tone signal on a second channel during frame reception. Carrier sensing is performed on this second channel. This solves the exposed terminal problem. The hidden terminal scenario is also solved, except in the rare cases where A and C start their transmissions simultaneously.

The RTS/CTS protocol attacks the hidden terminal problem using only a single channel. Consider the case that A has a data frame for B. After A has obtained channel access, it sends a short request to send (RTS) frame to B, indicating the time duration needed for the whole frame exchange sequence. If B receives the RTS frame properly, it answers with a clear to send (CTS) frame, which indicates the time needed for the remaining frame exchange sequence. Station A starts transmission after receiving the CTS frame. Any other station C hearing the RTS and/or the CTS frames defers its transmissions for the indicated time, thus not disturbing the ongoing frame exchange. It is a conservative choice to defer on any of these frames, but the exposed terminal problem still exists. If a station C defers only on receiving both frames, the exposed terminal problem is solved. However, there is the risk of bit errors in the CTS frame, which may lead C to start transmissions falsely. The RTS/CTS protocol does not resolve collisions of RTS frames at the receiver; furthermore, it introduces significant overhead.

CSMA Protocols with Collision Detection

If two or more stations collide without recognizing this, they would transmit their entire frames, which, however, are not useful for the receiver. If the stations could detect and abort the collision within a shorter

© 2005 by CRC Press LLC

time than needed to transmit the longest frame, less bandwidth is wasted. The class of carrier sense multiple access with collision detection (CSMA/CD) protocols enhances the basic CSMA method with a collision detection facility. The collision detection is performed by hearing back the signal on the cable during transmission and to compare the measured signal with the transmitted one. If the signals differ, a collision has occured [20, Section 6.1.3].

When a station experiences a collision, it can perform a backoff scheme. This scheme works with slotted time, where a time slot is large enough to accommodate the maximum round-trip time to make sure that all stations have the chance to recognize an ongoing transmission reliably. As an example, in the CSMA/CD method of IEEE 802.3 a truncated binary exponential backoff scheme is used: after the first collision a station chooses to wait either 0 or 1 slots. If another station starts transmission during the waiting time, the station defers. After the second collision a station chooses to wait between 0 and 3 slots, and for all subsequent collision the backoff window is doubled. After ten collisions the backoff window is kept fixed to 1024 slots, and after 16 collisions the station gives up and discards the frame.

A stochastic form of priorities can be introduced to CSMA/CD by using different initial sizes or evolution speeds for backoff windows, as is done in [11] for the CSMA variant used in the IEEE 802.11 wireless LAN standard.

In wireless LANs (e.g., in the IEEE 802.11 wireless LAN), frequently acknowledgement frames are used to give the transmitter a feedback, since wireless transceivers cannot transmit and receive simultaneously. The lack of an acknowledgement frame indicates either a collision or a transmission error. Furthermore, two colliding frames do not necessarily result in a total loss of information: when the signal strength of one frame is much stronger than the other one, the receiver may be able to decode the frame (near–far effect).

CSMA Protocols with Collision Resolution

A class of CSMA protocols reacts on collisions not by going into a backoff mode and deferring transmissions; instead, they try to *resolve* the collision, that is, to determine one station among the contenders, which is ultimately allowed to send its frame. Some examples of this class are the adaptive tree walking protocol [13] and protocols with bit-wise priority arbitration like the MAC protocol of controller area network (CAN) [18] and the protocol used for the D-channel of ISDN [31].

The adaptive tree walking protocol works as follows: the time is slotted, just as in the Ethernet CSMA/CD protocol. Furthermore, all stations are arranged in a balanced binary tree $\mathcal{T}$ and know their respective positions in this tree. All stations wishing to transmit a frame (called backlogged stations) wait until the end of the ongoing transmission and start to transmit their frame in the first slot (slot 0). If there is only one backlogged station, then it could transmit its frame without further disturbance. If two or more stations collide, then in slot 1 only the members of the left subtree $\mathcal{T}_L$ are allowed to try transmission again. If another collision occurs, only stations of the left subtree $\mathcal{T}_{LL}$ of $\mathcal{T}_L$ are allowed to transmit in slot 2, and so forth. On the other hand, if only one station from $\mathcal{T}_L$ transmits its frame, then for fairness reasons the next frame transmission is reserved for a station from the right subtree $\mathcal{T}_R$.

The bit-wise arbitration protocols use a similar idea as the tree-walking protocol; however, they do not keep any history information that is needed to achieve fairness. As an example, we present the MAC protocol of CAN. As a prerequisite, the transmission medium guarantees that overlapping signals do not destroy each other, but lead to a valid signal. If two stations transmit the same bit, the medium adapts the common bit value. If one station transmits a zero bit and the other a one bit, the medium adopts a well-defined state, for example, a zero bit. The CAN protocol uses a *priority field* of a certain length at the beginning of a MAC frame. Backlogged stations wait until the end of an ongoing frame and then transmit the first bit of their priority field. In parallel, they read back the state of the medium and compare it with the sent bit. If both agree, the station continues with the second bit of the priority field. If the bits differ, the station has lost contention and defers until the end of the next frame. If it can be guaranteed that all stations use different priority fields, no collisions occur. This protocol supports global frame priorities in a natural way, and the medium access time for the highest priority frame is bounded. However, the assignment of priorities to stations or frames is a nontrivial issue. If the priorities are assigned fixed on a per-station basis, the protocol is inherently unfair. If fairness is desired, the priorities should change

© 2005 by CRC Press LLC

over time. Therefore, in CAN applications, the priorities are assigned depending on the type of the message. Another drawback of the protocol is that all stations have to be synchronized with the precision of a bit-time, and the need for all stations to agree on the state of the medium limits either the bit rate or the geographical extension of CAN.

CSMA Protocols with Collision Avoidance

If it is technically not feasible to Immediately detect collisions, one might try to avoid them. Protocols belonging to this class are called carrier sense multiple access with collision avoidance (CSMA/CA) protocols. An important application area are wireless LANs, where: (a) stations cannot transmit and receive simultaneously on the same channel, and (b) the transmitter cannot directly detect collisions at the receiver due to path loss and the need for a minimum signal strength (see the discussion of the hidden terminal scenario in CSMA Protocols section).

One CSMA/CA approach is the RTS/CTS handshake protocol used in the IEEE 802.11 WLAN; see CSMA Protocols section. Other protocols use additional random waiting times. As an example, in the EY/NPMA protocol of HIPERLAN [16], the collision avoidance part consists of three phases: all stations wishing to transmit a frame wait for the end of the ongoing transmission. In the first phase (priority phase), the stations wait for a number of slots corresponding to the frames priority; there are five distinct priorities. If a station A decides to transmit in slot n and another station B starts in slot $m < n$, then A defers, since B has a higher priority frame. In the second phase (elimination phase), the surviving stations transmit a burst of random length before switching to the receive mode. If there is still energy present, the station gives up, since another station sends a longer burst. In the following third phase (yield phase), the surviving stations remain idle for a random amount of time. If another station starts to transmit meanwhile, the station defers. Otherwise, the station starts to transmit its data frame.

Fixed Assignment Protocols

In fixed assignment (FA) protocols, a station is assigned a channel resource (frequency, time, code, space) exclusively, that is, it does not need to contend with other stations for using its share and obtains medium access within a bounded time.

In frequency division multiple access (FDMA) systems, the available spectrum is subdivided into N subchannels, with some guard band between the channels. A channel is assigned exclusively to a station. When a frame arrives, the station can transmit immediately on the assigned channel, the intended receiver has to know the channel in advance. Idle subchannels cannot be used by highly loaded stations.

In code division multiple access (CDMA) systems, the stations spread their frames over a much larger bandwidth than needed while using different codes to separate their transmissions. The receiver has to know the code used by the transmitter; all parallel transmissions using other codes appear as noise. Like in FDMA, stations can transmit incoming frames immediately.

In time division multiple access (TDMA) systems, the time is divided into fixed-length *superframes,* which in turn are divided into *time slots.* Each station is assigned a set of slots in every superframe. During its slots, a station can use the full channel bandwidth. The stations need to be synchronized on slot boundaries; however, the slots contain some *guard times* to compensate for inaccurate synchronization. In a centralized setting where all stations transmit to a central station, such inaccuracies can be introduced by different propagation delays and the problems to determine the exact distance between a station and the central station.

In space division multiple access (SDMA) systems, spatial resources are divided among stations. In wireless systems where a central station is equipped with smart antenna arrays, the central station can form a number of spatially directed spot beams and focuses them to the stations. If a beam covers two or more stations, these have to share the channel by some other protocol; but stations in different beams can transmit in parallel. Another example is the use of sectored antennas in cellular systems.

In all these schemes, the allocation of channel resources to stations can be static or dynamic. In the static case, the allocation may be preconfigured or a station requests the resource once from some

© 2005 by CRC Press LLC

resource management facility (which may be part of a central station/access point). The Time-Triggered Protocol is an example of such a scheme [41]. Another example is the cyclic window in the WorldFIP protocol, which offers a preconfigured allocation of time slots. Some dynamics can be introduced by changing the allocation tables at appropriate times. The dynamic approach requires a separate channel, which a station can use to request channel resources from the resource manager. The fixed assignment of channel resources is advantageous specifically for industrial applications for the following reasons:

- It allows to guarantee a minimum bandwidth to a station.
- It allows to guarantee a strictly bounded medium access time as well as strictly isochronous service.

Demand Assignment Protocols

In demand assignment (DA) protocols, channel resources are also assigned exclusively to a station, but on a much shorter timescale than for fixed assignment protocols. In the latter case, assignment happens once and lasts for the lifetime of the session, while in DA protocols resources are assigned for the duration of a *data burst* and have to be requested explicitly using a signaling mechanism. We can broadly distinguish two classes of DA protocols: the distributed protocols use no central authority for resource allocation; instead they often use token-passing schemes. On the other hand, for centralized protocols the stations have to signal their demands to a centralized station, which assigns resources and schedules transmissions. The signaling channel can either be in-band (requests can be piggybacked to transmissions of data or control frames) or a separate logical signaling channel with its own medium access procedure is used.

For industrial applications, DA protocols have two major advantages: they can guarantee a bounded medium access time and they allow to use idle resources. However, for the distributed schemes there is inevitably some jitter in the medium access times, which hinders strictly isochronous services. The centralized schemes introduce a single point of failure, namely the resource manager.

Centralized Schemes: Hub-Polling Protocols and Reservation Protocols

As a very general description [34], a hub-polling system consists of a central station (called *hub)* and a number of stations, with each station conceptually having a queue for requests or frames. The hub carries out two different tasks: first it queries the queue states from the stations, and second, it assigns bandwidth to the stations according to the query results and some polling policy. Typically, it is assumed that a query is less costly than to serve a frame; otherwise, the query overhead could not be justified as compared to a pure TDMA system. To be queried, a station must *register* itself with the hub. Polling schemes differ in the sequence by which stations are polled:

- in *round-robin,* the stations are visited one after another,
- in *table-driven* schemes, the next station to be visited is determined from a prespecified table, and
- in *random polling,* the next station to poll is determined randomly

and in the type of service a polled station receives:

k-Limited service: up to *k* frames are served per station before proceeding to the next station.

Time-limited service: the station may transmit frames including retransmissions for no longer than a specified time.

Exhaustive service: a queue is serviced until it is empty.

Gated service: the server serves only those frames of station *i* that were already present when starting service for *i.*

As an example, the master-/slave protocol of PROFIBUS can be classified as a table-driven and time-limited service (however, with varying masters). In the BITBUS protocol [24], the role of the master does not change over time.

A variation of hub-polling protocols are *probing protocols* [32, 21]. These are based on the observation that polling each station separately is wasteful if the load is low. Instead, it is more effective to poll a group of stations as a whole. For example, the hub may announce that a random access slot follows,

© 2005 by CRC Press LLC

which can be used by stations belonging to a certain group to signal their transmission needs. If no station answers, the next group can be polled. If a single station answers, it is granted access to the medium, if two or more stations answer, their requests will collide in the random access slot. Different methods can now be applied to resolve this collision, for example, the tree walking approach discussed in CSMA Protocols with Collision Resolution section, or all stations in the group can be polled separately. In [44], the latter approach is introduced, along with a scheme that adapts the group sizes to the current load.

In reservation protocols, the stations have to send a *reservation message* to a resource management facility (often located in a central station). The reservation message may specify the length of the desired data transmission and its timing constraints. The central station can perform an *admission control test* to decide, whether the request can be satisfied without harming the guarantees given to already admitted requests. After successful admission control, the central station sends some feedback to the station indicating the allocated resources (e.g., the time slots to use). For signaling requests, three approaches are commonly used: (a) in *piggybacking schemes* the reservation requests are sent along with already admitted data or control frames; (b) the stations send request frames on a separate signaling channel under a contention-based MAC protocol (ALOHA or CSMA protocols); and (c) the central station may poll all stations that are currently idle and thus cannot use piggybacking. Many protocols developed in the context of wireless ATM [15] belong to this class, for example, the MASCARA protocol [29] of the European Union Magic Wand project. The FFT-CAN [10] protocol is another example of this class, where stations send reservation requests for periodic transmissions to a central master station.

Distributed Schemes: Token-Passing Protocols

In distributed schemes, there is no central facility controlling resource allocation or medium access. Instead, a special frame, called the *token frame* is sent between stations. The station that currently holds the token is allowed to initiate transmissions. After some time, the current token owner is required to pass the token to another station, that is, to send it a token frame. Token passing schemes can be applied in networks with a ring topology (examples: the IEEE 802.5 Token Ring [23] or FDDI [14, 25]) or with a bus/tree topology (examples: the IEEE 802.4 Token Bus [22] or the PROFIBUS with the FMS profile [42]).

To guarantee an upper bound on medium access delay, the IEEE Token-Bus, FDDI, and the PROFIBUS protocols use variants of the *timed-token protocol* [9]. In this protocol, all stations agree on a common parameter, the *target token rotation time* T_{TTRT}. Furthermore, each station is required to measure the time that passed between the last time it received the token and the actual token reception time. This time is called the *token rotation time.* If the difference $T_{TTRT} - T_{TRT}$ is positive, the arriving token is called an *early token;* otherwise, it is called a *late token.*

Token-passing protocols over broadcast media (bus, tree) construct a *logical token passing ring.* The token frame is passed among all stations in this ring, and each station gets the token once per cycle. The ring members have the additional burden to execute *ring maintenance* algorithms, which include among others: including new stations, excluding leaving or crashed stations, detect and repair lost tokens, etc. These mechanisms use a certain number of control frames and are designed in a way that they do not harm the timing guarantees given by the timed-token protocol.

Meta-MAC Protocols

In [17] "Meta-MAC" protocols are introduced. The basic idea is simple and elegant: a station contains not only a single MAC instance, but several of them, running in parallel. These can be entirely different protocols or the same protocol, but with different parameters. However, only one protocol is really active at a given time in the sense that its decisions (transmit/not transmit) are executed; the other instance decisions are only recorded. From time to time, a new active protocol is selected. This selection is based on history information about transmission outcomes (success, failure). For each candidate protocol, it is evaluated as to how "successful" the protocol would have been given the outcomes in the history. For example, a protocol that produced several "transmit" decisions in "successful" time slots would get a high

© 2005 by CRC Press LLC

ranking, while a protocol that "transmits" decisions would have resulted in collisions getting a bad ranking. Based on this ranking, a new protocol is chosen.

37.4 Error Control Techniques

When a packet is transmitted over a physical channel, it might be subject to distortions and channel errors. Potential error sources are noise, interference, loss of signal power, etc. As a result, a packet may either be completely or partially lost (e.g., when the receiver fails to acquire bit synchronization or loses it somewhere), or a number of the bits within a packet are modified. In some types of channels, errors occur quite frequently, for example, in wireless channels [56].

One option to deal with errors is to tolerate them. For example, in Voice-over-IP systems, a loss rate of speech packets of $\approx 1\%$ still gives an acceptable speech quality at the receiver, depending on the codec and the influence of error concealment techniques [47, Chapter 7].

However, in safety-critical industrial applications errors are often not tolerable, must be detected, and subsequently be corrected. There are the following fundamental approaches to *error control* [49]:

- In *open-loop approaches,* the transmitter receives no feedback from the receiver about the transmission outcomes. Redundancy is introduced to protect the transmitted data against errors.
- In *closed-loop schemes,* the transmitter receives feedback about erroneously received packets. The receiver requests *retransmission* of these packets from the transmitter.
- In *hybrid schemes,* these two approaches are combined.

The detection of errors is based on *checksums,* which are sent along with the packet, for example, as a *packet trailer.* Well-known kinds of checksums are cyclic redundancy checks (CRC) or parity bits [48]. However, no checksum algorithm is perfect; there are always bit error patterns that cannot be detected by a checksum algorithm. Hence, the *residual error probability* is nonzero. A study of the performance of checksum algorithms over real data is [55].

There is a rich literature about error control. Some standard references are [48–50].

Open-Loop Approaches

In general, open-loop approaches involve *redundant data transmission.* Several kinds of redundancy can be used:

- Send multiple copies of a packet.
- Add redundancy bits to the packet data.
- Diversity techniques.

In the multiple-copies approach, the transmitter sends K identical copies of the same packet [45], each one equipped with a checksum. If the receiver receives at least one copy without checksum errors, this is accepted as the correct packet. If the receiver receives all copies with checksum errors, it might apply a bit-by-bit majority voting scheme [52, Chapter 4] on all received copies and check the result again. A variation of the multiple-copies scheme is to not send multiple copies of the same packet, but to send each bit of the user data multiple times: instead of sending 00110101, the transmitter sends, for example, 000.000.111.111.000.111.000.111. Hence, each user bit is transmitted three times and the receiver applies majority voting to each group of three bits.

In *error correcting codes* or *forward error correction* (FEC) codes to k bits of user data, a number $n - k$ of redundancy bits are appended and the block of n bits is transmitted (the fraction k/n is called *code rate*), such that bit errors can be detected and a limited amount of bit errors can be *corrected* [48–50]. In *block coding schemes,* the user data are divided into blocks of k bits and each block is coded independently. Some well-known block FEC schemes are Reed–Solomon codes, Hamming codes, and Bose–Chaudhuri–Hocquenghem (BCH) codes. In *convolutional coding schemes,* the encoder has some "memory," such that the coding of the current bit affects coding of future bits. Therefore, there are no

© 2005 by CRC Press LLC

clear block boundaries. Recently, the class of *turbo codes* has attracted attention [54]. In this class of codes, two convolutional codes are concatenated: first an *inner code* is applied to the user data, and after this an *outer code* is applied to the result of the first coding stage.

Diversity techniques are often applied on wireless channels. In the case of receiver diversity, the receiver is equipped with two or more antennas. If these are appropriately spaced [51], the antennas receive two copies of the transmitted waveform, which, in the best case, are uncorrelated. Hence, it might happen that one antenna receives only a weak signal while the other one experiences good signal quality. The two antenna signals may then be combined in different ways.

Closed-Loop Approaches

In closed-loop approaches, the receiving station *B* checks the arriving packets sent by station *A* by means of checksums and provides *A* with feedback information indicating the transmission outcome (success or failure). Usually, *B* sends *acknowledgement frames* to provide this feedback to *A*; but the feedback information may as well be *piggybacked* onto data frames sent from *B* to *A*. Automatic Repeat reQuest (ARQ) protocols implement this approach [46, 20]. Four basic ARQ protocols are the Send-and-Wait protocol, the alternating bit protocol, the Goback-*N* protocol, and the Selective-Repeat protocol.

In the Send-and-Wait protocol, the transmitter sends a packet and starts a timer. The receiver sends an acknowledgement, if the packet is received correctly; otherwise, the receiver keeps quiet. If the transmitter receives the acknowledgment, the timer is resetted and the next packet is transmitted. If the transmitters timer expires without acknowledgment, the transmitter retransmits the packet. This protocol is simple, but does not fill "long fat pipes" (links with a high bandwidth-delay product) efficiently and cannot prevent duplicate data at the receiver. Duplicates can be created if not the data packet but the acknowledgment is lost or erroneous. In the alternating bit protocol, a one-bit sequence number is introduced to detect and remove duplicates. If the receiver receives a duplicate packet, the packet is acknowledged, but the data are not delivered to the user. This works reliably if the delay for data packets or acknowledgments can be upper-bounded. However, the alternating bit protocol is still inefficient on long fat pipes.

Both the Goback-*N* and the Selective-Repeat protocol are not restricted to a single unacknowledged or *outstanding* frames, but allow for multiple outstanding frames; these protocols are also called *sliding-window protocols.* The frames are identified by sequence numbers. In the Goback-*N* protocol, there may be *N* outstanding frames. The transmitter sets a timer for each transmitted frame and resets it as soon as an acknowledgment for this frame is received. If the receiver receives an insequence frame, it delivers the frame to its local user and sends a positive acknowledgment; otherwise the frame, is dropped (even if it is received correctly) and either the receiver sends a negative acknowledgment or keeps quiet. When the transmitter receives a negative ack for an outstanding frame or if the timer for this frame expires, he retransmits this frame and all subsequent outstanding frames. Therefore, it might happen that correctly received frames are retransmitted, which is inefficient.

This drawback is attacked by the Selective-Repeat protocol, which works similar to the Goback-*N* protocol, but allows the receiver to buffer and acknowledge frames that are not received in-sequence. As soon as the missing frames arrive, the buffered frames are delivered to the user and the buffer is freed.

Hybrid Approaches

Open-loop and closed-loop approaches can be combined, for example, by continuously increasing the amount of FEC applied to subsequent retransmissions of the same packet, or by adapting the number of copies in a multicopy approach to the feedback [45].

Further Countermeasures

The transmitter potentially has further control knobs to reduce the probability of packet errors at the receiver. One control knob is the packet length: in a scenario where a packet is equipped with a checksum but not with redundant FEC data, longer packets have a higher probability to be received in error, but the

© 2005 by CRC Press LLC

fixed overhead is only a small portion of a packet. In contrast, shorter packets have a higher probability to arrive successfully, but the fixed overhead requires a larger share of the overall bandwidth. When the transmitter receives feedback about transmission outcomes, it may adapt the packet size accordingly.

It is a fundamental communications law that the bit error rate at the receiver depends on the ratio of the energy expended per bit to the channel noise level [53]. There are two possibilities to use this relationship to increase transmission reliability:

- If the transmit power is increased, the energy per bit is increased and the bit error rate is reduced. However, often, the transmit power is technically or legally restricted.
- If the bits are transmitted at a lower speed, the energy per bit is also increased.

Hence, a transmitter might apply *transmit power control* or *modulation rate control*.

38.1 Introduction

The convenience of true mobility due to wireless connectivity has made wireless technologies gain more and more ground. Next to extensive infrastructure requiring cellular systems like GSM or UMTS, interest is now growing in commercial and industrial deployment of systems that function on a smaller scale and require no costly frequency licensing or infrastructure, systems that are used for wireless PANs and wireless LANs.

As a consequence, Bluetooth (a WPAN representative that costs little, consumes little power, is small in size, as well as flexible concerning the support of voice and data services), IEEE 802.11, and HIPERLAN/2 technologies (WLAN representatives that provide comparably high user data rates and a larger range) all receive a significant amount of public and scientific attention. It is only logical that their original purposes are enhanced. Bluetooth, for example, plays a larger role at the beginning less attended markets like warehousing, retailing, and industrial applications [Bea02b]. IEEE 802.11 is considered for seamless coverage of whole cities [Bea02a].

© 2005 by CRC Press LLC

Whatever the precise application is, the users of these technologies have expectations concerning quality and availability of the systems. How well they can be satisfied largely depends on the environment (i.e., unit density, traffic demand, mobility, changes in the environment, and interference) in which the systems are used. Having a good individual performance while at the same time optimizing the overall radio network capacity is in any case a vital issue. This paper identifies criteria on the network and physical layer level, which should be taken into consideration when deciding on one or the other (or all) technologies to employ. It also describes how well the technologies meet these criteria, especially when taking the specific properties of industrial applications/factory floor environments into account.

This chapter is structured as follows. Section 38.2 first of all defines the terms wireless LAN and wireless PAN and puts them in context to cellular systems, as none of the terms are currently unambiguously used. Section 38.3 introduces the (Quality-of-Service) requirements that are generally placed on a technology. A clear view of these requirements is necessary before starting to look for a technology to use. Sections 38.4–38.6 describe the WPAN technology Bluetooth and the WLAN technologies IEEE 802.11 and HIPERLAN/2. In each section, one part explains the technical background, while the other focuses on the performance of the systems. Section 38.7 shows how Bluetooth and IEEE 802.11b — both are placed in the same frequency band and are possibly used at the same time in the same location — coexist, before Section 38.8 closes this article with a summary and the conclusion.

38.2 Defining WLAN and WPAN

The expressions Wireless Local Area Network (WLAN) and Wireless Personal Area Network (WPAN) are commonly used, often though without consistency and/or explanation of what is exactly meant. Thus, in the following, a clarification of the terminology is given.

WLAN: A wireless LAN has the same functionality as a wired LAN with the difference that the wires are replaced by air links. This means that within a *restricted area* (home, office, hot spot) *intercommunication* between all devices connected to the network is possible and that the focus is on *data communication* as well as *high data rates.* The definition of WLAN says nothing on how the network is organized. The most likely approach is that an infrastructure of mounted access points (APs) enables wireless access to the wired LAN behind the APs. Nevertheless, a wireless LAN functioning on an *ad hoc* basis with the units in range is also imaginable.

WPAN: In a wireless PAN also all devices are *interconnectable.* The difference is that all units are somehow *associated* to someone or something or alike (either because they are yours or because they are shared or public devices you want to use) and are therefore very *near by.* A PAN can consist of a variety of devices and can even comprise different technologies. The applications are therefore not limited to *data transmission;* but *voice communication* can be used in a PAN as well.

While you move *within* the WLAN, you move *with* your WPAN. This means that several independent WPANs can coexist in the same area and that they are self-sufficient without any infrastructure, that is, they generally function on an *ad hoc* basis.

Also note that the expression *ad hoc* network is not unambiguously used. As is illustrated in Figure 38.1, there are several steps that lead to *ad hoc* networking: a "pure" *ad hoc* network employs neither any infrastructure nor a specific unit (like access point or base station) for central control; not for coverage, not for synchronization, and also not for the services. Nevertheless, a network can be "ad hoc" also when it supports only single hops.

It can be seen that WLAN technologies like IEEE 802.11 (infrastructure mode using the point coordination function (PCF)) or HIPERLAN/2 are, when looking at these criteria, in the same classification as typical "cellular" systems like GSM or UMTS/WCDMA; all have infrastructure and a specific unit for central control. A WLAN is equally likely to be laid out in cells and it would thus be correct to call it a "cellular" system. Despite this, common understanding has it that the distinction is made by coverage. This "wide" (instead of "local") area coverage of "cellular" systems like GSM has caused "cellular" systems to be generally associated with complete coverage and access everywhere. The actual differentiating term

© 2005 by CRC Press LLC

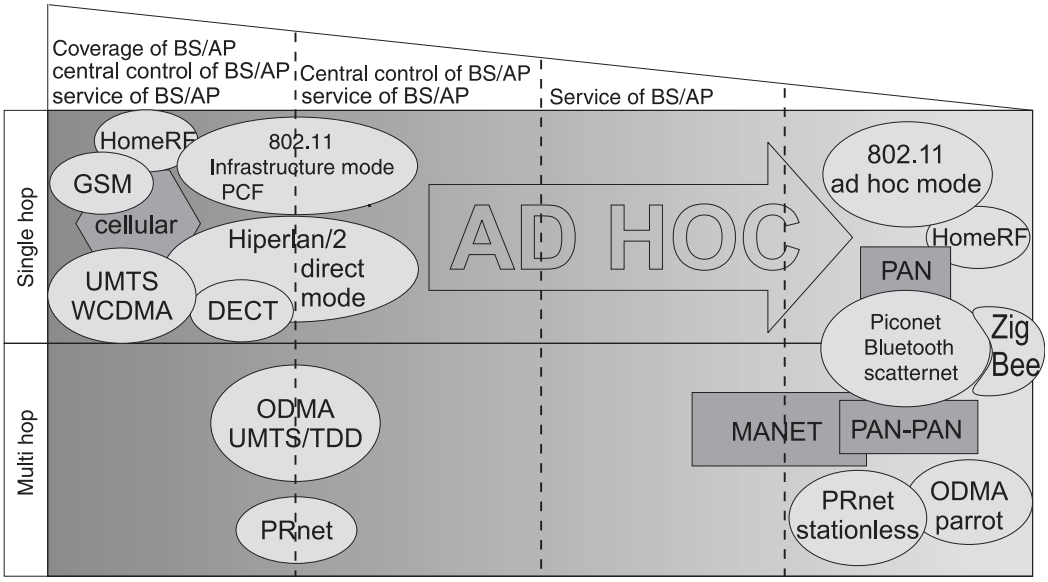

FIGURE 38.1 Classifying wireless technologies between cellular and *ad hoc*; MANET stands for Mobile (or Multihop [JIC99]) *Ad hoc* NETwork (aiming at Internet standards [IET]), PRnet stands for Public Radio network [Mal01], ODMA for Opportunity Driven Multiple Access [3rd99, RBM02]; a Bluetooth scatternet means several interlinked Bluetooth piconets; BS ≙ base station, AP ≙ access point.

should be wireless wide area network (WWAN). This chapter will use the common terminology, but wants to point out its inaccuracy.

Naturally, there are more differences: cellular networks focus on voice communication, while WLANs focus on data transmission. Cellular technologies are designed to support user mobility (and roaming) up to very high velocities, while WLANs had more the stationary or portable access in mind. Last but not the least cellular phones represent by far the highest volume product in the wireless market. From the radio network point of view, the most important technical distinction though — with far-reaching consequences to system design, network optimization, etc. — has to be made between systems organized in cells and *ad hoc* systems, for example, regular WLANs and WPANs (and not between cellular systems and WLANs):

As cellular networks are systematically laid out, the minimum distance to the next cochannel interferer (i.e., the next uncoordinated user transmitting at the same time on the same frequency) is generally controllable and known. In contrast, in *ad hoc* networks the next cochannel interferer can be uncontrollably close (see Figure 38.2).

The centralized control in cellular networks allows to distribute the resources effectively in a fair way, because of the accurate knowledge of the overall traffic demand and the possibility of a more global resource management. For *ad hoc* networks or several co-existing WPANs knowledge of overall traffic, demand is generally not available and the systems compete for the resources.

The consequences these differences have for the radio network performance are elucidated in later sections.

38.3 System Requirements and Quality-of-Service

When deciding on a technology to use (or when developing a new one), first of all the performance requirements the technology should fulfill have to be listed. Generally, aspects like throughput (i.e., user data rate), reliability, and delay (or delay variation) come to mind, but also range, cost, power consumption (a long battery life can be especially important for mobile systems) and security (in the sense that no

© 2005 by CRC Press LLC

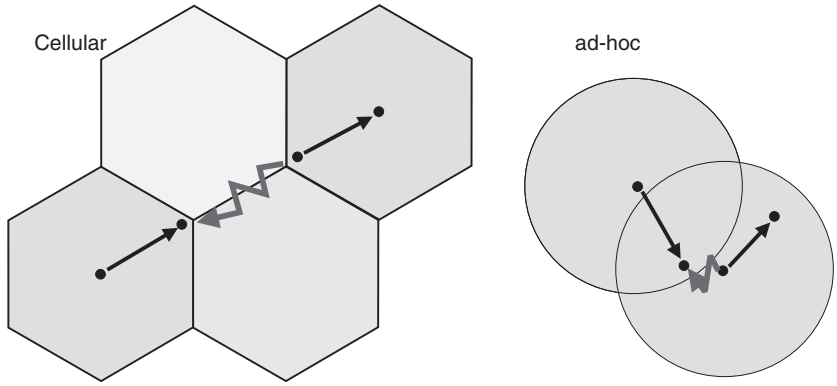

FIGURE 38.2 Possible nearness of next cochannel interferer in cellular and *ad hoc* networks.

unauthorized person can access the transmitted data and network resources) can be decisive parameters. The demands on reliability and delay are directly connected to the type of service intended:

Delay: Delay is especially important for voice transmission, interactive real-time services, and streaming of audio or video in case of small buffer sizes. For example, with a one-way delay larger than ~200 msec, the user in a normal voice communication will feel uncomfortable. At the same time, the user will quite likely still understand the person at the other end of the connection (and not even consider the connection to be inferior) even when 1% of the transmitted data are lost (provided an appropriate speech coding method is used). The delay is first of all caused by the bandwidth available to transmit the required data and the possible need to process the data. Additionally, the transmission itself (depending on the range), the access technology, and the fixed network (due to queuing) can add noteworthily to the overall delay. The main delay causing differences to wired systems are that, due to the air link, wireless systems often provide significantly smaller transmission rates and require additional processing due to extra algorithms needed for coping with the difficult transmission medium.

Reliability: While voice, audio, and video applications can tolerate some errors, typical data applications like web browsing or email require absolute reliability, that is, every bit has to arrive correctly. One mechanism to provide robustness against transmission errors is forward error correction (FEC) encoding (also known as channel coding [CC88, LC83]). To ensure that the bit errors are sufficiently isolated for the FEC to be able to correct them, intra- or interpacket interleaving can additionally be applied. In environments in which every transmitted packet faces different transmission conditions, it might be more effective though to provide an automatic repeat request (ARQ) scheme that initiates a retransmission as soon as the quality of the received packet does not meet the requirements [MZT03].

In case "best-effort" traffic is not sufficient, guarantees of delay, reliability, and throughput values (the latter being in close relation to delay and reliability) are often summarized in the term Quality-of-Service (QoS). There are four categories of QoS:

The *quantitative* QoS gives hard guarantees on the respective delay, throughput, and reliability values [SPG97]. It consequently guarantees the unhindered use of bandwidth and system for the necessary time. *In wireless systems hard quality guarantees cannot be given* due to the possibility of interference, adverse radio conditions,[1] or range limits. Systems requiring a certain amount of data rate within a strict time window because they are, for example, security relevant should not be wireless.

Statistical QoS means that certain requirements can be fulfilled with a certain probability. QoS requirements are thus met in the long run (i.e., in average), while they might not always be reached on short terms. Instead of quantitative QoS, wireless systems that provide QoS generally give statistical QoS guarantees.

[1]Note that in industrial environment, they can be especially difficult; metal walls have a significant impact on the transmission conditions. Metal shields radio transmissions while causing, respectively, more reflections.

© 2005 by CRC Press LLC

Subjective QoS gives a certain qualification to the QoS parameters. It naturally leaves more implementation freedom but also insecurity on what quality exactly to expect.

Relative QoS specifies the parameters relative to others. Relative QoS is sensibly used only when there are several traffic classes.

Once the necessary requirements and desired QoS criteria have been agreed upon, the discussion on the technology can commence.

38.4 Bluetooth Technology

Technical Background

Bluetooth (BT) is first of all a cable replacement technology aiming at effortless wireless connectivity in an *ad hoc* fashion, while supporting voice as well as data [Blu99, Blu, Haa98, BS00, Bis01]. Its desired key associations are: easy to use, low in power consumption, and low in cost.

To meet these intentions, the BT Special Interest Group (SIG) placed the technology in the unlicensed ISM-band at 2.4 GHz. This allows close to worldwide deployment without needing to pay fees for frequency licensing. Nevertheless, it requires complying with the respective sharing rules.[2] As a consequence, Bluetooth performs a rather fast frequency hopping (FH) over 79 carriers of 1 MHz bandwidth each such that every Bluetooth packet is transmitted on a newly chosen frequency (which results in a nominal hop rate of 1600 hops/sec). To further reduce cost and support the distribution of the Bluetooth technology, the Bluetooth specification is an open standard that can be used without even needing to pay for the use of its key patents, on the term that the strict qualification procedure is passed. The latter is to ensure the acceptance of the technology, as is the specification of profiles. The profiles describe in detail the implementation of the foreseen applications, thus also enabling units of different manufactures to communicate. The most important characteristics of the physical layer are as follows: The data are GFSK modulated at 1 Mbps and organized in packets consisting of access code, header, and payload. While the use of forward error correction (FEC) for the payload is optional with a 2/3 rate (15,10) shortened Hamming block code, there is no interpacket interleaving (which saves memory).

Bluetooth uses a master–slave concept in which the unit that initiates a connection is temporarily assigned master (for as long as the connection is up). The master organizes the traffic of up to seven other active units, called "slaves" of this "piconet." From the master's device address, the piconet's identity and with it the FH sequence is known. The header of a packet contains the actual addressee, the length of the packet, and other control information. Note though that within one piconet, the slave can only communicate with the master (and not directly with the other slaves) and that only after having been asked (i.e., "polled")[3].

The channel is organized in a TDMA/TDD [GL00] scheme (see Figure 38.3). It is partitioned into 625 μsec time slots. Within this slot grid, the master can only start transmission in the odd numbered slots while the slaves can only respond in even numbered ones. When a unit is not anyway in one of the specific power save modes ("sniff, hold, park"), this supports the "low in power consumption" intention, because every unit has to listen only during the first 10 μsec of its receive slot whether there is a packet arriving (and if not, can "close down" until the next receive slot[4]). This means it needs to listen only 10 μsec/(2.625 μsec)=0.8% of the time. Yet another facet to the long battery life is also the low basic transmit power of 0 dBm (resulting in a nominal range of 10 m)[5].

[2]For the U.S. [Fed02, Part 15], for Europe [Eur00b], for Japan [Min02]

[3]Every BT unit can simultaneously be a member of up to four piconets (although it can be master in only one of them). A formation in which several piconets are interlinked in that manner is called "scatternet." Aspects like routing — which are of interest in this constellation — will not be covered in this article. The chapter will thus focus on the properties of a single or multiple independent piconets.

[4]This is quite different from channel access schemes like CSMA as used in IEEE 802.11 (see Section 38.5). Unless asleep, IEEE 802.11 always has to listen into the channel.

[5]Bluetooth can also be used with up to 20 dBm transmit power. This results in a larger range but requires the implementation of power control to fulfill the FCC sharing rules.

© 2005 by CRC Press LLC

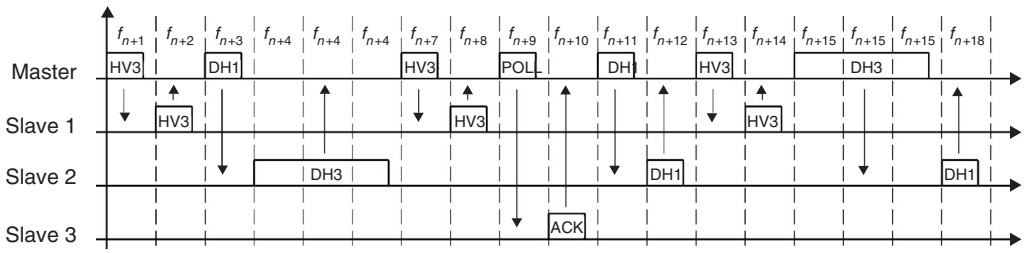

FIGURE 38.3 Example slot occupation within one piconet consisting of master and three slaves; to slave 1 there is an SCO link, to slave 2 (best effort) traffic is transmitted in both directions, slave 3 has currently nothing to send (but has to respond to the POLL-packet with an acknowledgement (ACK)); during the transmission of multislot packets, the frequency is not changed.

Bluetooth provides two different types of connections: an asynchronous connection-less (ACL) link foreseen for data transmission and a synchronous connection-oriented (SCO) link foreseen for speech transmission.

For ACL links, there are six packet types defined. The packets occupy either one, three, or five (625 μsec) time slots and their payloads are either uncoded (called DH1, DH3, DH5) or 2/3-rate FEC protected without any interleaving (called DM1, DM3, DM5). An automatic repeat request (ARQ) scheme reacting on a cyclic redundancy check (CRC, included in each ACL-payload) secures error-free reception of the transmitted information. Table 38.1 gives an overview on the throughput values achievable with ACL connections. The maximum (unidirectional) Bluetooth throughput is 723 kbps.

As speech transmission is delay sensitive, SCO links support three different packet types that are transmitted at fixed intervals. All types were designed to transport CVSD (continuous variable slope delta) encoded speech at 64 kbps. The packet types always occupy just one (625 μsec) time slot only, but they are differentiated by their payload FEC. The packet payloads are either unprotected (called HV3) or 2/3 rate FEC-encoded (HV2) or protected with a 1/3-rate repetition code (HV1). For an HV3 connection a packet is transmitted every 6th slot (see Figure 38.3), for HV2 every 4th slot, and for HV1 every 2nd slot (meaning that with one HV1 connection no other traffic can be transmitted in the piconet). For SCO links, there is currently no ARQ scheme. In case of an erroneous reception of the packet overhead, the SCO packet is replaced by an erasure pattern. In case noncorrectable bit errors occur in the payload only, these errors are forwarded to the speech decoder.

Security is supported in Bluetooth by the specification of authentication and encryption. Changes for future versions of the Bluetooth specifications are:

To further improve coexistence with other systems in the ISM-band, it is intended that upcoming versions of Bluetooth will have the possibility to perform adaptive frequency hopping (AFH), that is, to exclude interfered carriers from the hop sequence. With AFH, the nominal hop rate will be halved, because then the slave will respond on the same frequency as on which it received the packet from the master [Blu02].

A high rate mode is envisioned that allows direct slave-to-slave communication at about a tenfold transmission rate. For this, a 4 MHz channel is chosen at a specifically good location within the bandwidth.

The future SCO link will provide for (some) packet repetitions and negotiation of the transmission rate [Blu03].

Performance

On the factory floor, Bluetooth can be used as a wireless add-on to wired systems or as a replacement of existing cabling. It can cover machine-to-machine communication, wireless/remote monitoring, or tracking and

DM5	5	2/3	224	477.8k	36.3k	286.7k	286.7k

some type of positioning of moving entities [GGH01, Bea02b]. Considering the comparably short range of Bluetooth and the likely association to a specific unit (represented by a machine/person/task), it can happen that several independently active Bluetooth piconets coexist and overlap in space. The use of frequency hopping helps to mitigate the effects of interference among these piconets. When assuming more or less time-synchronized piconets, a worst-case approximation of the loss rate can be made with Equation (1). It calculates the probability $P(x,n)$ that of x other piconets n hop onto the same frequency as the considered piconet

$$P(x,n) = \binom{x}{n}\left(\frac{1}{79}\right)^{n}\left(\frac{78}{79}\right)^{x-n} \tag{1}$$

The probability that at least one of the other x piconets transmits on the same frequency is then $P(x) = l - P(x,0)$. The smaller the number of actually interfering piconets, the better an approximation this approach gives; as for larger numbers, the distances to some of the interferers are likely to be too large to be harmful. In [ZSMH00, Zür00, MZT03], thus, a more sophisticated approach has been chosen and Bluetooth–Bluetooth co-existence results have been obtained with the help of detailed radio network simulations that include traffic, distribution, and fading models as well as adjacent channel effects. All results have been obtained with an office of 10×20 m^2 in mind, assuming an average master–slave distance of 2 m. Naturally, a factory floor is likely to be significantly larger than 10×20 m^2. Nevertheless, the increased delay spread does not really affect Bluetooth due to its small range (which is different for WLAN technologies; see respective performance section). The overall number of piconets can be larger on a factory floor (at a comparable density). At the same time, location and traffic of the units are likely to be more predictable. The results of the aforementioned publications thus give a good idea of what performance is achievable:

A 10×20 m^2 room supports 30 HV3 simultaneous speech connections with an average packet loss rate of 1% (a limit that represents a still acceptable quality).

HV3 packet types are preferable to HV2 and HV1. The subjective quality will not increase with additional payload coding. Using a coded HV packet just increases (unnecessarily) the interference in the network and the power consumption.

100 (!) simultaneous WWW-sessions (bursty traffic with an *average* data rate of 33.2 kbps each) in the 10×20 m^2 size room result in a degradation of the aggregate throughput of only 5%.

The maximum aggregate throughput in the room is 18 Mbps (at 50 fully loaded piconets). These piconets then transmit at a unidirectional data rate of 360 kbps.

Long and uncoded packets are preferable to shorter and/or coded ones. It takes 60 interfering piconets using the same packet type, 10 interfering HV1 connections (worst case), or a link distance of 27 m (which is far beyond the envisioned range of 10 m) before another packet type yields a larger throughput than DH5. It is advisable not to use the optional FEC (DM-packet types). As the coding is

© 2005 by CRC Press LLC

not appropriate to handle the almost binary character of the Bluetooth (*ad hoc*) transmission channel,[6] the needed power can additionally be saved.

Bluetooth is cheap and consumes quite little power. The ACL link is reliable with best-effort traffic (with a maximum throughput of 723 kbps). The SCO link has reserved bandwidth (at a relatively small throughput of 64 kbps), although the packets might contain residual bit errors. In principle, Bluetooth is very robust against other Bluetooth interference and a good performance can be achieved even in very dense environments. In case of only one slave per piconet, statistical QoS guarantees can be given; else, the internal scheduler can only with future Bluetooth Specifications give priority to traffic other than SCO traffic. Note that customized implementations, which cannot be based on existing profiles, might be difficult to realize, as the specification of new profiles is quite time-consuming.

38.5 IEEE 802.11

Technical Background

IEEE 802.11 comprises a number of documents that define (only) the lower layers (mainly the physical (PHY) and medium access control (MAC) layers) for a WLAN technology [Ins99b, Ins99a, Ins, OP99]. Being part of the IEEE 802 group means that an interface can be used (IEEE 802.2) to connect to the higher layers, which are then not aware of the — with IEEE 802.11 wireless — network that is actually transporting the data. The key intentions of IEEE 802.11 are thus to provide a high throughput and continuous network connection like available in wired LANs.

To support the wide employment of the technology also the use of IEEE 802.11 does not cause frequency licensing fees. IEEE 802.11 uses either infrared (IR), transmits in the unlicensed ISM-band at 2.4 GHz (like Bluetooth), or (like HIPERLAN/2) in 5 GHz bands that are license exempt in Europe and unlicensed in the U.S. (UNII bands). Other than in case of Bluetooth though, the companies holding key patents within IEEE 802.11 can charge developers of IEEE 802.11 products for using the patents "on reasonable terms" [Ins02, Clause 6b].

In principle, it is possible to have an IEEE 802.11 WLAN consisting of mobile stations (MS) only. It is more likely though that IEEE 802.11 is used as a wireless access technology to a wired LAN to which the connection is made by IEEE 802.11 access points (APs). Should the access point only use the distributed coordination function,[7] the MAC layer supports collision avoidance by using carrier sense multiple access (CSMA). This means that before transmitting a packet, the respective unit has to listen for the availability of the channel.[8] If the channel is sensed free after having been busy, the unit waits a certain period (called "DIFS") and then enters a random back-off period[9] of

$$\underbrace{random\ (0...min(2^{n_{PHY}+n_r}-1,1023))}_{CW} \cdot t_{slot} \tag{2}$$

[6]The reasons are manifold. Without interference, the channel varies already due to hopping over 79 relatively narrowband channels. Additionally, with the wavelength used in Bluetooth, even small changes in position can cause large changes in the received signal strength. When there is interference, the effect becomes more pronounced. The existence or nonexistence of a close cochannel interferer can make the channel change from very good to very bad within the fraction of a moment (see also Figure 38.2).

[7]Which is likely and assumed in the following. In theory, the standard also provides additionally the use of a centralized point coordination function.

[8]The implementor can choose whether the units react (a) on just other IEEE 802.11 traffic, (b) on just other IEEE 802.11 traffic above a certain receive signal strength, or (c) on any signal above a certain receive signal strength [Ins99b, Section 18.4.8.4].

[9]The random back-off period is entered only when the channel was busy before. Else the unit will transmit at once after DIFS.

© 2005 by CRC Press LLC

with $^{n}{}_{PHY}$ *being* a parameter depending on the type of physical layer chosen, n_r the index of the retransmission of the packet, t_{slot} presenting the slot duration, and *CW* standing for contention window (with $CW_{min} = 2^{n_{PHY}} - 1$)). Should the cannel by then still not be occupied, the unit transmits its packet (consisting of PHY header, MAC header, and payload). Upon a correct reception, the addressee responds with an ACK packet a short period (called "SIFS") later; see also Figure 38.4. The realized ARQ mechanism secures reliable data.

The IEEE 802.11 WLAN MAC concept is obviously made for best-effort data traffic. Services for which strict delay requirements exist, like speech, cannot well be supported by IEEE 802.11 as it currently is. Any QoS is thus difficult to provide, especially when multiple units coexist in the network. The IEEE 802.11 MAC concept also includes a mechanism to solve the hidden terminal problem. Whether this "ready-to-send/clear-to-send" (RTS/CTS) packet exchange saves more bandwidth (due to avoided retransmissions) than it additionally needs though, depends on the terminal density and payload packet length [Bia00]. As the RTS/CTS mechanism is optional, it will be assumed in the following that the RTS/CTS mechanism is not used.

IEEE 802.11 has a significantly larger power consumption than Bluetooth. Note that this is not only due to the higher transmit power (20 dBm in Europe, 30 dBm in the U.S.) but also due to the CSMA concept. IEEE 802.11 units not specifically in sleep status have to listen into the channel *all* the time (and not like Bluetooth just at the beginning of the receive slot). Simultaneously though, the higher transmit power allows for a larger range of about 50 m (with 20 dBm).

There are four different options for the physical layer implementation of IEEE 802.11:

IR: The infrared mode transmits near visible light at 850–950 nm wavelength. The data are pulse position modulated at 1 or 2 Mbps. In principle, the signal needs line-of-sight (LOS) and cannot go through walls. This and the nonvisibility of IEEE 802.11 IR products are the reasons for not covering the IR-mode further in this chapter.

FHSS: The Frequency Hopping Spread Spectrum mode is placed (like Bluetooth) in the 2.4 GHz ISM-band. The data are GFSK modulated using two levels for 1 Mbps and four for the 2 Mbps modulation rate. The FHSS mode divides the 79 hop frequencies into three distinct sets with 26 different sequences each. The hopping rate can be as slow as 2.5 hops/sec. Despite its comparably good interference robustness [SFEM02], the popularity of the FHSS mode is limited due to its comparably low transmission rates. Note though that its principles have been incorporated in the HomeRF standard [HRF, BS00].

DSSS: The Direct Sequence Spread Spectrum mode is also used in the 2.4 GHz ISM-band. The nominal bandwidth of the main lobe is 22 MHz. The transmit power reduction in the first side lobes and the rest is supposed to be 30 and 50 dB resp. (see also Figure 38.5 for a measured spectrum). In principle, 11/13 (U.S./Europe) center frequencies are available for the DSSS system. Nevertheless, using several systems in parallel requires a spacing of 25/30 MHz (U.S./Europe), which consequently allows to use only three systems in parallel.

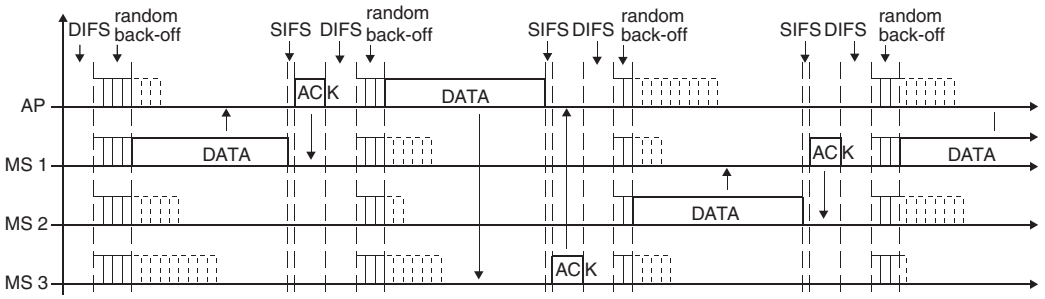

FIGURE 38.4 Principle time behavior of IEEE 802.11 under the distributed coordination function; note that the random back-off timer from units *not* the one to transmit continues after the next DIFS with the remaining number of slots.

© 2005 by CRC Press LLC

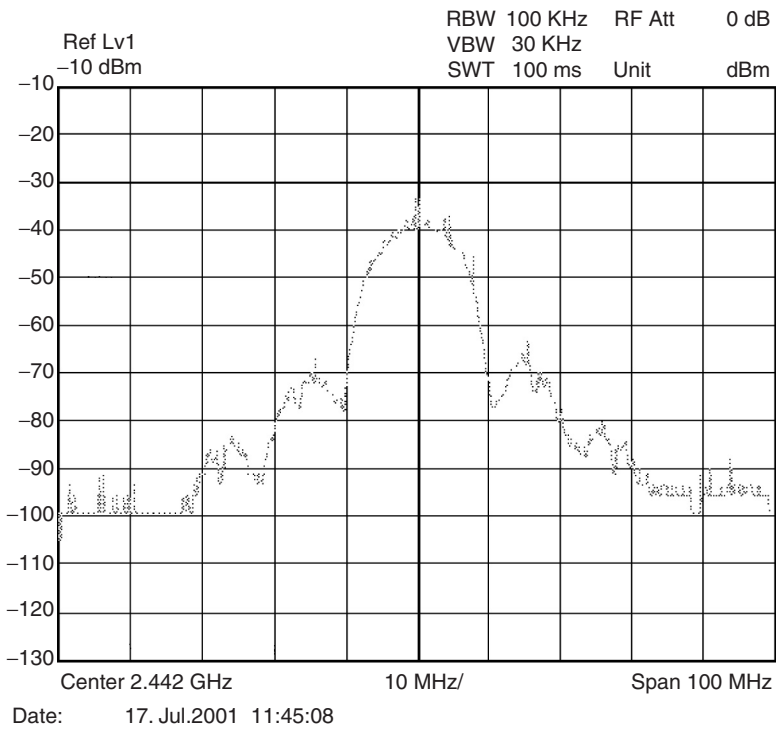

FIGURE 38.5 Measured spectrum of an IEEE 802.11b WLAN PCMCIA card.

The DSSS mode has the original mode (specified in IEEE 802.11) and a high-rate extension (specified in IEEE 802.11b). In the original mode, the chipping of the baseband signal is performed with 11 MHz, using an 11-chip pseudo-random code (Barker sequence). For the 1 Mbps modulation rate, a one-bit DBPSK symbol is spread with the Barker sequence; for the 2 Mbps modulation rate, a two-bit DQPSK symbol is spread with the same sequence.[10] The high-rate extension IEEE 802.11b was at the time of writing the most popular and widespread WLAN technology. For the PHY-header IEEE 802.11b uses the same 1 and 2 Mbps modulations as the plain DSSS mode. Note though that a shortened header of 96 μsec can be used. For the IEEE 802.11b PHY-payload (consisting of the MAC-header and the user data) a 5.5 and 11 Mbps Complementary Code Keying (CCK) modulation is used. The CCK uses a variation of M-ary orthogonal signaling (complex Walsh/Hadamard functions) with 8 complex chips in each spreading code word. For the 5.5 Mbps modulation rate 4 bits are mapped onto 8 chips and for 11 Mbps 8 bits are mapped onto 8 chips.

OFDM: The Orthogonal Frequency Division Multiplexing physical layer (also referred to as IEEE 802.11a) is placed in 5 GHz bands and nearly identical to the one of HIPERLAN/2 (see also Section 38.6). Seven modi are defined ranging from BPSK with rate R=1/2 FEC (lowest modulation rate with 6 Mbps) to 64-QAM with rate R=3/4 FEC (highest modulation rate with 54 Mbps, see also Table 38.2). The OFDM technique is based on a 64-point IFFT/FFT, while only using 52 of the subcarriers (48 for user data, 4 for pilot carriers). The subcarrier spacing is Δf = 20 MHz/64 = 0.3125 MHz. Note that always full OFDM symbols have to be transmitted, which means they possibly have to be filled up with dummy bits. To transmit one OFDM symbol $t_{sym} = 1/\Delta f + 1/4 \cdot 1/\Delta f = 4$ μsec is needed, with the latter part representing the time used for the guard interval that combats multipath propagation. The for synchronization, channel estimation, and equalization needed training sequence consists of ten repeated short and two repeated long OFDM symbols [Ins99c, vNAM+99].

[10]Note that in contrast to a typical CDMA system like UMTS, *all* users use the same spreading code.

						BPSK, R3/4	9	1.81	6.32	7.79	8.51
					4μs)	QPSK, R1/2	12	2.02	7.86	10.0	11.2
						QPSK, R3/4	18	2.25	10.4	14.1	16.3
						16-QAM, R1/2	24	2.38	12.3	17.6	21.2
						16-QAM, R3/4	36	2.59	15.2	23.7	30.3
						64-QAM, R1/2	48	2.64	17.1	28.5	38.4
						64-QAM, R3/4	54	2.70	17.9	30.8	42.2

Table 38.2 compares the theoretical maximum throughput values *TP* of the different IEEE 802.11 PHY versions after the MAC. The maximum payload length is 4095 bytes (which has to include the 34-byte MAC header). 1500 bytes is the common length of an Ethernet packet the values for 1500 bytes payloads (plus 34 bytes MAC header and check sum), 576 a typical length for a web browsing packet, and 60 bytes the length of a TCP acknowledgment. The throughput *TP* for the FHSS and the DSSS modes are calculated as follows:

$$TP_{FHSS,DSSS} = \frac{PayBytes \cdot 8}{\underbrace{DIFS}_{2t_{slot}+SIFS} + \underbrace{\frac{CW_{min}}{2} \cdot t_{slot}}_{\text{average back-off}} + \underbrace{t_{PHYh} + \underbrace{\frac{34 \cdot 8}{ModRate}}_{\text{MACheader}} + \frac{PayBytes \cdot 8}{ModRate}}_{t_{data\ packet}} + SIFS + \underbrace{t_{PHYh} + \frac{14 \cdot 8}{ModRate}}_{t_{ACK}}} \cdot \quad (3)$$

Due to the specific characteristics of the OFDM symbols, the duration of packet $t_{data\ packet}$ and acknowledgment t_{ACK} are calculated somewhat differently for the throughput of the OFDM mode ("ceil" stands for the next larger integer). The rest of Equation (3) remains the same

$$t_{datapacket} = t_{PHYh} + t_{sym}\, ceil\left(\frac{16 + (34 + PayBytes) \cdot 8 + 6}{ModRate/12\ \text{Mbps} \cdot 48}\right),\ t_{ACK} = t_{PHYh} + t_{sym}\, ceil\left(\frac{16 + 14 \cdot 8 + 6}{ModRate/12\ \text{Mbps} \cdot 48}\right). \quad (4)$$

For small payload sizes, the throughput values are very small. But when considering Ethernet packets, the highest theoretical throughput rates are 7.11 Mbps for IEEE 802.11b and 30.8 Mbps for IEEE 802.11a. Naturally, these wireless throughput rates are smaller than the wired ones (standard there is today 70–80 Mbps), but at least for the higher modulation rates with 1500 bytes Ethernet packets the throughput values are reasonably good. Note that the throughput rates given further decrease though as higher protocol levels produce additional overhead (or when the channel conditions cause packet losses). For example, measured throughput values for IEEE 802.11b are around 5 Mbps best-effort traffic in uninterfered environments [Mob01, MZ02].

For security IEEE 802.11 supports several authentication processes, which are listed in the specification (none is mandatory).[11] The most important future development of IEEE 802.11 is an extension to

[11]Neither Bluetooth nor IEEE 802.11 is renowned for their security concepts, and both have been criticized. Nevertheless, both systems have taken security aspects into consideration.

© 2005 by CRC Press LLC

the standard to enable QoS (IEEE 802.11e). For issues like roaming and hand-over higher protocol layers like mobile IP are responsible. They are not part of the standard.

Performance

Next to aspects like individual link throughput, network capacity, and interference robustness, the transmission environment has to be taken into consideration when intending to use IEEE 802.11 on the factory floor. As the scenarios envisioned for IEEE 802.11 were placed primarily in homes and offices, some differences occur when looking at the delay spread. While in homes and offices the delay spread is assumed to be <50 nsec and < 100 nsec resp., it takes on values of 200–300 nsec on factory floors [OP99].

In case of IEEE 802.11b, a conventional rake receiver supports (only) about 60 nsec delay spread in the 11 Mbps mode and 200 nsec in the 5.5 Mbps version [vNAM+99]. When using an IEEE 802.11b system with such a receiver on a factory floor intersymbol and/or interchip/codeword interference (ISI and/or ICI) are likely to degrade the performance noteworthily. When willing to provide adequate complexity though (in receiver algorithms and therefore in chip space), intelligent algorithms can be found that cope well with delay spreads of 1μsec [CLMK02, LMCW02] and even mobility of the user. It is just that the somewhat different factory floor environment has to be taken into account when making the choice. Another option, of course, is to use IEEE 802.11a (or HIPERLAN/2). Due to the guard interval inherent in the OFDM technology, delay spreads of several hundred nanoseconds can be easily supported [vNAM+99].

When considering the overall network performance and not just the individual link performance (or interference performance, as done in Section 38.7), note first of all that the number of publication presenting well-founded results is very limited. It seems to be general thinking that capacity in an IEEE 802.11a or b only network is not an issue. The three publications that do exist do not at all support this. In [Lin01], it is shown that cochannel interference with a carrier-to-interference ratio (CIR) of 5 dB still results in a packet loss rate of 10–20% ($BER=10^{-5}$) and that with a frequency offset of 5 MHz still CIR=3 dB is required to achieve the same result. Bianchi [Bia00] and Sadalgi [Sad00] present how the aggregate throughput in a single network decreases with the number of users, either due to hidden or exposed terminal problems or due to additional RTS/CTS overhead. With only 10 stations [Bia00] or a hidden node probability of 5% [Sad00], the system throughput is about halved (!) in case of 1500 byte payloads. Only when there are more than 25 stations is the RTS/CTS implementation justified, while the throughput is still reduced.

Thus, when installing IEEE 802.11a or b in a cellular fashion, some kind of frequency planning should be performed. For IEEE 802.11a or b, a respective mechanism has to be added (refer, e.g., to [Agh00] for frequency allocation algorithms). Note that the most relevant parameter for WLAN frequency planning is the number of mobile terminals that have to be served. From it the optimum number of access points (APs) and distance between APs can be determined. If it is desired that mobile stations can seamlessly change between APs (due to mobile deployment), hand-over algorithms have to be added.

Thus, IEEE 802.11 provides reliable best-effort traffic. The (theoretical) maximum transmission rates for IEEE 802.11a and b are 30.8 and 7.11 Mbps, respectively. To achieve network capacity values anywhere near three times these values (three parallel systems are possible), appropriate receivers and some sophisticated frequency planning should be provided, although a reduction should still be taken into account. In contrast to Bluetooth, IEEE 802.11 systems allow for higher data rates and larger ranges. IEEE 802.11 consumes (significantly) more power than Bluetooth and is not really suitable for speech connections. Currently, IEEE 802.11b chips are larger in size and more expensive than Bluetooth chips (IEEE 802.11a chips are not yet competitive).

38.6 HIPERLAN/2

Technical Background

HIPERLAN/2 is a WLAN standard that defines the physical (PHY), the data link control (DLC), and a convergence layer to enable the wireless access of Ethernet, PPP, UMTS, IEEE 1394, and ATM-based backbone networks with high data rates [Eur01b, Eur00c, Eur01a]. Due to the placement in the 5 GHz range

© 2005 by CRC Press LLC

also HIPERLAN/2 can operate globally without expensive frequency licenses. Like for IEEE 802.11 systems (but unlike for Bluetooth), the developers of HIPERLAN/2 products can nevertheless be charged for the use of the key patents on "fair, reasonable and nondiscriminatory terms" [Eur00a].

The PHY layer of HIPERLAN/2 is almost the same as the one of IEEE 802.11a: HIPERLAN/2 uses an OFDM-technique based on a 64-point IFFT/FFT with 48 user and 4 pilot carriers allowing various modulation and error control possibilities using the same carrier spacing and symbol duration as IEEE 802.11a. Depending on the transmit power used — in principle, values between 100 and 1000 mW are possible — the range is 30–60 m indoor and up to several hundred meters outdoor.

The main differences between the systems are found in the control layer. HIPERLAN/2 has a centralized structure that puts all traffic under the control of an access point (AP). Due to the thus smaller overhead but also due to the explicit specification of radio resource control (RRC) functions, larger transmission rates can be achieved with HIPERLAN/2 than with IEEE 802.11a (see also Table 38.3). The RRC functions do not only enable a dynamic frequency selection but additionally support mobility by providing for the required measurements for hand-over algorithms [KYW01]. Furthermore, the provision of radio bearers allows a differentiated treatment of the various traffic flows in the AP and thus enables a HIPERLAN/2 system to give QoS guarantees. Reliability of the data is given by a selective repeat ARQ mechanism [LLM+00]. Note that despite the central control of the AP, traffic can be transmitted directly between two mobile terminals (MTs). In this so-called "direct mode," the AP assigns a certain time window to the mobile units to comply this task.

HIPERLAN/2 organizes its traffic in MAC frames in a TDMA/TDD [GL00] fashion with adaptable time slot sizes. As shown in Figure 38.6, one 2 msec MAC-frame consists of a broadcast channel (BCH) that contains some identifiers and the transmission power, a frame channel (FCH) that defines the structure of the frame, an access feedback channel (ACH) that reports the results of previous access attempts, a period in which downlink or uplink protocol data units (PDUs) are transmitted and random access channels (RCHs) during which the mobile terminals can express their demands for transmit time. The durations of the downlink (**DL**, i.e., from AP to MT) and uplink (**UL**, i.e., from MT to AP) periods are flexible. Each PDU contains a preamble, control-PDUs (with, e.g., acknowledgement information) and user-PDUs. Only one PDU per MT can be transmitted per MAC-frame. Nevertheless, if the AP wants to serve one MT only it can decide to transmit a PDU that takes up the whole DL-period.

As the transmitted data flow are partitioned into 54 bytes long U-PDUs, the actual throughput values for HIPERLAN/2 do not depend so much on the packet sizes that arrive. Nevertheless, each PDU requires its own preamble (of $t_{p,DL} = 8$ μsec and $t_{p,UL,\ min} = 12$ μsec); hence, the system throughput decreases somewhat with the number of users N_U served within one MAC-frame. Assuming a constant overhead of $t_{OV,min} = 120$ μsec per MAC frame and that for each user served in the DL a 9 bytes long C-PDU has to be transmitted in

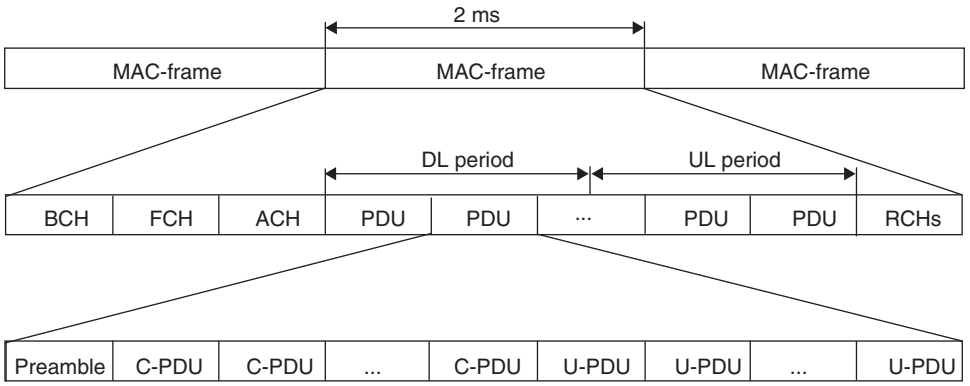

FIGURE 38.6 MAC-frame structure in HIPERLAN/2.

© 2005 by CRC Press LLC

TABLE 38.3 Comparison of different achievable maximum throughput rates in [Mbps] for 1500 bytes Ethernet packets considering different numbers of users that are simultaneously served by the AP

Modulation	CodeRate	ModRate [Mbps]	*TP* [Mbps] for N_U users			
			1	2	5	10
BPSK	1/2	6	5.36	5.36	4.93	4.5
BPSK	3/4	9	8.14	8.14	7.71	7.07
QPSK	1/2	12	10.9	10.7	10.3	9.43
QPSK	3/4	18	16.5	16.3	15.6	14.6
16-QAM	9/16	27	24.9	24.4	23.6	21.9
16-QAM	3/4	36	33.0	32.6	31.3	29.1
64-QAM	3/4	54	49.7	49.1	47.1	43.9

the UL the maximum system throughput values *TP* can be calculated with the help of Equations (5) and (6). Like for IEEE 802.11a $t_{\text{sym}} = 4\ \mu$ sec.

$$2ms - t_{OV,min} \geq N_U \underbrace{\left(t_{p,UL,min} + ceil\left(\frac{9 \cdot 8}{ModRate/12\ \text{Mbps} \cdot 48}\right) t_{sym}\right)}_{t_{C-PDU}} + \sum_{i=1}^{N_U} \underbrace{\left(t_{p,DL} + ceil\left(\frac{54 \cdot N_{PDU,i} \cdot 8}{ModRate/12\ \text{Mbps} \cdot 48}\right) t_{sym}\right)}_{t_{U-PDU,\,i}} \tag{5}$$

$$TP = \frac{54 \cdot 8}{2ms} \sum_{i=1}^{N_U} N_{PDU,i} \frac{PayBytes/54}{ceil(PayBytes/54)} \tag{6}$$

Naturally, for PayBytes values that just do not fit into one PDU (like PayBytes=60) the throughput values are reduced significantly (still not as badly as small payloads reduce the 802.11a throughput). Nevertheless, for better fitting or larger packet sizes good system throughput values can be achieved (see Table 38.3 for 1500 bytes Ethernet packets). While in this case the average PHY layer induced reduction is only around 13% for HIPERLAN/2, it is around 25% for IEEE 802.11a. The situation becomes more unfavorable for IEEE 802.11a, the smaller the payload size is.

For security, the HIPERLAN/2 specification foresees encryption (DES and TripleDES) and authentication.

Performance

The investigations of the HIPERLAN/2 performance show first of all that HIPERLAN/2 can well cope with a wide range of channel conditions. In case of delay spreads typical for industrial applications (around 250 nsec, which in outdoor environments corresponds to cell radii of at least 100 m), the system shows no performance degradation, thanks to the robustness of the OFDM PHY [KJSWW99].

The radio network performance in office and exhibition hall environments (the latter scenario being comparable to a factory floor) is promising, too. In office scenarios, system throughput values close to the maximum throughput can easily be reached [MKJST00]. In the exhibition hall, the performance depends somewhat more on the scheduling [LMP+00], link adaptation [TM99], and frequency planning algorithms used [HZ00] as well as on the antenna design [TM99]. With good algorithms though, also in the exhibition hall high throughput values are possible. In [HZ00], it is additionally shown that adaptive frequency planning outperforms a regular fixed frequency plan (which is what would — if at all — be possible for an IEEE 802.11 system), while the frequency reselection rate remains small (less than 1 per hour in the investigated exhibition hall scenario).

HIPERLAN/2 is thus a robust WLAN technology that, due to explicitly considering the obstacles of wireless networking, achieves maximum system throughput values of 50–44 Mbps for 1–10 users simultaneously served. This is the case even for more difficult industrial applications, that is, on factory floors.

© 2005 by CRC Press LLC

As HIPERLAN/2 organizes regular measurements of the channel conditions it can even cope with changing environments and mobility. Due to the centralized structure, HIPERLAN/2 is — compared with IEEE 802.11 systems — very power consumption friendly (the MTs know the periods when to listen) and supports QoS services. HIPERLAN/2 chip sets are not yet competitive.

38.7 Coexistence of WPAN and WLAN (Bluetooth and IEEE 802.11b)

It would be most desirable when every mobile unit can connect effortlessly using whatever technology is most suitable at the time. Multiple wireless technologies will thus coexist in the near future: within an enterprise, for example, WLAN technologies could be used for flexible access to large corporate databases while WPAN technologies handle specific tasks (and cellular systems the voice communication). This is generally not an issue unless the technologies are placed in the same frequency band and/or are linked by the application with each other (example: someone uses a Bluetooth head set with the mobile telephone). The two technologies that are placed in the same frequency band[12] and that are, due to their popularity, quite likely to be used in such a scenario (and possibly even in the same device) are Bluetooth and IEEE 802.11b.

Numerous publications cover the mutual interference and performance impairments of the systems (e.g., [Enn98, Zyr98, GvDS01, Fum01, How01, Mob01, MZ02]). Depending on the investigated scenarios, the assessment of the situation varies from "good reliability even in fairly dense environments" to "the effects of interference can be quite severe". A relative agreement exists in the causes that determine the systems' performances: link distances (BT–BT, 802.11b–802.11b, BT transmitter–802.11b receiver, BT receiver–802.11b transmitter), traffic load, Bluetooth packet type, density of units, local propagation conditions. Some of the results are briefly summarized in the following.

IEEE 802.11b requires about a CIR of 10dB to cope with a (narrow band) Bluetooth hop into its (wide) pass-band. IEEE 802.11b has the disadvantage that its back-off procedure was designed to optimize the IEEE 802.11b WLAN performance but not to handle external interferers: Each loss of a packet due to a collision with Bluetooth will increase the back-off window size by factor two (causing an unnecessary throughput reduction). Furthermore, the protocols overlaying WLAN often incorporate TCP, which includes the risk that packet losses on the air link are mistaken for network congestion, which then might initiate a slow start. In contrast, the main disadvantage of Bluetooth is that its transmit power is 20 dB below that of IEEE 802.11b. Another one is that the BT reverse link packet that contains the acknowledgement is transmitted on a different frequency than the forward link packet. This increases the packet loss probability in case of (frequency static) IEEE 802.11b interference. The packet loss rate PLR_{BT} then yields to

$$PLR_{BT} = PLR_{forward} + \underbrace{(1 - PLR_{forward}) \cdot PLR_{header}}_{PLR_{reverse}} \tag{7}$$

It would otherwise — were the forward and reverse link to use same hop frequency — be $PLR_{BT} \approx PLR_{forward}$ (depending on the IEEE 802.11b system load).

There are, in principle, three different approaches to assist otherwise interfering systems to coexist: Separation in time, separation in frequency, or separation in space.[13]

- *Separation in the frequency domain*:
  1. IEEE 802.11b can be used with an improved transmit filter that reduces the interference power on the side lobe frequencies and thus enhances the separation on those carriers.

[12]Next to other technologies like HomeRF networks [HRF], RF-ID systems [Fin00], microwave ovens, etc.

[13]The approaches "separation through code" (keyword "CDMA"), through the channel (keyword "MIMO"), or through the modulation ("I versus Q") allow to unlink several users of *the same* system. It is not obvious though to apply any of these latter methods to improve the coexistence of *different* systems, which is what is needed here.

© 2005 by CRC Press LLC

2. Bluetooth can perform adaptive frequency hopping (AFH) — which is currently being specified [Blu02] —, that is, exclude the most heavily interfered frequencies from its hop sequence. Note that in several realistic situations AFH is sufficient to combat the interference effects.

- *Separation in the time domain*:
  1. The IEEE 802.11b carrier sensing algorithm could also consider Bluetooth signals[14] as well as Bluetooth could be extended with a carrier sensing algorithm [ZKJ00]. The principle problem of carrier sensing though is, that to be really effective, the transmitter has to sense the situation at the receiver correctly, that is, the correlation between transmitter and receiver situation has to be high. In an uncoordinated WLAN–WPAN scenario, the hidden as well as the exposed terminal problems are likely to countermeasure any advantage there might be.
  2. A joint scheduler can allot alternating transmit time shares to both systems in a (to be specified) fair way. This, of course, only works (and with AFH is necessary only) when both systems are in one device, or even on one chip.

- *Separation in space*:
  1. Should IEEE 802.11b and Bluetooth co-exist in the same unit an intelligent antenna design and placement can optimize the isolation between the Bluetooth and IEEE 802.1 1b antennas. This will not prevent collisions but minimizes their impact by maximizing the CIRs for the two systems.[15]
  2. Antenna diversity can help each of the two technologies individually to improve its performance.

38.8 Summary and Conclusions

When deciding on a wireless technology to use, first the characteristics of the foreseen application have to be clarified: do you want to move with or within the network, do you have mobility within a small range or in a larger area, at what speed do the units move, do you need access to large data basis or just locally, is battery life a critical issue, what maximum length can the wireless link have, what length does it have in average, etc.? As a next step, the existing technologies can be viewed for their applicability.

Between the WLAN and WPAN technologies discussed here the main distinction is the range in which connectivity can be established (WPAN small, WLAN larger) and thus whether movement takes place rather with (WPAN) or within the network (WLAN).

Bluetooth is a WPAN technology that is very power efficient. Like any other wireless system, it cannot provide hard throughput guarantees. Bluetooth is nevertheless quite robust for best-effort traffic in coexistence environments. One hundred Bluetooth piconets can transmit at an average data rate of 95%·33.2 kbps in an area of 10×20 m^2. Fifty fully loaded piconets can transmit at an average, unidirectional transmission rate of 360 kbps. Similar results are likely to be achieved on larger factory floors (with comparable piconet density), as the disadvantage of a larger number of units can be outweighed by the more structured and predictable unit location.

IEEE 802.11 is a WLAN technology that is not too power consumption friendly. Additionally, in a relatively dense network scenario, the maximum aggregate throughput of three times 7.11/30.8 Mbps is likely to be seriously impaired. To aid the WLAN performance on a factory floor, it is thus advisable to take the following two measures: apply means to combat the increased delay spread (in case of IEEE 802.11b) and additionally (for any IEEE 802.11 system) carefully plan the frequency layout and access point placement.

[14]As has been mentioned before, the IEEE 802.11b specification already provides for the possibility that IEEE 802. 11b senses and not transmits if other than systems IEEE 802.11b systems are active [Ins99b, Section 18.4.8.4]. Next to the fact that most implementations do not seem to support this option, the principle problem is that IEEE 802.11b will refrain from transmission when it senses that Bluetooth *transmits.* To improve coexistence though IEEE 802.11b should refrain from transmission when the nearby Bluetooth units receive.

[15]Helpful to minimize the interference power is of course also power control (when applied by the interfering unit). Nevertheless, even though it can be recommended to implement power control (let alone to save power [MZT03]), in real life situations it cannot be relied upon that the interfering unit can indeed live with less power.

© 2005 by CRC Press LLC

Within HIPERLAN/2, means for dynamic frequency selection are already included and HIPERLAN/2 is certainly the more suitable WLAN technology for industrial applications. Next to allowing for higher throughput rates (three times 44 Mbps should be achievable without problem), HIPERLAN/2 is due to its centralized structure more power efficient and supports different Quality-of-Service classes.

The most efficient measure to aid the coexistence of Bluetooth and IEEE 802.11b is to use Bluetooth with adaptive frequency hopping. If this is not sufficient, hardware-related improvements and/or a common scheduler have to be added.

39.1 Basics

Fieldbuses are industrial communication systems with bit-serial transmission that use a range of media such as copper cable, fiber optics, or radio transmission to connect distributed field devices (sensors, actuators, drives, transducers, analyzers, etc.) to a central control or management system. Fieldbus technology was developed in the 1980s with the aim to save cabling costs by replacing the commonly used central parallel wiring and dominating analog signal transmission (4–20 mA- or ± 10 V interface) with digital technology. Due to the different industry-specific demands, to sponsored research and development projects or preferred proprietary solutions of large system manufacturers, several bus systems with varying principles and properties were established in the market. The key technologies are now included in the recently adopted standards IEC 61158 and IEC 61784 [1]. *PROFIBUS is an integral part of these standards.* Fieldbuses create the basic prerequisite for distributed automation systems. Over the years, they evolved to instruments for automated processes with high productivity and flexibility compared to conventional technology (Figure 39.1).

PROFIBUS is an open, digital communication system with a wide range of applications, particularly in the fields of factory and process automation, transportation, and power distribution. PROFIBUS is suitable for both fast, time-critical applications, and complex communication tasks.

© 2005 by CRC Press LLC

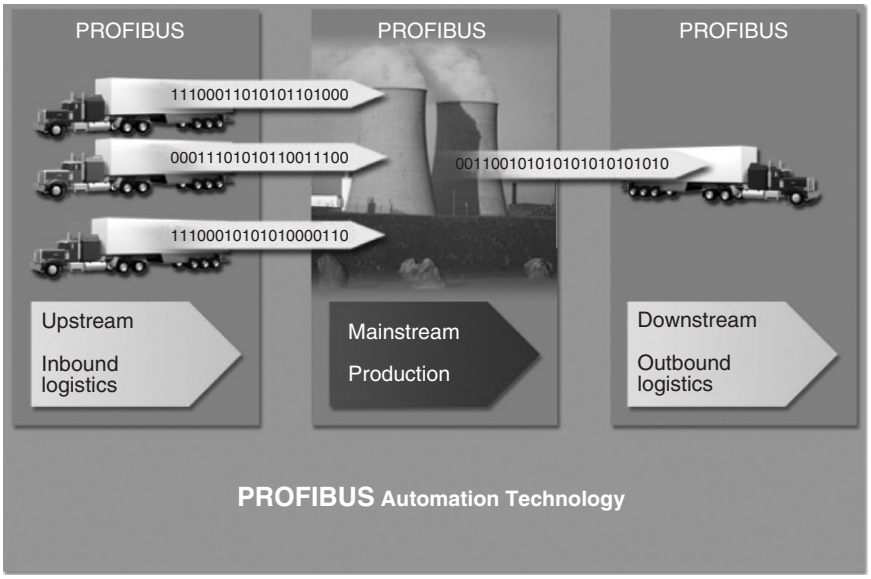

FIGURE 39.1 PROFIBUS suitable for all decentralized applications.

The application and engineering aspects are specified in the generally available guidelines of the PROFIBUS User Organization [2]. This fulfills user demand for standardization, manufacturer independence and openness, and ensures communication between devices of various manufacturers.

Based on a very efficient and extensible communications protocol, combined with the development of numerous application profiles (communication models for device type families) and a fast growing number of devices and systems, PROFIBUS began its record of success, initially in factory automation and, since 1995, in process automation. Today, PROFIBUS is the world market leader for fieldbuses with more than a 20% share of the market, approx. 500,000 equipped plants, and more than 10 million nodes. Today, there are more than 2000 PROFIBUS products available from a wide range of manufacturers.

The success of PROFIBUS stems in equal measures from its progressive technology and the strength of its noncommercial PROFIBUS User Organization e.V. (*PNO*), the trade body of manufacturers and users founded in 1989. Together with the 22 other regional PROFIBUS associations within countries all around the world, and the international umbrella organization PROFIBUS International (*PI*) founded in 1995, this organization now totals more than 1200 members worldwide. Objectives are the continuing further development of PROFIBUS technology and increasing worldwide acceptance.

PROFIBUS has a modular structure (PROFIBUS Tool Box) and offers a range of *transmission and communication technologies*, numerous *application and system profiles* as well as *device management and integration tools*. Thus PROFIBUS covers the various and application-specific demands from the field of factory to process automation, from simple to complex applications, by selecting the adequate set of components out of the toolbox (Figure 39.2).

39.2 Transmission Technologies

PROFIBUS features four different transmission technologies, all of which are based on international standards. They all are assigned to PROFIBUS in both IEC 61158 and IEC 61784: RS485, RS485-IS, and MBP-IS (IS stands for intrinsic safety protection), and Fiber Optics.

RS485 transmission technology is simple and cost-effective and is primarily used for tasks that require high transmission rates. Shielded, twisted pair copper cable with one conductor pair is used. No expert knowledge is required for installation of the cable. The bus structure allows addition or removal of stations or the step-by-step commissioning of the system without interfering in other stations. Subsequent expansions (within defined limits) have no effect on stations already in operation.

© 2005 by CRC Press LLC

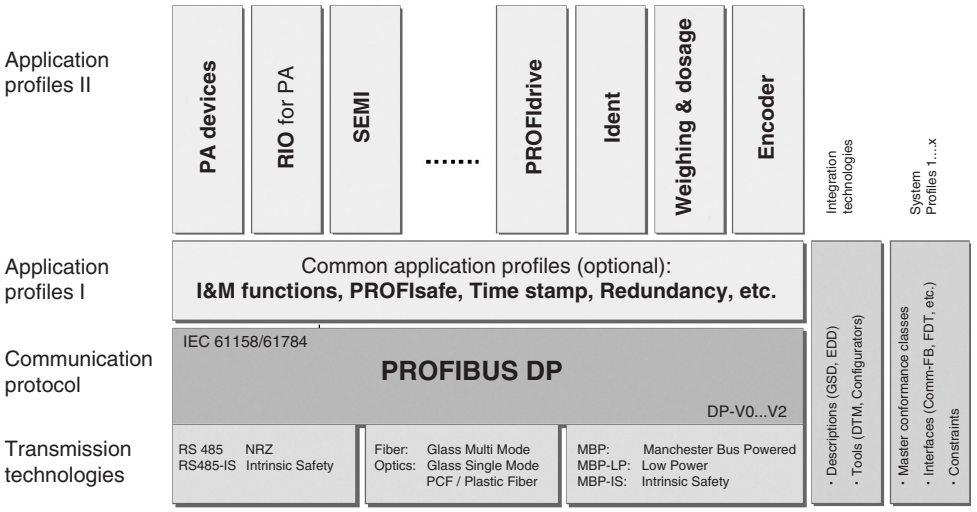

FIGURE 39.2 Structure of PROFIBUS system technology.

Various *transmission rates* can be *selected* from 9.6 Kbit/sec up to 12 Mbit/sec. One uniform speed is selected for all devices on the bus when commissioning the system. Up to *32 stations* (master or slaves) can be connected in a single segment. For connecting more than 32 stations, repeaters can be used. The maximum permissible *line length* depends on the transmission rate.

Different cable types (type designation A – D) for different applications are available on the market for connecting devices either to each other or to network elements (segment couplers, links and repeaters). When using RS485 transmission technology, PI recommends the use of *cable type A*.

RS485-IS transmission technology responds to an increasing market demand to support the use of RS485 with its fast transmission rates within intrinsically safe areas. A PROFIBUS guideline is available for the configuration of intrinsically safe RS485 solutions with simple device interchangeability. The interface specification details the levels for current and voltage that must be adhered to by all stations in order to ensure safe operation during interconnection. An electric circuit limits currents at a specified voltage level. When connecting active sources, the sum of the currents of all stations must not exceed the maximum permissible current. In contrast to the FISCO model (see below), *all* stations represent active sources. Up to 32 stations may be connected to the intrinsically safe bus circuit.

MBP type transmission technology ("**M**anchester Coding" and "**B**us **P**owered") is a new term that replaces the previously common terms for intrinsically safe transmission such as "Physics in accordance with IEC 61158-2," "1158-2," etc. In the meantime, the current version of the IEC 61158-2 (physical layer) describes *several different* transmission technologies, MBP technology being just one of them. Thus, differentiation in naming was necessary.

MBP is a *synchronous, Manchester-coded transmission with a defined transmission rate of 31.25 Kbit/sec.* In its version **MBP-IS,** it is frequently used in process automation as it satisfies the key demands of the chemical and petrochemical industries for *intrinsic safety* and *bus powering using two-wire technology*.

MBP transmission technology is usually limited to a specific segment (field devices in hazardous areas) of a plant, which is then linked to an RS485 segment via a *segment coupler* or *links* (Figure 39.3).

Segment couplers are signal converters that modulate the RS485 signals to the MBP signal level and *vice versa*. They are transparent from a bus protocol's point of view. In contrast, *links* are providing more computing power. They virtually map the entire field devices connected to the MBP segment into the RS485 segment as a single slave. Tree or line structures (and any combination of the two) are network topologies supported by PROFIBUS with MBP transmission with up to 32 stations per segment and a maximum of 126 per network.

© 2005 by CRC Press LLC

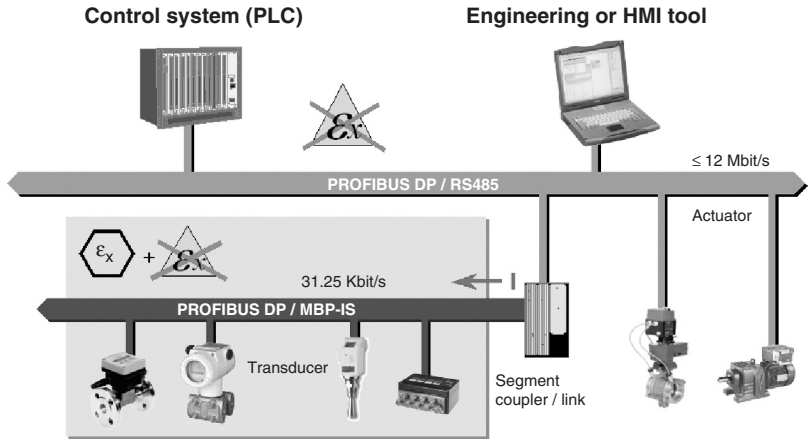

FIGURE 39.3 Intrinsic safety and powering of field devices using MBP-IS.

Fiber Optic transmission technology is used for fieldbus applications with very high electromagnetic interference or that are spread over a large area or distance.

The PROFIBUS guideline for fiber optic transmission [3] specifies the technology available for this purpose including multimode and single-mode glass fiber, plastic fiber, and HCS® fiber. Of course, while developing these specifications, great care was taken to allow problem-free integration of existing PROFIBUS devices in a fiber optic network without the need to change the protocol behavior of PROFIBUS. This ensures *backward compatibility* with existing PROFIBUS installations.

The internationally recognized **FISCO model** considerably simplifies the planning, installation, and expansion of PROFIBUS networks in potentially explosive areas. FISCO stands for *Fieldbus Intrinsically Safe Concept*. It has been developed by the German PTB [4]. The model is based on the specification that a network is intrinsically safe and requires no individual intrinsic safety calculations when the relevant four bus components (field devices, cables, segment couplers, and bus terminators) fall within predefined limits with regard to voltage, current, output, inductance, and capacity. The corresponding proof can be provided by certification of the components through authorized accreditation agencies, such as PTB (Germany) or UL, and FM (USA) and others.

If FISCO-approved devices are used, not only is it possible to operate more devices on a single line, but the devices can be replaced during runtime by devices of other manufacturers or the line can be expanded — all without the need for time-consuming calculations or system certification. So you can simply plug & play, even in hazardous areas!

39.3 Communication Protocol

PROFIBUS DP

At the protocol level, PROFIBUS with Decentralized Peripherals (DP) and its versions DP-V0 to DP-V2 offer a broad spectrum of optional services, which enable optimum communication between different applications.

DP has been designed for *fast data exchange at field level*. Data exchange with the distributed devices is primarily cyclic. The communication functions required for this are specified through the DP basic functions (*version DP-V0*). Geared toward the special demands of the various areas of application, these basic DP functions have been expanded step-by-step with special functions, so that DP is now available in three versions, DP-V0, DP-V1, and DP-V2, whereby each version has its own special key features. All versions of DP are specified in detail in the IEC 61158 and IEC 61784, respectively.

© 2005 by CRC Press LLC

Version DP-V0 provides the basic functionality of DP, including cyclic data exchange as well as station diagnosis, module diagnosis, and channel-specific diagnosis.

Version DP-V1 contains enhancements geared toward process automation, in particular, acyclic data communication for parameter assignment, operation, visualization, and alarm handling of intelligent field devices, in coexistence with cyclic user data communication. This permits online access to stations using engineering tools. In addition, DP-V1 defines alarms. Examples for different types of alarms are status alarm, update alarm, and a manufacturer-specific alarm.

Version DP-V2 contains further enhancements and is geared primarily toward the demands of drive technology. Due to additional functionalities, such as isochronous slave mode and slave-to-slave(s) communication (DXB), etc., the DP-V2 can also be implemented as a drive bus for controlling fast movement sequences in drive axes.

System Configuration and Device Types

DP supports implementation of both mono-master and multi-master systems. This affords a high degree of flexibility during system configuration. A maximum of 126 devices (masters or slaves) can be connected to a bus segment. In *mono-master systems,* only *one* master is active on the bus during operation of the bus system. Figure 39.4 shows the system configuration of a mono-master system. In this case, the master is hosted by a PLC.

The PLC is the central control component. The slaves are connected to the PLC via the transmission medium. This system configuration enables the shortest bus cycle times. In **multi-master systems,** several masters are sharing the same bus. They represent both independent subsystems, comprising masters and their assigned slaves, and/or additional configuration and diagnostic master devices. The masters are coordinating themselves by passing a token from one to the next. Only the master that holds the token can communicate. PROFIBUS DP differentiates three groups of device types on the bus.

DP master class 1 (DPM1) is a central controller that cyclically exchanges information with the distributed stations (slaves) at a specified message cycle. Typical DPM1 devices are programmable logic controllers (PLCs) or PCs. A DPM1 has active bus access with which it can read measurement data (inputs) of the field devices and write the setpoint values (outputs) of the actuators at fixed times. This continuously repeating cycle is the basis of the automation function (Figure 39.4).

DP masters class 2 (DPM2) are engineering, configuration, or operating devices. They are put in operation during commissioning and for maintenance and diagnostics in order to configure connected

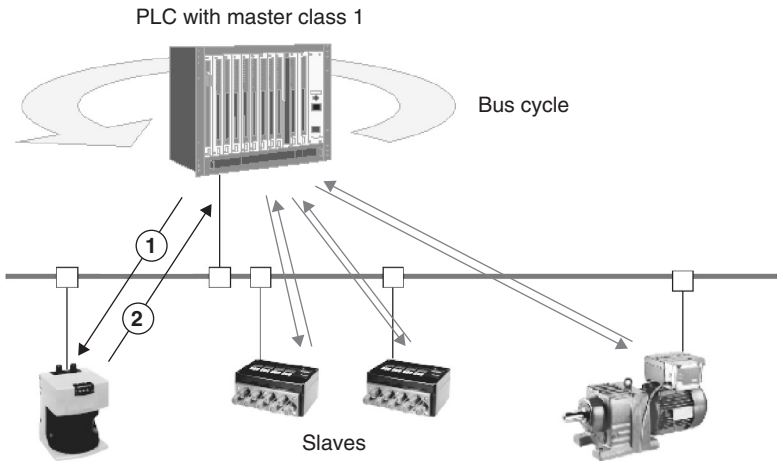

FIGURE 39.4 PROFIBUS DP mono-master system (DP-V0).

© 2005 by CRC Press LLC

devices, evaluate measured values and parameters, and request the device status. A DPM2 does not have to be permanently connected to the bus system. The DPM2 also has active bus access.

Slaves are peripherals (I/O devices, drives, HMIs, valves, transducers, analyzers), which read in process information and/or use output information to intervene in the process. There are also devices that solely provide input information or output information. As far as communication is concerned, slaves are passive devices; they only respond to direct queries (see Figure 39.4, sequence ① and ②). This behavior is simple and cost-effective to implement. In the case of DP-V0, it is already completely included in the Bus-ASIC.

Cyclic and Acyclic Data Communication Protocols

Cyclic data communication between the DPM1 and its assigned slaves is automatically handled by the DPM1 in a defined, recurring sequence (Figure 39.4). The appropriate services are called MS0. The user defines the assignment of the slave(s) to the DPM1 when configuring the bus system. The user also defines which slaves are to be included/excluded in the cyclic user data communication. DPM1 and the slaves are passing three phases during start-up: parameterization, configuration, and cyclic data exchange (Figure 39.5).

Before entering the cyclic data exchange state, the master first sends information about the transmission rate, the data structures within a PDU, and other slave-relevant parameters. In a second step, it checks whether the user-defined configuration matches the actual device configuration. Within any state, the master is enabled to request slave diagnosis in order to indicate faults to the user.

An example for the message structure for the transmission of information between master and slave is shown in Figure 39.6. The message starts with some synchronization bits, the type (SD) and length (LE) of the message, source and destination address, and a function code (FC). The function code indicates the type of message or content of the "load" (Processing Data Unit) and serves as a guard to control the state machine of the master. The PDU, which may carry up to 244 bytes, is followed by a safeguard mechanism Frame Checking Sequence (FCS) and a delimiter.

One example for the usage of the function code (FC) is the indication of a fault situation on the slave side. In this case, the master sends a special diagnosis request instead of the normal process data exchange that the slave replies with a diagnosis message. It comprises 6 bytes of fixed information and additional user definable device, module, or channel-related diagnosis information [1,7].

In addition to the single station-related user data communication, which is automatically handled by the DPM1, the master can also send control commands to all slaves or a group of slaves simultaneously. These control commands are transmitted as multicast messages and enable sync and freeze modes for *event-controlled synchronization* of the slaves [1,7].

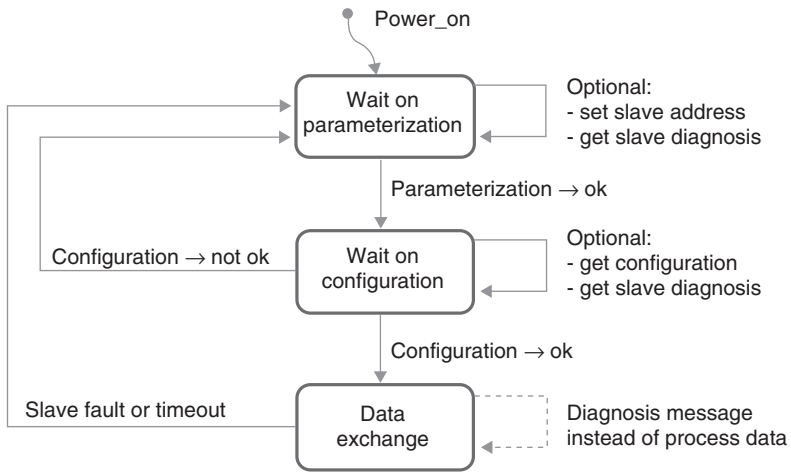

FIGURE 39.5 State machine for slaves.

© 2005 by CRC Press LLC

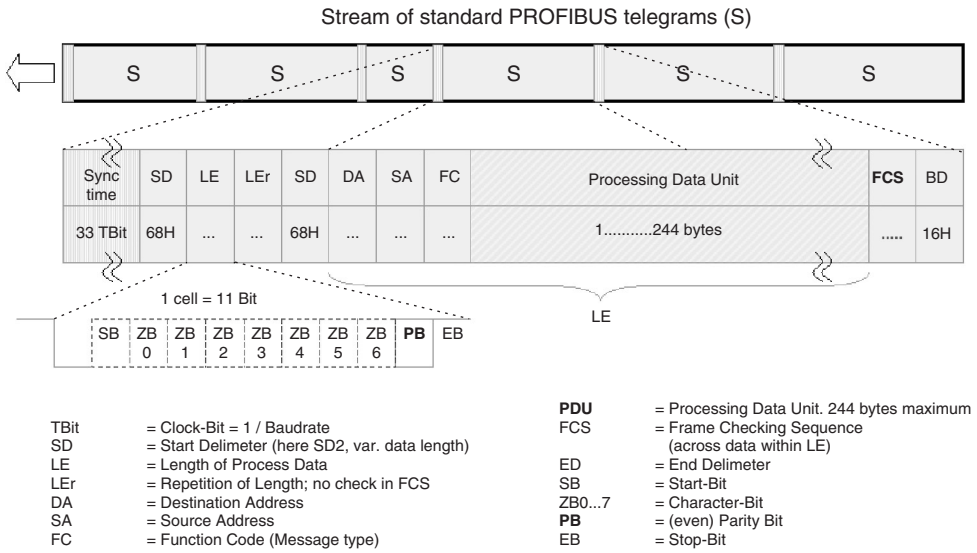

FIGURE 39.6 PROFIBUS DP message structure (example).

For safety reasons, it is necessary to ensure that DP has effective *protective functions* against incorrect parameterization or failure of transmission equipment. For this purpose, the DP master and the slaves are fitted with monitoring mechanisms in the form of time monitors. The monitoring interval is defined during configuration.

Acyclic data communication is the key feature of version DP-V1. This forms the requirement for parameterization and calibration of the field devices over the bus during runtime and for the introduction of confirmed alarm messages. Transmission of acyclic data is executed parallel to cyclic data communication, but with a lower priority. Figure 39.7 shows some sample communication sequences for a master class 2, which is using MS2 services. In using MS1 services, a master class 1 is able to execute acyclic communications also.

Slave-to-Slave Communications (DP-V2) enable direct and timesaving communication between slaves using broadcast communication without the detour over a master. In this case, the slaves act as "publisher," that is, the slave response does not go through the coordinating master, but directly to other slaves embedded in the sequence, the so-called "subscribers" (Figure 39.8). This enables slaves to directly read data from other slaves and use them as their own input. This opens up the possibility of completely new applications; it also reduces response times on the bus by up to 90%.

Isochronous mode (DP-V2) enables clock synchronous control in masters and slaves, irrespective of the busload.

The function enables highly precise positioning processes with clock deviations of $<1\mu$sec. All participating device cycles are synchronized to the bus master cycle through a "global control" broadcast message. A special sign of life (consecutive number) allows monitoring of the synchronization.

Clock control (DP-V2) via a new master slave service synchronizes all stations to a system time with a deviation of <1msec. This allows the precise tracking of events. This is particularly useful for the acquisition of timing functions in networks with numerous masters. This facilitates the diagnosis of faults as well as the chronological planning of events.

Upload and download (DP-V2) allows the loading of any size of data area in a field device with the help of a few commands. Within IEC 61158, these services are called *load region*. This enables, for example, programs to be updated or devices replaced without the need for manually loading processes.

Addressing with slot and index is used both for cyclic and acyclic communication services (Figure 39.9) When addressing data, PROFIBUS assumes that the physical structure of the slaves is *modular* or can be

© 2005 by CRC Press LLC

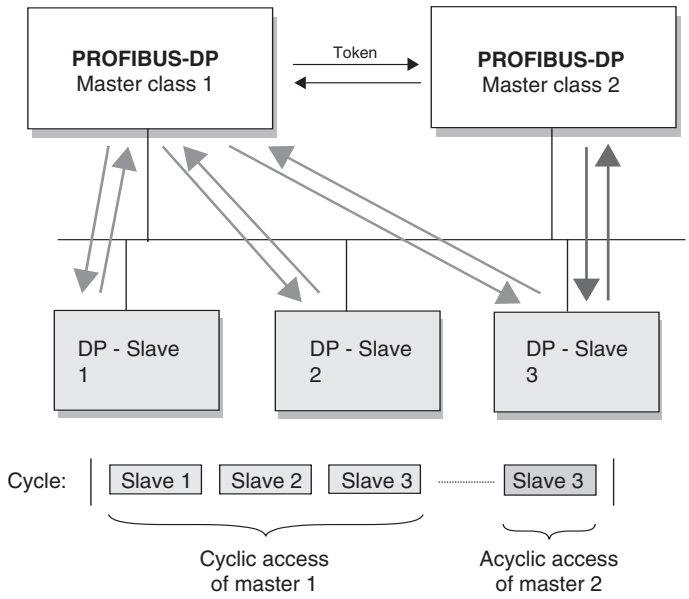

FIGURE 39.7 Cyclic and acyclic data communication with DP-V1.

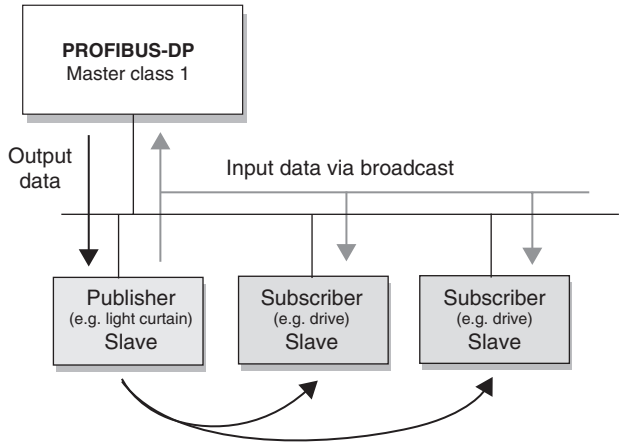

FIGURE 39.8 Slave to slaves data exchange.

structured internally in logical functional units, so-called *modules* (Figure 39.9). The slot number addresses the module and the index addresses the data records assigned to a module. Each data record can be up to 244 bytes. The modules begin at slot 1 and are numbered in ascending contiguous sequence. The slot number 0 is for the device itself. Compact devices are regarded as a unit of virtual modules. These can also be addressed with slot number and index.

39.4 Application Profiles

Profiles are used in automation technology to define specific properties and behavior for devices, device families, or entire systems. Only devices and systems using a vendor-independent profile provide interoperability on a fieldbus, thereby fully exploiting the advantages of a fieldbus. Profiles take into account application and type-specific special features of field devices, controls, and methods of integration (engineering). The

© 2005 by CRC Press LLC

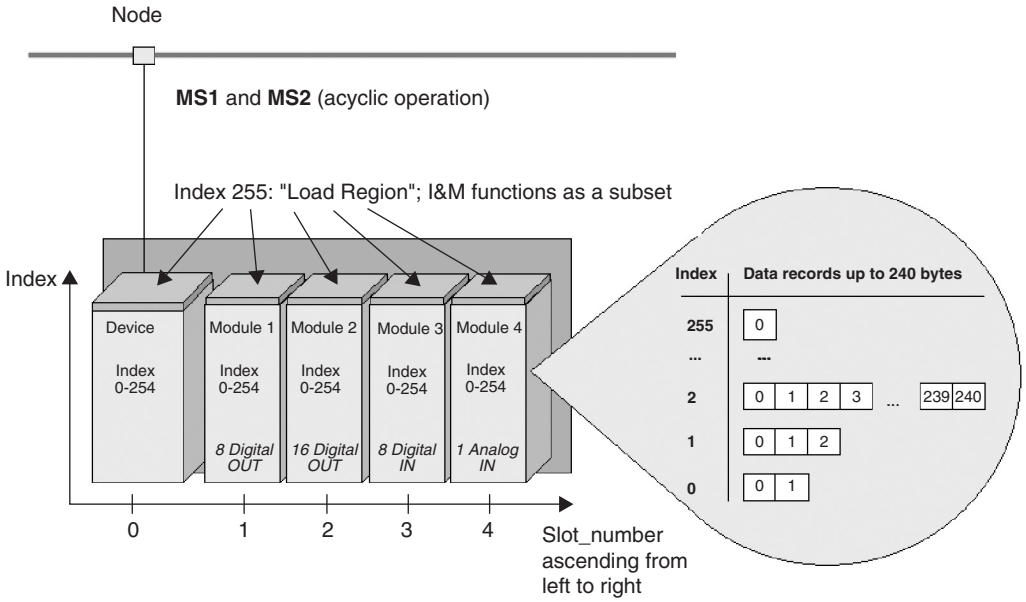

FIGURE 39.9 Slot/index address model of a slave.

term profile ranges from just a few specifications for a specific device class through comprehensive specifications for applications in a specific industry. The generic term for all profiles is *application profiles*.

A distinction is then drawn between *general application profiles* with implementation options for different applications (this includes, e.g., the profiles I&M functions, PROFIsafe, Redundancy, and Time stamp), *specific application profiles*, which are developed for a specific application, such as PROFIdrive, SEMI, or PA Devices, and *system and master profiles,* which describe specific system performance that is available to field devices.

PROFIBUS offers a wide range of such application profiles, which allow application-oriented implementation.

General Application Profiles

Identification and maintenance functions are mandatory for all PROFIBUS devices with MS1 and/or MS2 services. The main purpose of the I&M functions described hereinafter is to support the end user during various scenarios of a device's life cycle be it configuration, commissioning, parameterization, diagnosis, repair, firmware update, asset management, audit trailing, and alike. It is kind of a "type plate" or "boiler plate." The corresponding parameters all are stored at the same address space within the PROFIBUS slot/index address model.

Using the "call" mechanism of the load region services [1] opens up an additional subindex address space of 65,535 data records. The I&M functions are assigned a space between 65,000 and 65,199 for basic, profile-specific, and manufacturer-specific items. Table 39.1 itemizes the individual parameters.

The usage of IDs may not be very helpful for the user if a tool is displaying the information directly out of the device (Figure 39.10). However, nowadays, laptops or engineering tools normally have access to the Internet, at least temporarily. Thus, it is quite easy to reference a central database (e.g., on the PROFIBUS web server) and retrieve comprehensive and always actual information even in a desired language.

PROFIsafe is a comprehensive, open fieldbus solution for safety-relevant applications without the use of a second relay-based layer or proprietary safety buses. PROFIsafe defines how fail-safe devices (emergency stop pushbuttons, light curtains, level switches, etc.) can communicate over PROFIBUS with

TABLE 39.1 Basic Identification and Maintenance Functions

I&M function	Data Format	Notes
MANUFACTURER_ID	2 Octets	I&M functions are using company IDs instead of names. These IDs are harmonized with the list of the HART Foundation and comprise extensions for additional companies.
ORDER_ID	20 Octets	Order number for a particular device type. For virtual modular devices the root or highest level of the basic device.
SERIAL_NUMBER	16 Octets	Unique identifier for a particular device (counter).
HARDWARE_REVISION	2 Octets	The content of this parameter characterizes the edition of the hardware only.
SOFTWARE_REVISION	4 Octets	The content of this parameter characterizes the edition of the software or firmware of a device or module. The structure supports coarse and detailed differentiation that may be defined by the manufacturer: Vx.y.z.
REV_COUNTER	2 Octets	Indicates unplugging of modules or write access.
PROFILE_ID	2 Octets	Device or module corresponds to a particular PROFIBUS profile.
PROFILE_SPECIFIC_TYPE	2 Octets	This identifier references a device class defined within a PROFIBUS profile.
IM_VERSION	2 Octets	Version of the I&M functions implemented within a device or module.
IM_SUPPORTED	2 Octets	Directory for the subset of I&M functions implemented within a device or module.
TAG_FUNCTION	32 Octets	User definable information about the "role"of the device within a plant facility.
TAG_LOCATION	22 Octets	User definable information about the "location coordinates" of the device within a plant facility.
INSTALLATION_DATE	16 Octets	Indicates the data of installation or commissioning of a device or module. E.g. **1995-02-04 16:23**
DESCRIPTOR	54 Octets	User defined comments.
SIGNATURE	54 Octets	Allows parameterization tools to store a "security" code as a reference for a particular parameterization session and audit trail tools to retrieve the code for integrity checks. Used for safety applications according 21 CFR 11 [6] or hazardous machinery (PROFIsafe).

fail-safe controllers in such a manner that they can be used for safety-relevant automation tasks up to category 4 compliant with EN954 (ISO 13849) or SIL3 (**S**afety **I**ntegrity **L**evel) according to IEC 61508. It implements safe communications over a profile, that is, over a special PROFIsafe data frame and a special protocol. PROFIsafe is a single-channel *software solution*, which is implemented in the devices as an additional layer "above" layer 7 (Figure 39.11); the standard PROFIBUS components, such as lines, ASICs, or protocols, remain unchanged. This ensures redundancy mode and retrofit capability. Devices with the PROFIsafe profile can be operated in coexistence with standard devices without restriction on the same bus (cable).

PROFIsafe takes advantage of the acyclic communication (DP-V1) for full maintenance support of the devices and can be used with RS485, fiber optic, or MBP transmission technology. This ensures both fast response times (important for the manufacturing industry) and low power consumption with intrinsically safe operation (important for process automation).

HART on PROFIBUS DP integrates HART devices installed in the field, in existing or new PROFIBUS systems. It includes the benefits of the PROFIBUS communication mechanisms without any changes required to the PROFIBUS protocol and services, the PROFIBUS PDUs (Protocol Data Units) or the state machines, and functional characteristics. This profile is implemented in the master and slave above layer 7, thus enabling mapping of the HART client–master–server model on PROFIBUS. The cooperation of the HART Foundation on the specification work ensures complete conformity with the HART specifications. The HART-client application is integrated in a PROFIBUS master and the HART master in a PROFIBUS slave (Figure 39.12), whereby the latter serves as a multiplexer and handles communication to the HART devices.

The *Time Stamp* application profile describes mechanisms on how to supply certain events and actions with a time stamp, which enables precise time assignment. Precondition is a clock control in the slaves through a clock master via special services. An event can be given a precise system time stamp and

© 2005 by CRC Press LLC

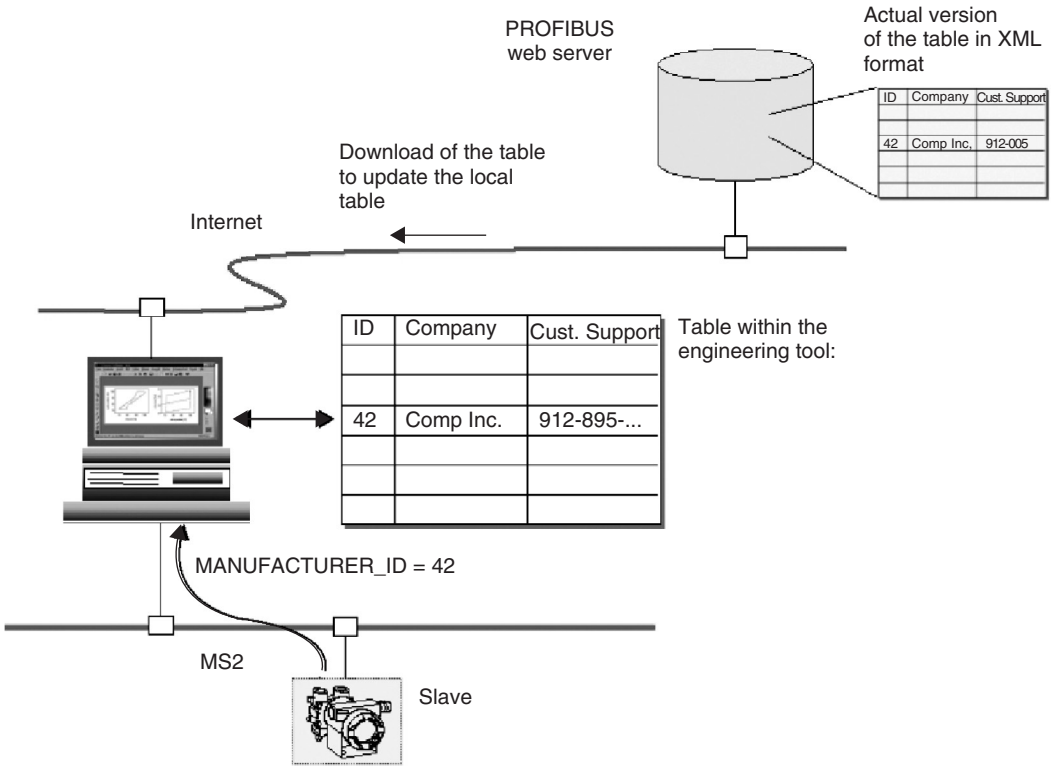

FIGURE 39.10 Referencing IDs via the Internet.

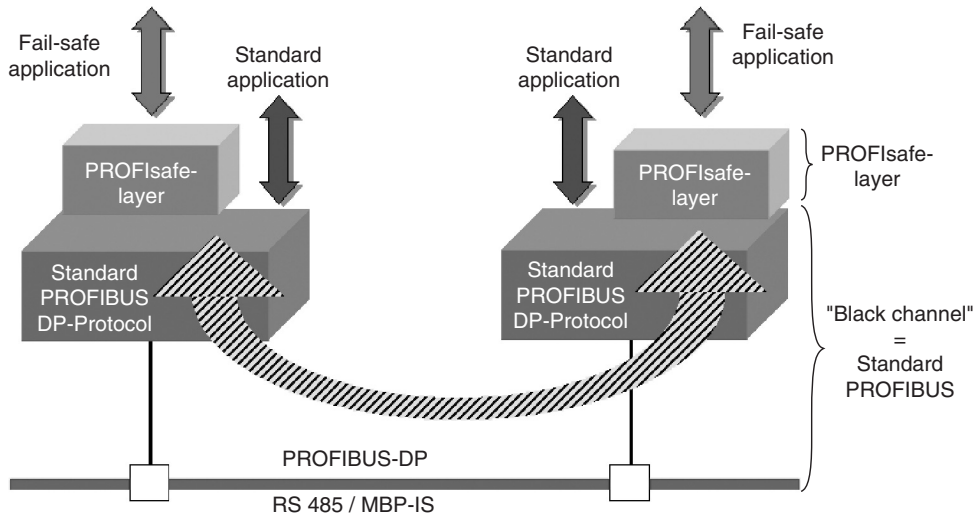

FIGURE 39.11 Safe communication on PROFIBUS DP.

read out accordingly. A concept of graded messages is used. The message types are summarized under the term *"Alerts"* and are divided into high-priority "alarms" (these transmit a diagnostics message) and low-priority "events." In both cases, the master acyclically reads the time-stamped process values and alarm messages from the alarm and event buffer of the field device (Figure 39.13).

© 2005 by CRC Press LLC

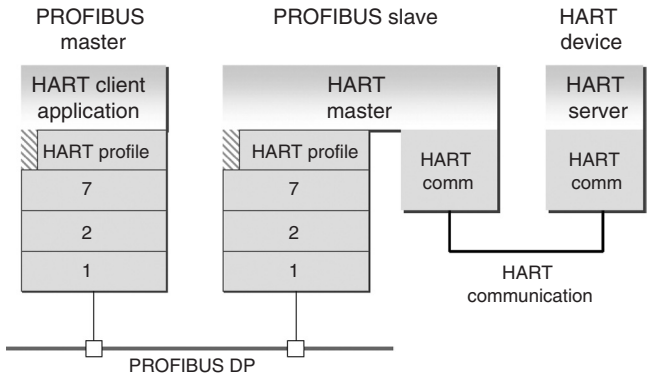

FIGURE 39.12 Operating HART devices over PROFIBUS DP.

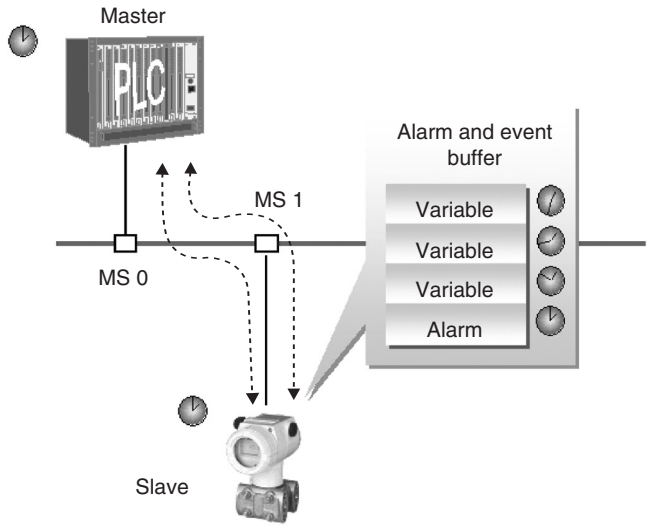

FIGURE 39.13 Time-stamping and alarm messages.

The *Slave redundancy* application profile provides a *slave-redundancy mechanism* (Figure 39.14): Slave devices contain two different PROFIBUS interfaces that are called *primary* and *backup* (slave interface). These may be either in a *single* device or distributed over *two* devices.

The devices are equipped with two independent protocol stacks with a special *redundancy expansion*.

A redundancy communication (RedCom) runs between the protocol stacks, that is, within a device or between two devices. It is independent of PROFIBUS and its performance capability is largely determined by the redundancy reversing times.

Only one device version is required to implement different redundancy structures, and no additional configuration of the backup slave is necessary. The redundancy of PROFIBUS slave devices provides high availability, short reversing times, no data loss, and ensures fault tolerance.

Specific Application Profiles

The **PROFIdrive** application profile defines device behavior and the access procedure to drive data for electric drives on PROFIBUS, from simple frequency converters through to highly dynamic servo-controls.

© 2005 by CRC Press LLC

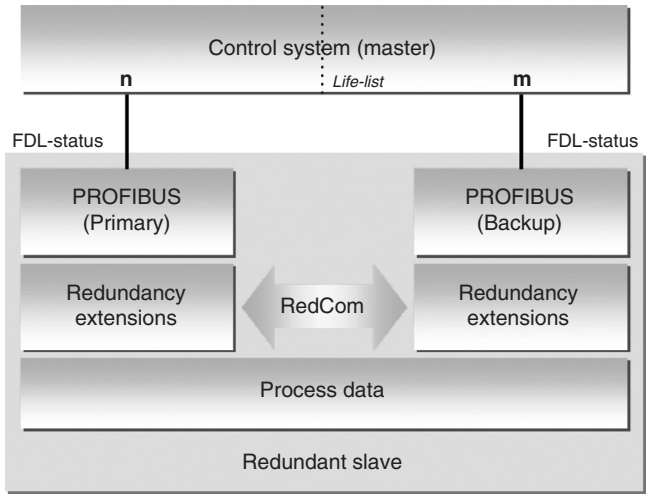

FIGURE 39.14 Slave redundancy in PROFIBUS.

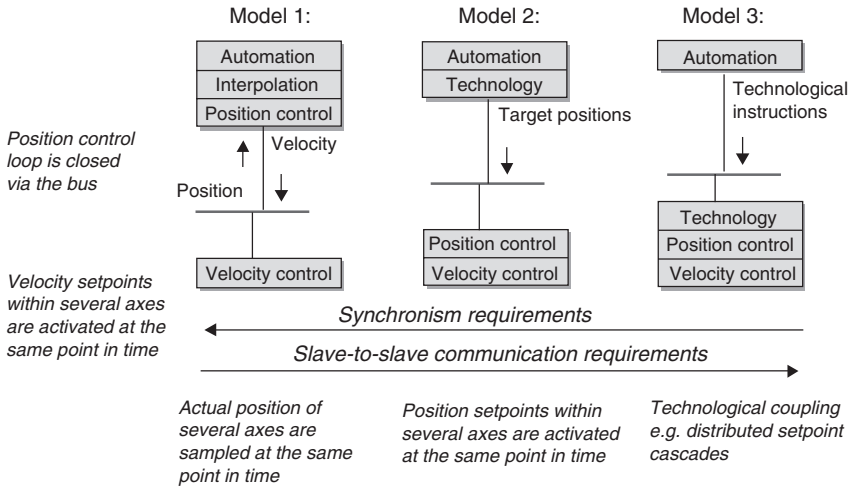

FIGURE 39.15 Different requirements for distributed drive applications.

The method of integrating drives in automation solutions is highly depending on the task of the drives (Figure 39.15). The more the drives act independently from central host controllers, the more they require slave-to-slave communication capabilities. On the other hand, the more the central host controllers are taking over the computing tasks, the more synchronization of the involved drives is required.

For this reason, PROFIdrive defines six classes covering the majority of applications (Figure 39.16).

With *standard drives (class 1)*, the drive is controlled by means of a main setpoint value (e.g., rotational speed), whereby the speed control is carried out in the drive controller. In case of *standard drives with technological function (class 2)*, the automation process is broken down into several subprocesses and some of the automation functions are shifted from the central programmable controller to the drive controllers. PROFIBUS serves as the technology interface in this case. Slave-to-slave communication between the individual drive controls is a requirement for this solution.

The positioning drive (class 3) integrates an additional position controller in the drive, thus covering an extremely broad spectrum of applications (e.g., the twisting on and off of bottle tops). The positioning

© 2005 by CRC Press LLC

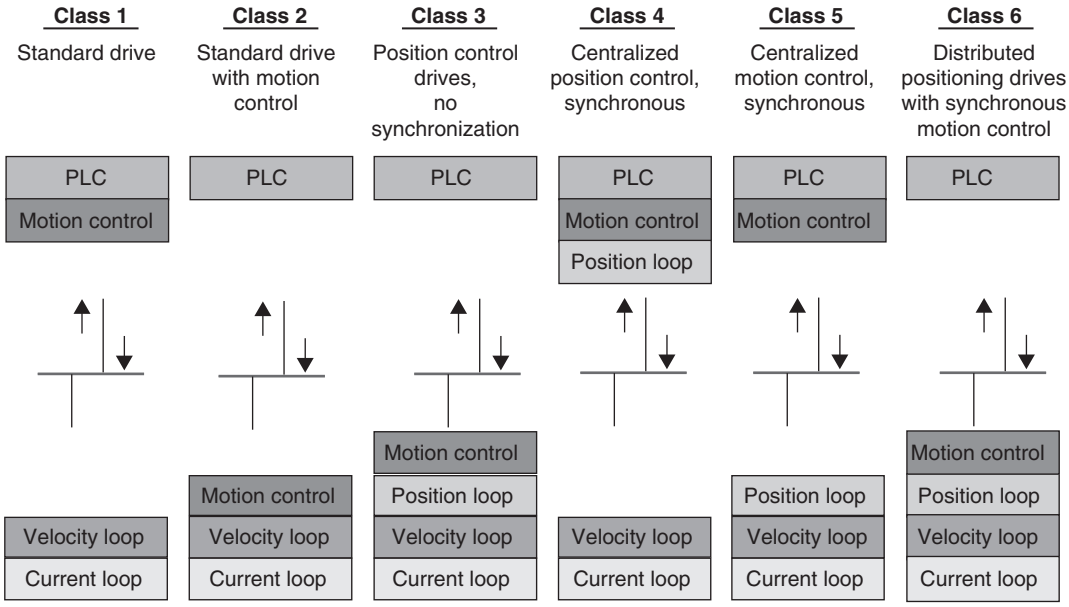

FIGURE 39.16 PROFIdrive defines six application classes.

tasks are passed to the drive controller over PROFIBUS and started. The *central motion control (classes 4 and 5)* enables the coordinated motion sequence of multiple drives. The motion is primarily controlled over a central numeric control (CNC). PROFIBUS serves to close the position control loop as well as synchronize the clock (Figure 39.17).

The position control concept (Dynamic Servo Control) of this solution also supports extremely sophisticated applications with linear motors. *Distributed automation* by means of clocked processes and electronic shafts *(class 6)* can be implemented using slave-to-slave communication and isochronous slaves. Sample applications include "electrical gears," "curve discs," and "angular synchronous processes."

In contrast to other drive profiles, PROFIdrive only defines the access mechanisms to the parameters and a subset of approx. 30 *profile parameters,* which include fault buffers, drive controllers, device identification, etc.

All other parameters (which may number more than 1000 in complex devices) are *manufacturer-specific*, which provide drive manufacturers great flexibility when implementing control functions.

The profile for *PA Devices* defines all functions and parameters for different classes of devices for process automation with local intelligence. They can execute part of the information processing or even take over the overall functionality in automation systems. The profile includes all steps of a typical signal flow – from process sensor signals through the preprocessed process value that is communicated to the control system together with a value qualifier (Figure 39.18).

The profile for PA Devices is documented in a *general model description* containing the currently valid specifications for all device types and in *device data sheets* containing the agreed additional specifications for individual device classes. Version 3.0 of the profile for PA devices includes device data sheets for quantity measurement of pressure and differential pressure, level, temperature, flow rate, and data sheets for valves, actuators, analyzers, analog, and digital inputs and outputs.

In process engineering, it is common to use *blocks* for describing the characteristics and functions of a measuring point or manipulating point at a certain control point and to represent an automation application through a combination of these types of blocks. Therefore, the specification for PA Devices uses a *function block model* according to IEC 61804 to represent functional sequences as shown in Figure 39.19. The blocks are implemented by the manufacturers as software in the field devices and, taken as a whole, represent the functionality of the device.

© 2005 by CRC Press LLC

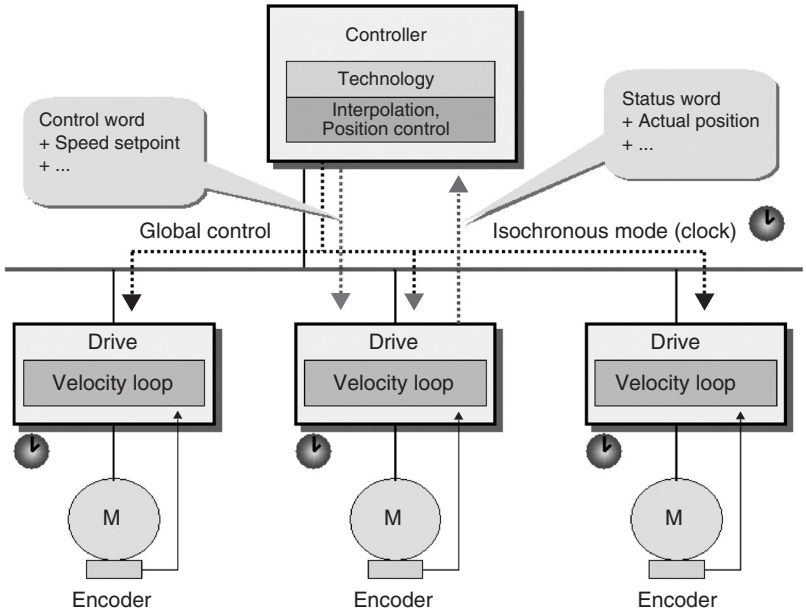

FIGURE 39.17 Positioning with central interpolation and position control.

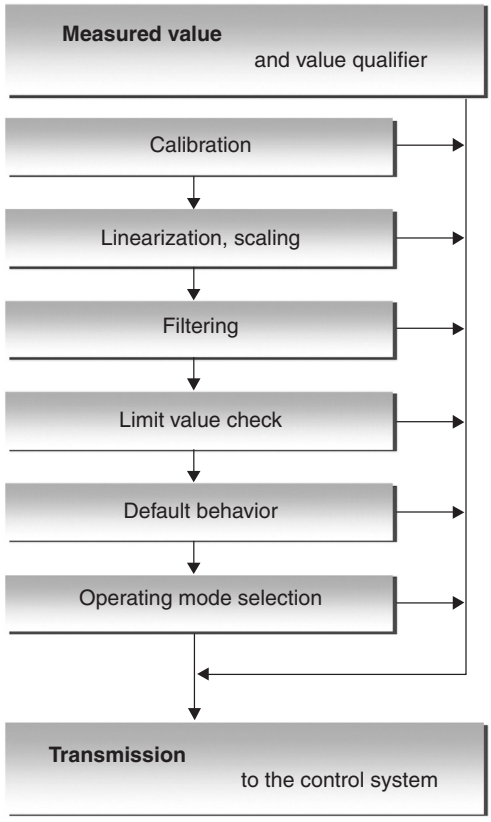

FIGURE 39.18 Signal processing defined in profile PA devices.

© 2005 by CRC Press LLC

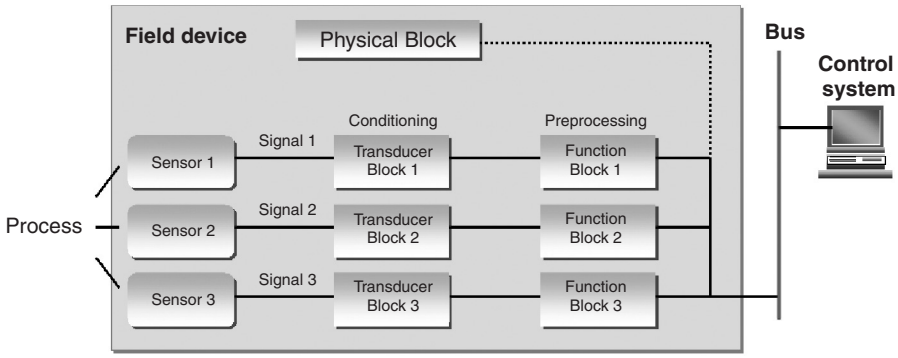

FIGURE 39.19 Block structure of a PA field device.

The following *three block types* are used:

A *Physical Block* (*PB*) contains the characteristic data of a device, such as device name, manufacturer, version, serial number, etc. There can only be one physical block in each device.

A *Transducer Block* (*TB*) contains all the data required for processing an unconditioned signal delivered from a sensor for passing onto a function block. If no processing is required, the TB can be omitted.

Multifunctional devices with two or more sensors have a corresponding number of TBs.

A *Function Block* (*FB*) contains all data for final processing of a measured value prior to transmission to the control system, or on the other hand, for processing of a setting before the setting process.

Different FBs are available: *Analog Input Block* (*AI,* delivers the measured value from the sensor/TB to the control system), *Analog Output Block* (*AO,* provides the device with the value specified by the control system), *Digital Input* (*DI,* provides the control system with a digital value from the device), and *Digital Output* (*DO,* provides the device with the value specified by the control system).

The profile for *Ident Systems* defines complete communication and processing models for barcode readers and transponder systems. These are primarily intended for extensive use with the DP-V1 functionality. While the cyclic data transmission channel is used for small data volumes to transfer status/control information, the acyclic channel serves the transmission of large data volumes that result from the information in the barcode reader or transponder. The definition of standard PROXY function blocks [5] according to IEC 61131-3 has facilitated the use of these systems and paves the way for the application of open solutions on completion of international standards, such as ISO/IEC 15962 and ISO/IEC18000.

The profile for *Weighing and Dosage Systems* follows similar approaches as the Ident Systems. Communication and processing models are defined for four classes of devices or systems:

- Simple scale
- Comfort scale
- Continuous scale
- Batch scale.

These new types of profiles will dramatically reduce the engineering costs and improve the bidding process during project execution.

Summary of Specific Application Profiles

PROFIdrive: The profile specifies the behavior of devices and the access procedure to parameters for variable-speed electrical drives on PROFIBUS DP.

PA devices: The profile specifies the data formats for cyclic data exchange and the characteristics for *process engineering* of devices for process automation.

Robots/NC: The profile describes how *handling and assembly robots* are controlled via PROFIBUS.

© 2005 by CRC Press LLC

Panel devices: The profile describes the interfacing of simple *human machine interface (HMI) devices* to control components.

Encoders: This profile describes the interfacing of rotary, angle, and linear *encoders* with single-turn or multi-turn resolution.

Fluid power: The profile describes the control of hydraulic drives via PROFIBUS.

SEMI: The profile defines models of devices for semiconductor production such that they comply with the PA model and the SEMI model.

Low-voltage switchgear: The profile describes data exchange for low-voltage switchgear like circuit breakers, switches, and starters.

Weighing/Dosage: The profile describes the communication and processing models for simple and comfort scales as well as for batch and continuous scales.

Ident systems: The profile describes the communication and processing models for bar code readers and transponders.

Remote I/O for PA devices: This profile takes into account the special conditions of physically modular slaves like limited communication resources and extreme cost sensitivity. The profile follows the model of PA devices as much as possible but has some simplifications.

Master and System Profiles

Master Profiles for PROFIBUS describe classes of controller, each of which support a specific "subset" of all the possible master functionalities, such as cyclic and acyclic communications, diagnostics, alarm handling, clock control, slave-to-slave communication, isochronous mode, and safety.

System Profiles for PROFIBUS go a step further and describe classes of systems including the master functionality, the possible functionality of *Standard Program Interfaces* (FB in accordance with IEC 61131-3, safety layer and FDT), and *integration options* (GSD, EDD and DTM). Figure 39.20 shows the standard platforms available today.

In the PROFIBUS DP system, the master and system profiles provide the much-needed counterpart to the application profiles: master and system profiles describe specific system parameters that are made available to the field devices; application profiles require specific system parameters in order to simplify their defined characteristics.

By using these profiles, the *device manufacturers* can focus on existing or specified system profiles and the *system manufacturers* can provide the platforms required by the existing or specified device application profiles.

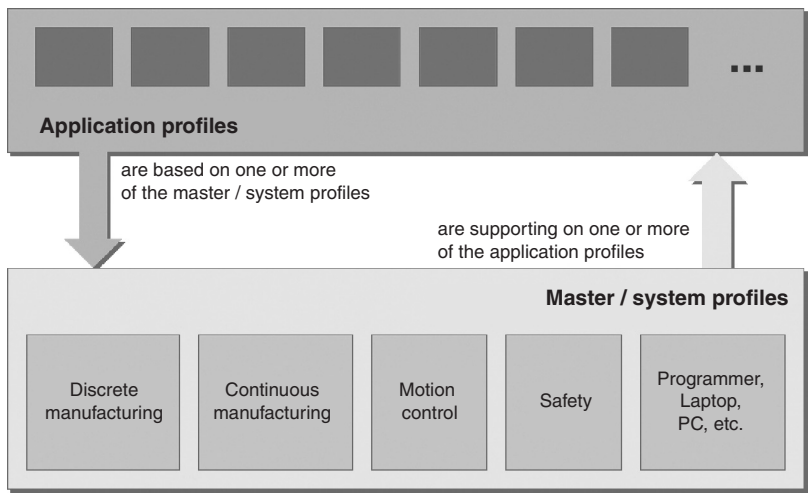

FIGURE 39.20 Master and system profiles for PROFIBUS DP.

© 2005 by CRC Press LLC

39.5 Integration Technologies

Modern field devices in both factory and process automation provide a wide range of information and also execute functions that were previously executed in PLCs and control systems. To execute these tasks, the tools for commissioning, maintenance, engineering, and parameterization of these devices require an exact and complete description of device data and functions, such as the type of application function, configuration parameters, range of values, units of measurement, default values, limit values, identification, etc. The same applies to the controller/control system, whose device-specific parameters and data formats must also be made known (integrated) to ensure error-free data exchange with the field devices.

PROFIBUS has developed a number of methods and tools ("integration technologies") for this type of device description, which enable standardization of device management. The performance range of these tools is optimized to specific tasks (Figure 39.21), which has given rise to the term *scaleable device integration*. GSD and EDD are both a kind of "electronic device data sheets," developed with different languages according to the special scope, whilst a Device Type Manager (DTM) is a software component containing specific field device functions for parameterization, configuration, diagnostics, and maintenance, generated by mapping and to be used together with the universal software interface Field Device Tool (FDT), which is able to implement software components.

A GSD is an electronically readable ASCII text file and contains both general and device-specific specifications for *communication* (General Station Description) and network configuration. Each of the entries describes a feature that is supported by a device. By means of keywords, a configuration tool reads the device identification (ID number), the adjustable parameters, the corresponding data type, and the permitted limit values for the configuration of the device from the GSD. Some of the keywords are *mandatory*, for example, Vendor_Name. Others are *optional*, for example, Sync_Mode_supported. A GSD replaces the previously conventional manuals and supports automatic checks for input errors and data consistency, even during the configuration phase.

Distinction is made between a *device GSD* (for an individual device only) and *profile GSD*, which may be used for devices that comply exactly with a profile such as PROFIdrive version 3 or PA devices version 3.

GSD for *compact* devices, whose block configuration is already known on delivery, can be created completely by the device manufacturer.

GSD for *modular* devices, whose block configuration is not yet conclusively specified on delivery, must be configured by the user in accordance with the actual module configuration using the configuration tool.

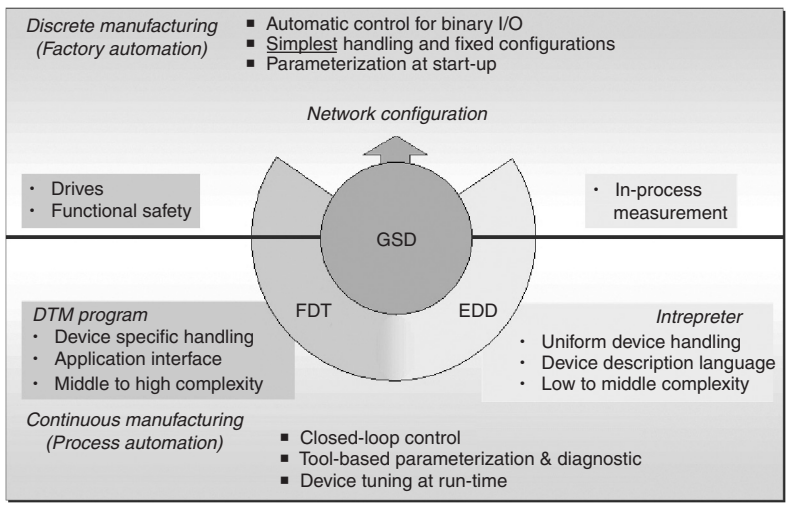

FIGURE 39.21 Integration technologies for PROFIBUS DP.

© 2005 by CRC Press LLC

The device manufacturers are responsible for the scope and quality of the GSD of their devices. Submission of a profile GSD (contains the information from the profile of a device family) or an individual device GSD (device-specific) is essential for certification of a device.

An Electronic Device Description (EDD)

is, like a GSD, an electronic device data sheet, but developed by using a more powerful and universal language, the Electronic Device Description Language (EDDL). An EDD typically describes the *application*-related parameters and functions of a field device such as configuration parameters, ranges of values, units of measurement, default values, etc. An EDD is a versatile source of information for engineering, commissioning, runtime, asset management, and documentation. It also contains support mechanisms to integrate existing profile descriptions in the device description, allow references to existing objects, to access standard dictionaries, and to allow assignment of the device description to a device.

An EDD is independent of operating systems and supports the user by its uniform user and operation interface (only one tool, reliable operation, reduced training, and documentation costs) and also the device manufacturer (no specific knowledge required, existing EDDs and libraries can be used).

The EDD concept is suitable for tasks of low to middle complexity.

A Device Type Manager (DTM)

is a software that is generated by mapping the specific functions and dialogs of a field device for parameterization, configuration, diagnostics, and maintenance, complete with user interface, in a *software component*. This component is called DTM and is integrated in the engineering tool or control system over the FDT interface. A DTM uses the routing function of an engineering system for communicating across the hierarchical levels. It works similar to a printer driver, which the printer supplier includes in delivery and must be installed on the PC by the user. The DTM is generated by the device manufacturer and is included in delivery of the device.

DTM generation may be performed using one of the following options:

- Specific programming in a higher programming language.
- Reuse of existing components or tools through their encapsulation as DTM.
- Generation from an existing device description using a compiler or interpreter.
- Use of the DTM toolkit of MS Visual Basic.

With DTMs, it is possible to obtain direct access to all field devices for planning, diagnostics, and maintenance purposes from a central workstation. A DTM is not a stand-alone tool, but an ActiveX component with defined interfaces. The FDT/DTM concept is protocol-independent and, with its mapping of device functions in software components, opens up interesting new user options. The DTM/FDT concept is very flexible; it resolves interface and navigation needs nowadays, and is suitable for tasks of middle to high complexity.

Quality Assurance

In order for PROFIBUS devices of different types and manufacturers to correctly fulfill tasks in the automation process, it is essential to ensure the error-free exchange of information over the bus. The requirement for this is a standard-compliant implementation of the communications protocol and application profiles by device manufacturers. To ensure that this requirement is fulfilled, the PNO has established a *quality assurance procedure* whereby, on the basis of test reports, certificates are issued to devices that successfully complete the test.

The basis for the certification procedure is the standard EN 45000 (Figure 39.22). The PROFIBUS User Organization has approved manufacturer-independent *test laboratories* in accordance with the specifications of this standard. Only these test laboratories are authorized to carry out device tests, which form the basis for certification.

© 2005 by CRC Press LLC

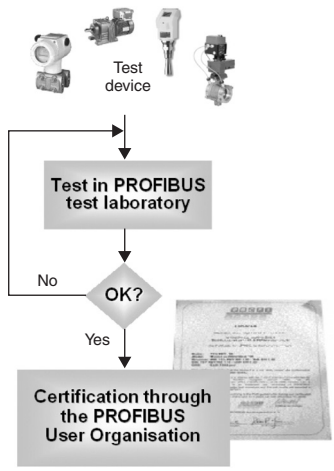

FIGURE 39.22 Certification procedure.

The *test procedure,* which is the same for all test laboratories, is composed of several parts:

- The *GSD/EDD Check* ensures that the device description files comply with the specification.
- The *Hardware Test* tests the electric characteristics of the PROFIBUS interface of the device for compliance with the specifications. This includes terminating resistors, suitability of the implemented drivers and other modules, and the quality of line level.
- The *Function Test* examines the bus access and transmission protocol and the functionality of the test device.
- The *Conformity Test* forms the main part of the test. The objective is to test the conformity of the protocol implementation with the standard.
- The *Interoperability Test* checks the test device for interoperability with the PROFIBUS devices of other manufacturers in a multivendor plant. This checks that the functionality of the plant is maintained when the test device is added. Operation is also tested with different masters.

Once a device has successfully passed all the tests, the manufacturer can apply for a *certificate* from the PROFIBUS User Organization. Each certified device contains a certification number as a reference. The certificate is valid for 3 years but can be extended after undergoing a further test.

Implementation

For the device development or implementation of the PROFIBUS protocol, a broad spectrum of standard components and development tools (PROFIBUS ASICs, PROFIBUS stacks, monitoring, and commissioning tools) as well as services are available, which enable device manufacturers to realize cost-effective development. A corresponding overview is available in the product catalog of the PROFIBUS User Organization [2].

PROFIBUS Interface Modules are ideal for a low/medium volume of devices to be produced. These credit card size modules implement the entire bus protocol. They are fitted on the master board of the device as an additional module.

PROFIBUS Protocol Chips (Single Chips, Communication Chips, Protocol Chips) are recommended for an individual implementation in the case of a high volume of devices.

The implementation of single-chip ASICs is ideal for *simple slaves* (I/O devices). All protocol functions already are integrated on the ASIC. No microprocessor or software is required. Only the bus interface driver, the quartz, and the power electronics are required as external components.

For *intelligent slaves*, parts of the PROFIBUS protocol are implemented on a protocol chip and the remaining protocol parts are implemented as software on a microcontroller. In most of the ASICS

© 2005 by CRC Press LLC

available on the market, all cyclic protocol parts have been implemented, which are responsible for transmission of time-critical data.

For *complex masters*, the time-critical parts of the PROFIBUS protocol are also implemented on a protocol chip and the remaining protocol parts are implemented as software on a microcontroller. Various ASICs of different suppliers are currently available for the implementation of complex master devices. They can be operated in combination with many common microprocessors.

An overview for commercially offered PROFIBUS chips and software (PROFIBUS stacks) is available at the PROFIBUS website [2]. For further information, please contact the suppliers directly.

Modem Chips are available to realize the (low) power consumption, which is required when implementing a bus-powered field device with MBP transmission technology. Only a feed current of 10–15 mA over the bus cable is available for these devices, which must supply the overall device, including the bus interface and the measuring electronics. These modems take the required operating energy for the overall device from the MBP bus connection and make it available as feed voltage for the other electronic components of the device. At the same time, the digital signals of the connected protocol chip are converted into the bus signal of the MBP connection modulated to the energy supply.

39.6 Prospects

While the fieldbuses were pioneering the field of distributed automation in discrete and continuous manufacturing facilities within the past 15 years, Ethernet was gaining great success in office automation. The technology matured more and more and evolved a high degree of comfort and flexibility such as high transmission speed, easy-to-handle cables and connectors, efficient control protocols, network devices like switches, and the tremendous success of the Internet. The fieldbus organizations are now eager to provide solutions for a steadily growing demand of the market. The solution from the PROFIBUS organization is PROFINET.

PROFINET Communication

PROFINET is a new automation concept that has emerged as a result of the trend in automation technology toward modular, reusable machines (mechatronic components), and plants with distributed intelligence. With its comprehensive design (uniform model for engineering, communication, and migration architecture to other communication systems, such as PROFIBUS and OPC), PROFINET fulfills all the key demands of automation technology for

- consistent communications from field level to corporate management level such as **E**nterprise **R**esource **P**lanning (**ERP**) and **M**anufacturing **E**xecution **S**ystems (**MES**) using Ethernet,
- a vendor-independent plant-wide engineering model for the entire automation landscape,
- openness to other systems,
- implementation of IT standards, and
- integration capability of PROFIBUS segments without changes.

PROFINET is available as a *specification* and as an operating system-independent *source software* for Ethernet-based communications [9].

PROFINET IO

The PROFINET component model is ideal for intelligent field devices and programmable controllers with data format interfaces that can be standardized. Simple field devices with many IO signals do not fit into the engineering model of PROFINET. Thus, the version PROFINET IO offers an integration methodology based on the PROFINET communication protocols such that a manufacturer of PROFIBUS DP slave devices feels comfortable to switch over. He will find the services described for PROFIBUS DP in PROFINET IO also and more. The most essential feature of this integration is the use of distributed field devices with their input and output data to be processed within the application program of a PLC.

© 2005 by CRC Press LLC

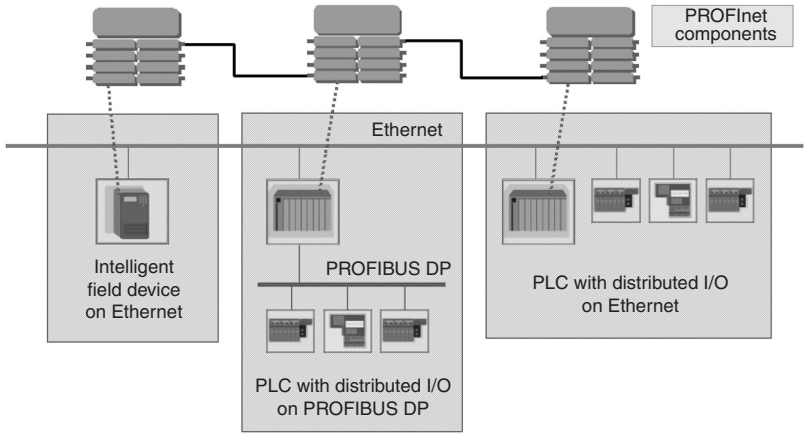

FIGURE 39.23 The migration concept of PROFINET and PROFINET IO.

The PROFINET Migration Model

Allows the integration of PROFIBUS DP segments in PROFINET using *proxies*. These assume a *proxy function* for all the devices connected to PROFIBUS. This means that when rebuilding or expanding plants, the entire spectrum of PROFIBUS devices, including products of PROFIdrive and PROFIsafe can be implemented unchanged, thus providing users with maximum investment protection. Proxy technology also allows integration of other fieldbus systems (Figure 39.23). A second possibility is the usage of PROFINET IO devices directly connected to the host controller (PLC) via PROFINET. Intelligent field devices may be connected directly as a component.

This way the user has all the possibilities to migrate from the current situation to PROFINET at his convenience.

40.1 Introduction

This chapter is dedicated to the study of the WorldFIP[1] Fieldbus. It is one of the first fieldbuses that emerged in the beginning of the 1980s. But it is also at the origin of several main concepts, which are now implemented in other, different fieldbuses. For example, the Producer–Consumer model, the timeliness attributes to qualify the validity of a data, and the time coherence and consistency attributes are some of the most important WorldFIP contributions. A good many of them are coming from research activities (academic and industrial) and from very distributed and real-time requirements analysis. That is why the first sections will briefly relate the origin of this fieldbus (Section 2), the requirements (Section 3), and the choices of WorldFIP specifications (Section 4). The technical aspects will be studied more in detail in the following four sections: the architecture in Section 5, the physical layer in Section 6, the data link layer in Section 7,

[1] WorldFIP is the current name of the previous FIP network. FIP stands for "Factory Instrumentation Protocol," but in the French language, the acronym means Flux d'Information (de et vers le) Processus.

© 2005 by CRC Press LLC

and finally the application layer in Section 8. The current state of this fieldbus is given in the last section (Section 9) before conclusion and bibliography. Several theoretical works have been developed for more than 15 years to prove the protocols, to evaluate the performances, and to guarantee the time constraints (Song et al., 1991), or to estimate the performances of distributed applications (Bergé et al., 1995). It is impossible to cite all the authors, but we thank them for their contributions.

40.2 WorldFIP Origin

The first works on the WorldFIP specification started in September 1982, in a working group under the aegis of the French Ministry of Research and Technology. This working group was composed of representatives of end-users, engineering companies, and laboratories. It was important not to include providers and manufacturers of networks at the beginning in order to organize a real end-users needs analysis, without having to consider the possible influence of existing products or existing projects.

The first objective of this work was to analyze the needs for communication in automatic control systems. But it was necessary to take into account in our reflection the following points:

- It was really the starting development of local area networks.
- It was the beginning of the MAP project in the U.S.A. (MAP, 1988).
- And some new ideas appeared on the application architectures, especially the idea of really distributed systems.
- The intelligent devices started their development thanks to the progress of the microelectronics.

The development of WorldFIP started in this context, with essentially two main types of contributions coming from research and from end-users' experiences.

The functional analysis of the communication needs in automatic control systems led to the distinction between two mains flows:

- a flow of information associated to the control rooms in continuous processes, or associated to the plant in discrete part manufacturing applications;
- another flow associated to the field devices called "Flow of Information of the Process," which will be analyzed later and that led to the WorldFIP fieldbus profiles.

To satisfy the former type, different local area networks were already existing when nothing exists for the latter. It was then decided to specify a so-called Instrumentation Network.[2] The first specification of the FIP Fieldbus was then published in May 1984 (Galara and Thomesse, 1984). That is, it was only in the beginning of the 1990s that the name has been transformed in WorldFIP. More information on the origins may be found in Thomesse (1993b, 1998). The first results were presented for sustaining a standardization process at IEC (Gault and Lobert, 1985).

40.3 Requirements

The first (and abstract) requirement was to define a communication system that should take the place of usual connections standards (as 4–20 mA) between the devices and the controllers in an automation system. Another expression was more complete but abstract: the objective was the design of an operating system for instrumentation. It was, in fact, a real need in order to build not only a communication systems but also really distributed systems. It was then important to provide the right and well-suited services for the distribution of the applications (facilities for the management of coherence and consistencies, for the management of the impossible common global state, and of clock synchronization).

The requirements could be specified at different abstraction levels. Starting from the most general (see above), they have led to the following:

The connection between the field devices and the control functions was expensive enough to try the specification of another communication technique.

The access to the data by the network should be standardized.

[2] At this moment, the word "Fieldbus" was not yet in use.

© 2005 by CRC Press LLC

The location of data should be transparent for the user.
The system should be built to meet different dependability requirements by using the same basic components.
The competitiveness of companies should be improved by such technologies.
The development should go through the international standardization.
The protocols should be implemented in silicon.
The data flows between the functions and between the set of field and control equipment have then been identified and analyzed, leading to the identification of special needs for a so-called Instrumentation Network.

This led to the identification of the traffics and then to the more technical following requirements:

The exchanged data are coming from sensors or are placed in actuators. Most of them are known and identified (temperature, pressure, speed, position, and so on). But other transmitted data are not identified in the same sense and usual messages must also be transmitted.
The exchanges are periodic or not. They are time constrained, in terms of period and of jitter, as well as in terms of deadline, lifetime, promptness, or refreshment.
Most critical traffic must be periodically managed. But sporadic traffic must also take place.
The timeliness is important for the quality of service and the dependability of the applications.
The distributed decisions must be consistent, that is, the data and the physical process must be seen in a coherent manner by all the application processes. The impossible global state must be approached by a reliable broadcasting of states and events.

40.4 Choices of WorldFIP

According to the previous requirements, the WorldFIP solution is based on a few basic ideas, which give the right quality of service to this fieldbus. These ideas are:

- The distinction of two types of "messages": the notion of identified data vs. the concept of classical messages, associated to the respective cooperation models, producer–consumer vs. client–server.
- The predefined scheduling of periodic traffics, with periods suited to the physical needs, especially the sampling theory.
- The on-line scheduling of sporadic traffic, of messages with priority to the critical traffic.
- The cyclic updating of real-time data at the consumers' sites.
- The timeliness attributes and mechanisms for time-critical systems.

These choices will be presented and analyzed below.

Identified Data vs. Classical Messages

Data provided by sensors, data sent to the actuators, more generally I/O data, and control data are all identified in a given process. They are known within the application. These data are also called identified variables or identified objects. They are often simple objects (temperature, pressure, speed, etc.) and of fixed syntax (integer, real, Boolean, record, list, or other structured data). For instance, a temperature sensor can produce a temperature value coded as an integer, or as real, and the manufacturer identification as a character chain.

The identified data receive a name, which is a global name for the entire application. This name is also used for managing the access to the medium.

Each variable value has a single producer and one or more consumers. Since transferred values correspond to variables in the process, an identifier is attached to each variable whose value is to be transmitted on the network. This identifier is used as the source address to control the medium access. The destination is not indicated. Consumers are responsible for deciding the update of their copy of data on receiving data by recognizing the corresponding identifier. This is the so-called source addressing.

© 2005 by CRC Press LLC

This addressing technique represents several advantages. It allows the communication in a manner "one to many" with broadcast. The communication channel is then not only used efficiently when the same information has to be transmitted to more than one consumer but also, with reliable broadcast, the coherence may be obtained. A new receiver may be added without address modification.

Identifying the variables instead of the sources of the information on the variables offers an additional advantage; the variable is no longer bound to a node of the network. For example, in case of failure of the node providing the variable value, a new source may become active and replace the failed node without any modification of the receivers.

With respect to an identified object, a single active producer is defined and all the other stations may be defined as consumers.

Periodic and Aperiodic Traffics

The control systems are usually based on the system sampling theory; then, the data in inputs and/or in outputs should be transferred periodically.

WorldFIP has chosen to privilege the periodic traffic of identified objects between producer and consumers. Variable values are stored in erasable buffers rather than in queues. There is neither acknowledgement nor retransmission for variable transfers. From this point of view, WorldFIP is a time-triggered system (Kopetz, 1990).

WorldFIP may also be seen as a distributed database updating and management system.

The producer of an identified object updates periodically his own buffer, the WorldFIP protocol updates periodically the buffers at the consumer locations, and then, these consumers may use periodically the copy of the producer value. If a failure occurs during the transmission, the last value is always available for the consumer until it receives a new one.

In WorldFIP, a one-place erasable buffer is associated with each variable at its production and each consumption location. The usual acknowledgements are not necessary and the retransmissions are avoided in case of error.

The question is how to handle some critical data like alarms or rarely occurring events. In WorldFIP, there are two possible ways depending on the criticality. If no real-time reaction is required, the best is to use the usual message transfer. Otherwise, the only good solution is to transform the alarm into a variable whose value reflects the presence of an alarm or not and transfers this value periodically. One may think that this would result in a waste of bandwidth. This is true but is the price to pay to ensure a deterministic response time.

Moreover, multicast transfers are complex when acknowledgements from each receiver are required. In FIP, the choice to suppress acknowledgements drastically simplifies the solution to multicast; for a simple broadcast, appropriate filters in the receivers may be used.

Timeliness attributes and mechanisms for time-critical systems. Due to the periodic transfer of identified data between a producer and their consumers, no acknowledgement has been proposed. No retransmission is basically allowed.

We consider the following three elements: a producer, the consumers, and the bus.

The producer is a process producing a data named X at a given period. Several processes consume X at different periods, and the bus updates at a given period the copy of X at each consumer site from the original of X. The question at each consumption site is: is the value of X fresh, or too old, or obsolete? Therefore, some timeliness attributes have been defined in order to indicate to the consumers if the data are correct or not and in this case the cause of error.

These attributes are called refreshments and promptness. The former type indicates if the production is timely correct or not, and the latter indicates if the reception is correct or not. Based on these elementary attributes, it is then possible to define the time coherence of actions, that is, the fact that different distributed actions take place in a given time interval. This is also the definition of simultaneity of actions.

Other mechanisms have been introduced as synchronization mechanisms between the local operations and the behavior on the network. All these mechanisms will be detailed in Section 8.

© 2005 by CRC Press LLC

40.5 WorldFIP Architecture

The WorldFIP architecture is described by the Figures 40.1 and 40.2, according to the OSI architecture model (Zimmermann, 1980). All the elements were standardized in France in 1992 (AFNOR, 1989). This architecture shows that two main profiles may be used. One is defined to solve the traffic of identified objects; the second one is defined for the usual messaging exchanges. This architecture is directly issued from the need analysis. It is important to remark that the messaging services in the data link layer are related to the point-to-point exchanges of frames, with storage in queues, with or without acknowledgement, and replication detection. The identified traffic services are related to the exchanges of data in a broadcast manner, with storage in erasable buffers, without acknowledgement, except by the space consistency mechanism at the application layer.

Messaging for Periodic and aperiodic Services (MPS) is the service element for the periodic and aperiodic exchanges of identified data. It uses the services of identified traffic at the data link layer. Manufacturing message specification (MMS) is a subset of the well-known MMS standard (ISO, 1990) and uses the messaging services at the data link layer.

We may say that the first profile (left of the figure) is a profile for real-time traffic management, with guaranteed quality-of-service and timeliness properties. The second profile is more used for noncritical exchanges as during commissioning, for maintenance and configuration, or more generally for management. Notice that the messaging services are based on the same Medium Access Control.

Architecture and Standardization

The European Standard EN 50170 (Figure 40.3) contains three national standards in Europe.[3] The volume 3 contains all the WorldFIP specifications according to the following organization: EN 50170 volume 3 (Table 40.1)

Several profiles of WorldFIP have been defined. One of them, the simpler one providing only periodic traffic of identified data, is called DWF (Device WorldFIP) and is standardized (AFNOR, 1996, CENELEC, 1996b).

40.6 Physical Layer

The physical layer of WorldFIP was obviously the first to be conformed to the IEC 1158-2 standard,[4] because this standard has been defined starting from the FIP French standard number C46 604.

The medium may be as well be a twisted shielded pair or a fiber optic.

Some Figures

Data Rates

The standard defines three data rates for the shielded twisted pair:

31.25 kbps, 1 Mbps, 2.5 Mbps, and for the fiber optic a fourth data rate, 5 Mbps.

But some experiences have been built with other data rates as, for example, 25 Mbps with the transfer of speed and video.

[4] This number was the previous number of the current 61158 standard.

© 2005 by CRC Press LLC

TABLE 40.2 Data Rate and Maximum Possible Lengths

Data Rate	Length Without Repeater	Length With Four Repeaters
31.25 kbps	10 km	50 km
1 Mbps	1 km	5 km
2.5 Mbps	700 m	3.5 km

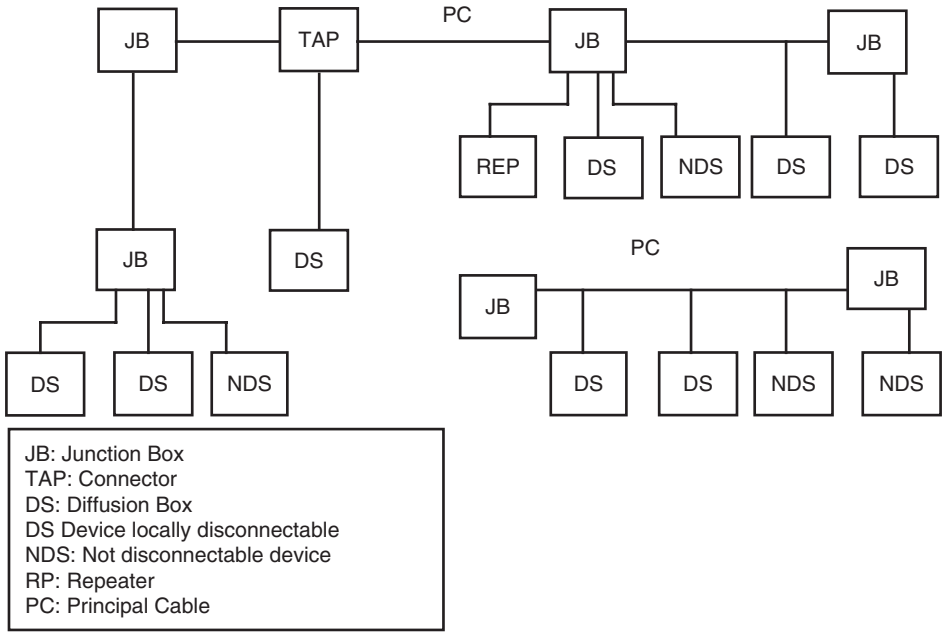

FIGURE 40.4 Example of topology.

Maximum Length

The maximum number of stations is 256 and the maximum number of repeaters is 4. According to the data rate and the number of repeaters, Table 40.2 gives the maximum length.

Topology

The topology for twisted shielded pair may be the following (Figure 40.4).

Coding

The coding is based on a Manchester code. A physical data frame is composed of three parts: a sequence of frame starting composed of a preamble and of a start delimiter (PRE and FSD), the data link information, and the end delimiter (FED). Twenty-four bits are added to each data frame.

40.7 Data Link and Medium Access Control Layers

Introduction

The WorldFIP medium access control is centralized and managed by a so-called bus arbitrator (BA). All the exchanges are under the control of this BA. They are currently scheduled according to the timing requirements and the time constraints (Cardeira and Mammeri, 1995) But the scheduling policy is not relevant of the standard.

© 2005 by CRC Press LLC

The data link layer provides two types of services: for the identified objects and for the messages. But both may or may not take place periodically. Thanks to the MAC protocol, it is obviously easy to manage the periodic traffic, which may be prescheduled before the run time. But it is then necessary to provide the well-suited services for the requirement of sporadic or random traffic, and the associated protocol mechanisms. As is usually known, the random traffic is managed by a periodic server. When a station is polled, it may express a request for an extra polling. Such requests corresponding to the aperiodic traffic are managed dynamically by the bus arbitrator.

Basic Mechanism

The medium access control is based on the following principle: each exchange is composed of two frames: a request and a response. All the exchanges are based on the couple (name of information, value of the information) implemented by two frames: an identification frame and a value frame.

Thus, to exchange a value of an object, the BA sends a frame, which contains the identifier of this object. This frame is denoted ID-DAT (as Identification of Data) (Figure 40.5.1). This frame is received by all the active current stations and recognized by the so-called producer station of the identified object, and also by the consumer stations, which subscribed to this object[5] (Figure 40.5.2). The station that recognizes itself as the producer sends the current value of the identified object.

This value is transferred in a so-called RP_DAT frame (as Response) (cf. Figure 40.5.3). All the interested stations, including all the subscribers and the BA, receive this RP_DAT frame (cf. Figure 40.5.4).

The ID and the RP frames have the following format:

ID Frame:

- a control field (CF) of eight bits, whose roles will be developed later,
- the identifier of the object (16 bits), and
- a CRC (16 bits).

RP Frame:

- a CF of eight bits, whose roles will be developed later,
- the value of the identified object in the previous frame (maximum 256 bytes), and
- a CRC (16 bits).

Now, the idea is to extend this simple mechanism of polling by designation of the data to be sent, in order to solve the problem of messages transfer and of the transfer of aperiodic data or messages.

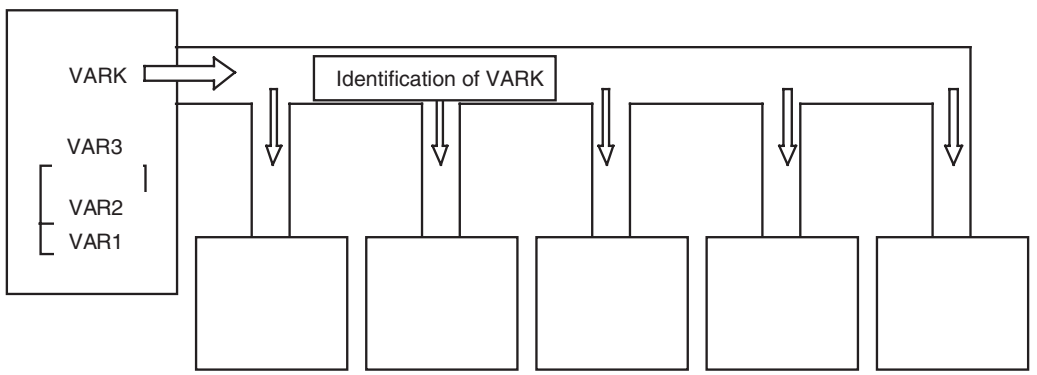

FIGURE 40.5.1 Broadcasting of an identifier by the BA.

[5] Notice that the Producer–Consumer model is also called Publisher–Subscriber, following this concept of subscribing to the data by the Consumers.

© 2005 by CRC Press LLC

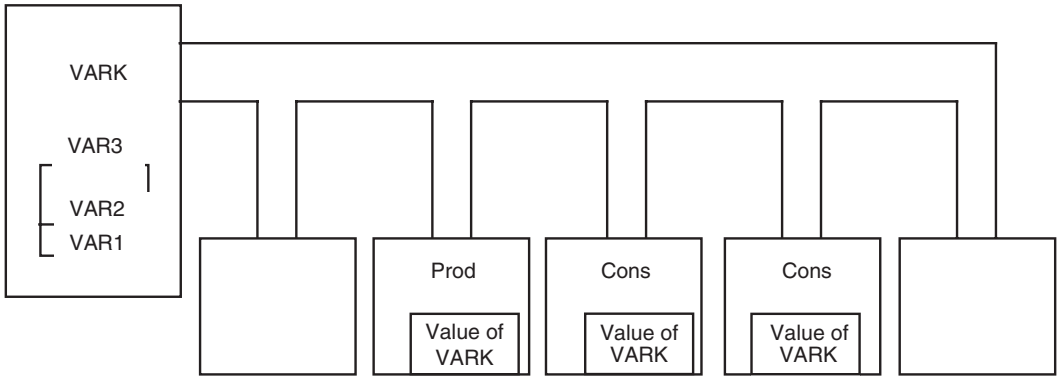

FIGURE 40.5.2 Recognition of the identifier by the producer and by the consumers.

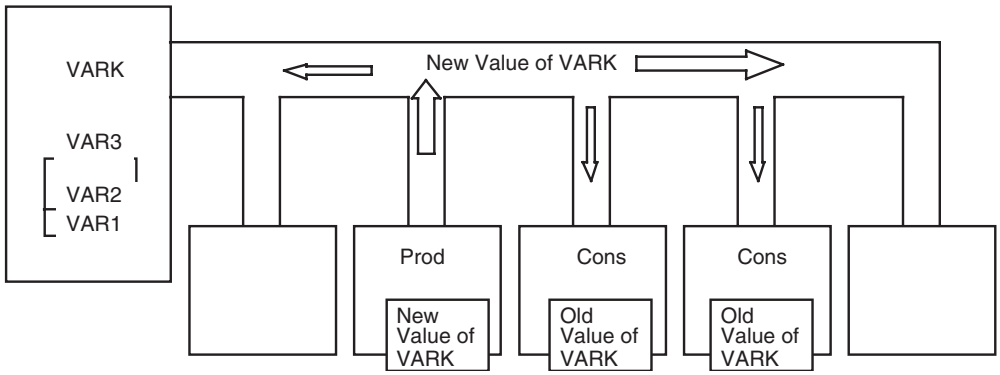

FIGURE 40.5.3 Transmission of the value by the producer.

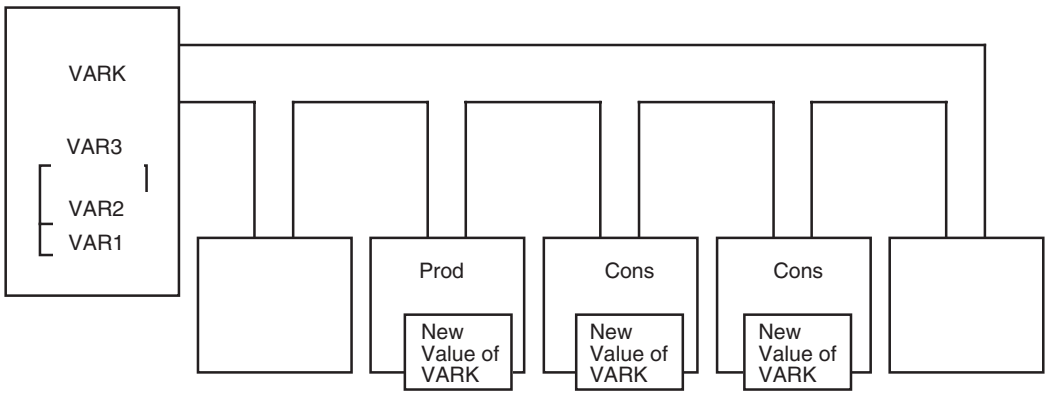

FIGURE 40.5.4 Reception and updating of copies of the value by the consumers.

The Aperiodic Server

The needs for an aperiodic transfer have been identified in Section (40.4). This aperiodic transfer takes place in the free time slots of the periodic one. The aperiodic traffic is dynamically managed by the bus arbitrator.

© 2005 by CRC Press LLC

First Stage

The first stage is the expression of the request to the BA by a station. Any producer may request a new exchange by an indication in the control field of the RP frame, when it is polled by an ID_DAT frame. This indication specifies the type of the RP frame.

We may then observe the following three RP frames types as answers to an ID_DAT frame:

RP_DAT: response to ID DAT without any request.
RP_DAT_RQ: response to ID DAT with request for random exchange of other identified objects.
RP_DAT_MSG: response to ID DAT with request for random exchange of message.

Second Stage

The second stage is to satisfy the request. The BA then has to place the right ID frames in a free time slot of the scanning table, according to its own scheduling policy. The ID frames corresponding to the possible requests are ID_RQ and ID_MSG. The former satisfies the RP_DAT_RQ and the latter satisfies the RP_DAT_MSG.

Following the reception of ID_RQ, the station at the origin of the request sends an RP_RQ frame with, in the data field, a list of identifiers, which have to be sent as ID Frames by the BA.

Following the receipt of ID_MSG, the station at the origin of the request sends an RP_MSG frame with a message in the data field. This message is specified with or without acknowledgment. Both these RP_MSG frames are called RP_MSG NOACK or RP_MSG_ACK. In this last case, the receiver sends an RP_ACK after receipt of the message. A special frame RP_FIN allows the BA to continue its polling.

Variable Transfer Services

To each identified object, the data link layer associates a buffer B_DAT_prod at the producer station and a buffer B_DAT_cons at each consumer station.

Two main services are defined for writing and reading a buffer: L_PUT and L_GET, respectively.

The write service (L_PUT) places the new value in the producer buffer. The previous buffer content is overwritten. The read service (L_GET) gets the value from the consumer buffer. These services do not cause any traffic on the bus (Figure 40.8). The content of each consumer buffer is updated with the value stored in the producer buffer under the control of the Bus Arbitrator. (Figure 40.7) as seen in Section 40.8. A L_SENT.indication informs the producer when the transmission takes place. The consumers are informed by an L_RECEIVED indication when the update occurs.

Message Transfer

For the message as for the identified objects, WorldFIP defines periodic and aperiodic (or on request) message transfers. To periodic messages, an identifier and a queue are assigned. According to the application needs, more than one identifier and one queue may be used when one wants to have different polling periods. Messages are deposited at the source side and the transfer of the content of the queue is periodically triggered by the BA (ID-MSG frame). If the queue is not empty, the source DLL sends the first message in the queue in an RP_MSG_xx frame. The destination data link layer stores the message in the receive queue and, if requested, immediately acknowledges the transfer using an RP_ACK frame. The end of the transaction is signaled by the source to the Bus Arbiter using an RP_FIN frame. If the queue is empty, no transfer takes place, and only the RP_FIN frame is sent. The polling period is a configuration parameter.

For aperiodic message transfer, on the source side, the data link layer defines a single queue F_MSG aper that will hold the pending messages. On the destination side, a receiving queue F_MSG rec is defined. As for an aperiodic variable, transfer requests are signaled to the Bus Arbiter as piggy backs on RP_DAT frames sent in response to ID_DAT frames.

© 2005 by CRC Press LLC

Synthesis on the Data Link Layer

Three types of objects are exchanged according to the basic principle based on the exchange of the couples (name, value) (Thomesse and Rodriguez, 1986).

These objects are: Identified objects or List of identifiers of identified objects, or Messages with or without acknowledgment.

The data link layer protocol may be considered with connection established at the configuration stage. These connections are multicast and the corresponding Services Access Point (SAP) are represented by the identifiers. Associated to each SAP, different Connection End Point (CEP) are represented by the associated objects and necessary resources (Figure 40.6).

A CEP for data exchange represented by the buffer storing the successive values.

A CEP for the list of identifiers exchange represented by another buffer.

A CEP for the sending of messages represented by a queue.

Each of these CEPs is addressed firstly by the identifier addressing the SAP and secondly by the indication in the control field of the ID frame, specifying the corresponding resource.

40.8 Application Layer

Two Application Service Elements compose the WorldFIP Application layer. The first is MPS for real-time data exchange (Thomesse and Delcuvellerie, 1987; Thomesse and Lainé, 1989) and sub-MMS for usual messaging service and compatibility with other networks.

For the real-time data exchange, FIP behaves like a distributed database being refreshed by the network periodically or aperiodically on demand. All the application services related to the periodic and aperiodic data exchange are called MPS.

MPS provides local read/write services (periodic) as well as remote read/write services (aperiodic) of the values of variables or lists of variables. The read services associate indications on the age of the object value. Considering a producer (producer of data named X) at a given period, and the consumers of X consuming X at different periods, the bus itself updating at a given period the copies of X consumers from the original of X, the question at a consumption site is: is the value of X fresh, or too old, or obsolete.

In WorldFIP, this information is based on local mechanisms and provided as two types of status: the *refreshment status* elaborated by the producer and the *promptness status* elaborated by the consumer (Thomesse et al., 1986; Decotignie and Raja, 1993; Lorenz et al., 1994). These statuses are returned by the read services with the value itself. This information may also be used to check whether a set of variables are timely coherent.

As a variable may have several consumers, there is a need to know whether the different copies of the variable value available to the various consumers are identical or not. This information, called spatial coherency status (or spatial consistency) (Saba et al., 1993), is provided by the MPS read services related to lists of variables. The same services also offer a temporal coherence status.

Services Associated to the Variables

A variable can be of simple type such as integer, floating, Boolean, character, or composite-like array and records. It may have different semantics: variable, synchronization variable, consistency variable, and variable descriptor. Synchronization variables are used to synchronize application processes and also in the elaboration of the temporal and spatial status associated with ordinary variables. Consistency variables are used to elaborate the spatial coherence status. Variable descriptors hold all information concerning variables, type, semantics, periodicity, etc. for configuration, commissioning, maintenance, and management.

Three request services, A_READ, A_WRITE, and A_UPDATE, and two indication services, A_SENT and A_RECEIVED, are available. A_UPDATE is used to request an aperiodic transfer of a variable. A_SENT and A_RECEIVED are optional services. When used, A_RECEIVED informs the consumer at its local communication entity of the reception of new variable value. Similarly, A_SENT notifies the producer of the transmission of the produced value. These indication services can be used by Application Processes (AP) to verify the proper operations of the communication entity and also to synchronize with each other by receiving synchronization variables (see synchronization services later). A_READ and A_WRITE exist in two forms: local and remote.

A local read of a variable (denoted A_READLOC) provides the requesting AP with the current value of the local variable image. A local write (denoted A_WRITELOC), invoked by an AP, updates the local value of the variable to be sent at a next scanning, specified in the request. As already mentioned, these operations do not invoke any communication. The transfer of the value from the producer to its copies in all consumers concerns the distribution function of application layer. The variable value given in a A_WRITELOC will be available for the distributor who is in charge of broadcasting it to all the consumers of this value. The variable value, returned by a A_READLOC at a consumer site, will be the last value updated by the distribution function.

A remote write, A_WRITEFAR, is used by a producer to update the content of the local buffer assigned to the variable specified in the request and to ask for the transfer of this value to the producers. It may been seen as the combination of the invocation of an A_WRITELOC service followed by an A_UPDATE. However, as for the A_WRITELOC, this service may only be invoked by the producer of the variable (Figure 40.7).

Operations:

1. Remote READ request.
2. Ask the distributor for updating.
3. Transfer order from the distributor.
4. Transfer of the producer's variable value to the users.
5. Confirmation of remote READ.

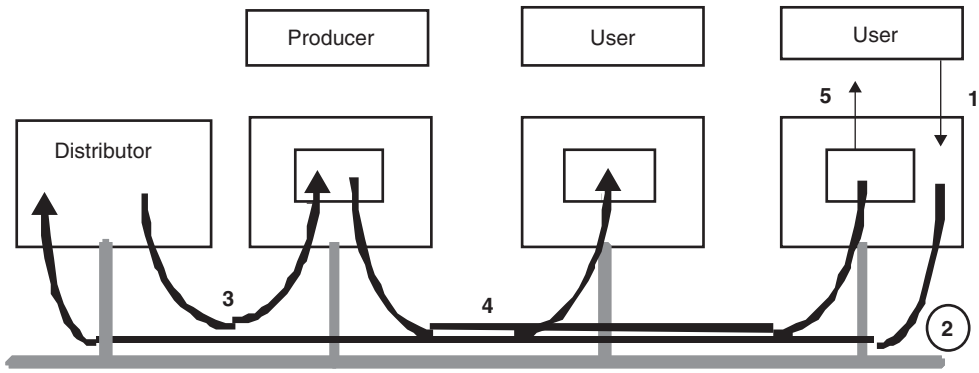

FIGURE 40.7 Remote READ using PDC model.

© 2005 by CRC Press LLC

In a similar way, with a remote read, A_READFAR, a consumer requires the transfer of the variable value from the producer to all consumers. This value is returned as a result of this request. This service is hence a combination of an A_UPDATE service invocation followed by the invocation an A_READLOC service. However, read services may only be invoked on a consumer.

Figure 40.8 shows this service from the Producer–Consumer model point of view. Consider an AP, which is a consumer of variable X. In order to request a transfer explicitly, this AP should also be producer of a variable (Y in the example). Figure 40.8 depicts in detail all necessary primitive calls and frame exchanges to achieve the remote READ of X.

We can see that these remote operations are not symmetrical. The remote write is a service without confirmation, while the remote read is not.

Temporal Validity of Variables

Normally, according to the Producer–Consumer model, operations should proceed in the following order: production, transfer, and consumption. As the receipt of an identifier triggers the transfer, a production and a consumption may be triggered by a production or consumption order. These behaviors may lead to abnormal situations. For example, several productions may occur successively without any transfer. Conversely, a number of transfers may take place between two successive productions of a variable. The same problems may arise on the consumer side. A consumer may read several times the same value of a variable or may not have enough time (or may not be interested) to consume all the received values. It is thus important to detect these deviations from normal behavior. This means that any consumer should be able to know whether the producer has produced on time, the transfer has been handled on time, and the consumer itself has consumed on time. Finally, the consumer should be able to check whether the value is still temporally valid or not (Lorenz et al., 1994).

Refreshment

The refreshment status type for a variable is a Boolean that indicates if a production occurred in the right time window. It is elaborated by the application layer of the producer. The time window is defined by a start event and a duration. From a simplified point of view, the refreshment is correct (true) if the production occurs in the time window, and it remains true during a given delay, which is the normal production period. It is false after this period deadline. The value of the current refreshment status is sent

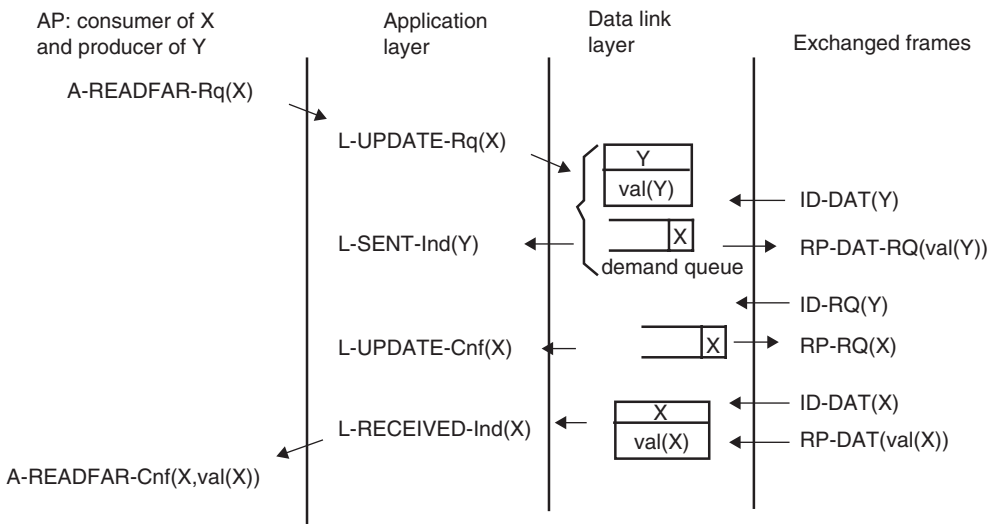

FIGURE 40.8 Primitives and frame exchanges to achieve a remote READ service.

© 2005 by CRC Press LLC

with the value and indicates to the consumer whether from the point of view of the producer and of the transmission the value is valid or not.

In summary, the refreshment status indicates to a consumer that the producer has produced its value by respecting a production delay called production period.

Promptness

The promptness status type for a variable value indicates if the transmission of the data has been done in a right time window. It is elaborated by the communication entities of its consumers. It is returned with the variable value and the refreshment status as a result of an invocation of A_READ.

Synchronous and Asynchronous

Refreshments and Promptness are the timeliness attributes associated to a given variable. They indicate if an event occurs in a time window defined by a starting event and a duration.

The WorldFIP fieldbus has defined two types of timeliness attributes: the synchronous type and asynchronous type.

An attribute is considered synchronous when the starting event of the time window is a Received-indication of a dedicated variable. It is normally periodic, and the BA is, as for other variables, in charge of the respect of the period. The duration is the period of production and is managed by the network, through the BA behavior.

An attribute is considered asynchronous when the starting event is the previous occurrence of this event. The duration is the period of production and is managed here by the device itself.

In fact, in WorldFIP, two attributes are relevant of the synchronous type: the so-called "synchronous" as defined previously and the so-called "ponctual" attribute where the stating event is the same as for the synchronous attributes, but the duration is no more than the period of production. It is a shorter delay.

Further details and the finite state machines of these mechanisms can be found in C46-602 standard and in Lorenz et al. (1994a) and Lorenz et al. (1994b) (Figure 40.9).

Remark

The terms synchronous and asynchronous could be better replaced by "synchronized by the network" and "locally synchronized."

Synchronization Services

The processes of an application can be synchronized or asynchronous. An asynchronous application process is one whose execution is independent of the network behavior. An application process is said to

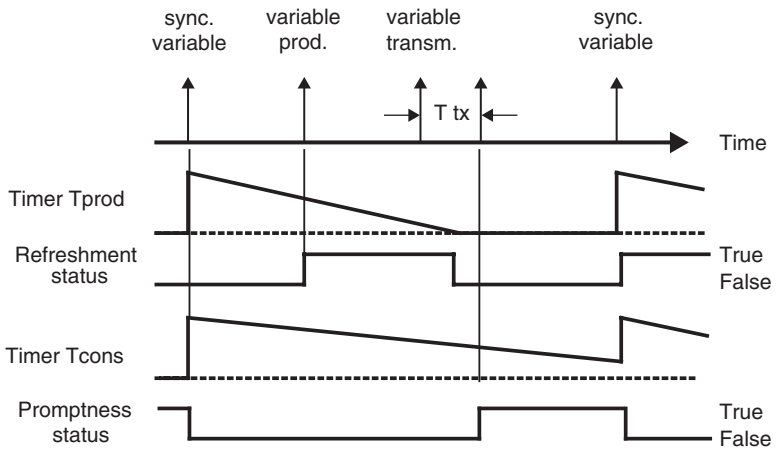

FIGURE 40.9 Refreshment and promptness status elaboration in the synchronous case.

© 2005 by CRC Press LLC

be synchronized when its execution is related to the receipt of some indication of the network. In many cases, the various distributed processes of an application are synchronized. This synchronization may be ensured through the indication of receipt of variables. However, some Application Processes (APS) of an application may not be able to handle synchronization with others. For such asynchronous APs that need to participate in a synchronized distributed application, FIP provides a resynchronization mechanism.

In addition to the existing buffer, called the public buffer, for each variable, the resynchronization mechanism associates a second buffer: the private buffer. The private buffer is only accessible to the corresponding AP. The access can be performed by the local A_READ if the variable is consumed or A_WRITE if the variable is produced. The public buffer is only accessible to the network (Figure 40.10). The resynchronization mechanism consists of copying the content from one buffer to the other according to the synchronization order via the network. Both variable production and variable consumption can be resynchronized.

When a variable consumption has to be resynchronized, its value in the private buffer is kept unchanged until the resynchronization order. If a new value is transferred on the network, it will be kept in the public buffer. This occurs only on receipt of a resynchronization order, so that the value in the public buffer will be copied in the private buffer. It is similar for variable production.

In both cases, the resynchronization order is given by a synchronization variable specified with each variable, produced or consumer, that needs to be resynchronized.

Services Associated with Variables Lists

A variable list is an unordered set of variables that must verify the following property: the time coherence, that is, the fact that they are all produced in a given time window. All the variables of a list are consumed at the same time by at least one consumption process.

In the case of more than one process with respect to the consumption of a list, another property must be verified: the space consistency, that is, the fact that all the copies of all the variables of the list are the same on all the consumption sites.

The variables that compose the list may be produced on different sites. They need not all be produced by the same producer as in the usual application layers such as MMS or MMS-like (FMS or some sub-MMS' e.g.). Usually, the productions are synchronous operations.

The only service defined on lists is A_READLIST, which allows to read all variables of a list in a single invocation. This service returns the last received values for the variables in the list and three optional statuses: a production coherence status, transmission coherence status, and a spatial consistency status. These statuses are provided to account for two important needs in the systems using fieldbuses.

First, a consumer of several variables is interested in knowing whether the corresponding values have been sampled nearly at the same time, which is called time coherence (Kopetz,1990).

Second, when the value of a variable has been distributed to several consumers, it might be useful to know if all the values are identical. This is referred to as spatial consistency. The idea in FIP is not to ensure temporal coherence and spatial consistency but rather to indicate if these properties are present or not. In FIP, temporal coherence indication is given by two statuses: the production coherence status and the transmission coherence status (Saba et al, 1993).

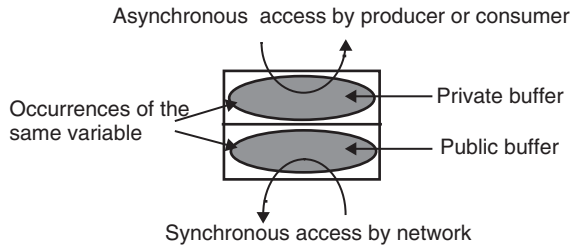

FIGURE 40.10 Resynchronization mechanism.

© 2005 by CRC Press LLC

The production coherence status is a Boolean information elaborated by the consumer application layer. This status corresponds to a logical AND operation of all the corresponding refreshment statuses.

Similarly, a transmission coherence status is calculated as the logical AND of all promptness statuses of the variables in the list. The production coherence status and the transmission coherence status together are an indication of the temporal coherence of the variables in the list.

The space consistency status of a list is elaborated by the application layer of each consumer of the list. The elaboration mechanism relies on the broadcast of a consistency variable by each of the consumers. This variable indicates for each copy of the variable list if it has been received correctly and in a given window or not. After the receipt of all the consistency variables by all the consumers, each of them will have knowledge about the validity of the variables in the list at all consumers. A logical AND operation of all the consistency variables will give the spatial consistency status.

To make the variable list transfer more reliable, FIP defines an error recovery mechanism. If needed, a consumer can trigger a retransmission of its consumed variables when any error is detected. This mechanism performs a retransmission request (using aperiodic variable transfer service of data link layer) for a number of times limited to a maximum defined for each of the instances of this list. The duration of the whole transaction of the list (including retransmission) must be bounded by a time window T smaller than the delay between two consecutive synchronization orders. It has been shown in (Song et al., 1991) that this recovery mechanism (a kind of grouped acknowledgement technique) is very efficient and can be recommended for use for other multicast protocols.

40.9 WorldFIP State and Technology

Technology

Several integrated circuits and of software libraries are available in order to build devices compatible to the standard. They conform to the European standard EN 50170. The circuits cover all the physical-layer protocols, all the profiles of data link layer, and of the application layer. They are referenced as FIPIU2, FULLFIP2 MICROFIP for the communication component. The circuits for the physical layer are essentially FIELDRIVE, CREOL for copper wire, and OPERA-FIPOPTIC for fiber optic. It is important to notice that a redundant channel may be used with the FIELDUAL component. TransoFIP and FIELDTR are possible transformers for connection on a copper wire.

The libraries are used in order to create the link between the user application and the communications controller. Each library is dedicated to a communication component.

FIP: Fieldbus Internet Protocol

FIP may be now be interpreted as a FieldBus Internet Protocol. Indeed, the messaging services are used to transfer HTTP PDU, and then each site on a WorldfIP fieldbus may host a Web server. For remote maintenance applications, for remote configuration, it is then possible to access the stations through a browser.

Two solutions are currently in use.

In the first one, a single station may be seen as the image of all the stations of the fieldbus.

In the second one, each station is directly accessed by tunneling HTTP in the WorldFIP PDUs.

The interest of WorldFIP is that the data flow generated by Internet connections is managed in complete compatibility with the time constraints of the process, and then with its own dependability. The time-critical traffic is always satisfied in priority.

New Development

In 2001, WorldFIP has been certified as safe according to the procedure "proven in use" defined by the IEC 61 508 standard. According to this standard, a fieldbus is considered as a subsystem. It has been certified by Bureau Veritas after considering very reliable applications from detailed records from field users,

© 2005 by CRC Press LLC

with a sufficient number of applications, with a high level of confidence in the operational figures. It is the only fieldbus in the world with such a certification.

40.10 Conclusion

The WorldFIP fieldbus is now 20 years old if we considered the beginning of its specification. It is only some years old if we consider the very recent dates of the international standards (Leviti, 2001), knowing that the definition of profiles standard (CENELEC, 2003b) is not yet finished. The current integrated circuits (the third generation for the first IC) are based on the last development of microelectronics. The WorldFIP fieldbus is the only certified SIL3 in the world (Froidevaux et al., 2001). WorldFIP occupies a special place in the international market. It is used in all the types of industry (iron–steel industry, car manufacturing, bottling, power plant, etc.) but also in several time-critical applications, in embedded systems in trains, in autobus, in ships, or in subways and in a very important application : the Large Hadron Collider in CERN (Centre Européen de Recherche Nucléaire) in Switzerland. The main reason for this must be searched in the technical specifications, in the services provided, and in the quality of services, essentially from the timeliness point of view. WorldFIP guarantees that time constraints will be met, periods without jitter, synchronization of distributed actions (productions, consumptions, data acquisitions, controls, etc.). The validation of data is also an important element of the quality of service and the dependability of WorldFIP-based systems. The quality of the physical layer (IEC, 1993) and the redundancy capabilities are also important points for choosing WorldFIP for critical applications. Several of these concepts and mechanisms have been repeated in the TCCA report (ISO, 1991; Grant, 1992) and in the "standard" IEC TS 61158 (CENELEC, 2003a).

With respect to other and newer requirements, WorldFip is able to transport voice and video, without disturbing or influencing the real-time traffic. Some examples of voice transport are already industrial in trains. WorldFIP is also able to transport HTTP protocol data units, allowing the remote access to WorldFIP-based systems for monitoring, maintenance, configuration, and so on.
