Using priority-based schedulers, the flexibility is increased (compared to table-driven schedulers), since the schedule is created on-line, based on the currently active task's constraints. Hence, priority-based schedulers can cope with changes in work-load and added functions, as long as the schedulability of the task-set is not violated. However, the exact behavior of priority-based schedulers is harder to predict. Therefore, these schedulers are not used as often in the most safety-critical applications.

Two common priority-based scheduling policies are *Fixed Priority Scheduling (FPS)* and *Earliest Deadline First (EDF).* The difference between these scheduling policies is whether the priorities of the real-time tasks are fixed or if they can change during execution (i.e., they are dynamic).

In FPS, priorities are assigned to the tasks before execution (offline). The task with the highest priority among all tasks that are available for execution is scheduled for execution. It can be proved that some priority assignments are better than others. For instance, for a simple task model with strictly periodic noninterfering tasks with deadlines equal to the period of the task, a Rate Monotonic (RM) priority assignment has been shown by Liu and Layland [LL73] to be optimal. In RM, the priority is assigned based on the period of the task. The shorter the period, the higher the priority assigned to the task.

Using EDF, the task with the nearest (earliest) deadline among all available tasks is selected for execution. Therefore, the priority is not fixed; it changes with time. It has been shown that EDF is an optimal dynamic priority scheme [LL73].

In order for the priority-based schedulers to cope with aperiodic tasks, different service methods have been presented. The objective of these service methods is to give a good average response-time for aperiodic requests while preserving the timing properties of periodic and sporadic tasks. These services are implemented using special *server* tasks. In the scheduling literature, many types of servers are described. Using FPS, for instance, the Sporadic Server (SS) is presented by Sprunt et al. [SSL89]. SS has a fixed priority chosen according to the RM policy. Using EDF, Dynamic Sporadic Server (DSS) [SB94, SB96] extends SS. Other EDF-based schedulers are the Constant Bandwidth Server (CBS), presented by Abeni [AB98], and the Total Bandwidth Server (TBS) by Spuri and Buttazzo [SB94, SBS95]. Each server is characterized partly by its unique mechanism for assigning deadlines, and partly by a set of variables used to configure the server. Examples of such variables are bandwidth, period, and capacity.

In Section 81.6, we give examples of how timing properties of FPS can be calculated.

81.5 Real-Time Communications

As RTSs become distributed, data need to be transmitted between the system nodes. In many cases, this transmission must be timely and deterministic. Hence, there is a demand for real-time communication networks providing real-time guarantees. There are real-time communication networks of different types, ranging from small fieldbus-based control systems to large Ethernet/Internet-distributed applications. There is also a growing interest in wireless solutions.

© 2005 by CRC Press LLC

In this section, we give an introduction to common techniques in communications in general and real-time communications in particular. We also provide an overview of the most popular real-time communication systems and protocols used today, both in industry and academia.

Communications Techniques

Common access mechanisms used in communication networks are CSMA/CD (Carrier Sense Multiple Access/Collision Detection), CSMA/CA (Carrier Sense Multiple Access/Collision Avoidance), TDMA (Time Division Multiple Access), Tokens, Central Master, and Mini Slotting. These techniques are all used both in real-time and non-real-time communication, and each of the techniques has different timing characteristics.

In CSMA/CD, collisions between messages are detected, causing the messages involved in the collision to be retransmitted. CSMA/CD is used, for example, in Ethernet. CSMA/CA, on the other hand, is avoiding collisions and is therefore more deterministic in its behavior compared to CSMA/CD. Hence, CSMA/CA is more suitable for hard real-time guarantees, whereas CSMA/CD can provide soft real-time guarantees. Examples of networks that implement CSMA/CA are CAN and ARINC 629.

TDMA is using time to achieve exclusive usage of the network. Messages are sent at predetermined instances in time. Hence, the behavior of TDMA-based networks is very deterministic, that is, very suitable to provide real-time guarantees. One example of a TDMA-based real-time network is TTP.

An alternative way of eliminating collisions on the network is to use tokens. In token-based networks, only the owner of the (unique within the network) token is allowed to send messages on the network. Once the token holder is done or has used its allotted time, the token is passed to another node. Tokens are used in, for example, Profibus.

It is also possible to eliminate collisions by letting one node in the network to be the master node. The master node is controlling the traffic on the network, and it decides which and when messages are allowed to be sent. This approach is used in, for example, LIN and TTP/A.

Finally, mini slotting can also be used to eliminate collisions. When using mini slotting, as soon as the network is idle and some node would like to transmit a message, the node has to wait for a unique (for each node) time before sending any messages. If there are several competing nodes wanting to send messages, the node with the longer waiting time will see that there is another node that already has started its transmission of a message. In such a situation, the node has to wait until the next time the network will become idle. Hence, collisions are avoided. Mini slotting can be found in, for example, FlexRay and ARINC 629.

Fieldbuses

Fieldbuses are a family of factory communication networks that have evolved as a response to the demand to reduce cabling costs in factory automation systems. By moving from a situation in which every controller has its own cables connecting the sensors to the controller (parallel interface), to a system with a set of controllers sharing a bus (serial interface), costs could be cut and flexibility could be increased. Pushing for this evolution of technology was both the fact that the number of cables in the system increased as the number of sensors and actuators grew, together with controllers moving from being specialized with their own microchip, to sharing a microprocessor with other controllers. Fieldbuses were soon ready to handle the most demanding applications on the factory floor.

Several fieldbus technologies, usually very specialized, were developed by different companies to meet the demands of their applications. Fieldbuses used in the automotive industry are, for example, CAN, TT-CAN, TTP, LIN, and FlexRay. In avionics, ARINC 629 is one of the more used communication standards. Profibus is widely used in automation and robotics, while in trains, TCN and WorldFIP are very popular communication technologies. We will now present each of these fieldbuses in some more detail, outlining key features and specific properties.

Controller Area Network (CAN). The CAN [CAN02] was standardized by the International Standardization Organization (ISO) [CAN92] in 1993. Today, CAN is a widely used fieldbus, mainly in automotive systems but also in other real-time applications, for example, medical equipment. CAN is an event-triggered broadcast bus designed to operate at speeds of up to 1 Mbps. CAN is using a

© 2005 by CRC Press LLC

fixed-priority-based arbitration mechanism that can provide timing guarantees using Fixed-Priority Scheduling (FPS) type of analysis (Tindell et al. [TBW95, THW94]). An example of this analysis will be provided in the section Example of analysis.

CAN is a collision-avoidance broadcast bus, using deterministic collision resolution to control access to the bus (so-called CSMA/CA). The basis for the access mechanism is the electrical characteristics of a CAN bus, allowing sending nodes to detect collisions in a nondestructive way. By monitoring the resulting bus value during message arbitration, a node detects if there are higher priority messages competing for access to the bus. If this is the case, the node will stop the message transmission, and try to retransmit the message as soon as the bus becomes idle again. Hence, the bus behaves like a priority-based queue.

Time-Triggered CAN. Time-Triggered communication on CAN (TT-CAN) [TTC] is a standardized session layer extension to the original CAN. In TT-CAN, the exchange of messages is controlled by the temporal progression of time, and all nodes are following a predefined static schedule. It is also possible to support original event-triggered CAN traffic together with the time-triggered traffic. This traffic is sent in dedicated arbitration windows, using the same arbitration mechanism as native CAN.

The static schedule is based on a time division (TDMA) scheme, where message exchanges may only occur during specific time slots or in time windows. Synchronization of the nodes is either done using a clock synchronization algorithm, or by periodic messages from a master node. In the latter case, all nodes in the system are synchronizing with this message, which gives a reference point in the temporal domain for the static schedule of the message transactions, that is, the master's view of time is referred to as the network's global time.

TT-CAN appends a set of new features to the original CAN, and being standardized, several semiconductor vendors are manufacturing TT-CAN-compliant devices.

Flexible Time-Triggered CAN. Flexible Time-Triggered communication on CAN (FTT-CAN) [AFF98, AFF99] provides a way to schedule CAN in a time-triggered manner with support for event-triggered traffic as well. In FTT-CAN, time is partitioned into Elementary Cycles (ECs), which are initiated by a special message, the Trigger Message (TM). This message triggers the start of the EC and contains the schedule for the time-triggered traffic that shall be sent within this EC. The schedule is calculated and sent by a master node. FTT-CAN supports both periodic and aperiodic traffic by dividing the EC into two parts. In the first part, the asynchronous window, the aperiodic messages are sent, and in the second part, the synchronous window, traffic is sent in a time-triggered manner according to the schedule delivered by the TM. FTT-CAN is still mainly an academic communication protocol.

Time-Triggered Protocol (TTP). TTP/C [TTT, TTT99], or the Time Triggered Protocol Class C, is a TDMA-based communication network intended for truly hard real-time communication. TTP/C is available for network speeds of up to 25 Mbps. TTP/C is part of the Time-Triggered Architecture (TTA) by Kopetz et al. [TTT, Kop98], which is designed for safety-critical applications. TTP/C has support for fault tolerance, clock synchronization, membership services, fast error detection, and consistency checks. Several major automotive companies are supporting this protocol, for example, Audi, VW, and Renault.

For the less hard RTSs (e.g., soft RTSs), there exists a scaled-down version of TTP/C called TTP/A [TTT].

Local Interconnect Network (LIN). LIN [LIN] was developed by the LIN Consortium (including Audi, BMW, Daimler Chrysler, Motorola, Volvo, and VW) as a low-cost alternative for small networks. LIN is cheaper than, for example, CAN. LIN is using the UART/SCI interface hardware, and transmission speeds are possible up to 20 kbps. Among the nodes in the network, one node is the master node, responsible for synchronization of the bus. The traffic is sent in a time-triggered manner.

FlexRay. FlexRay [BBE+02] was proposed in 1999 by several major automotive manufacturers, including Daimler-Chrystler and BMW, as a competitive next-generation fieldbus replacing CAN. FlexRay is a real-time communication network that provides both synchronous and asynchronous transmissions with network speeds up to 10 Mbps. For the synchronous traffic, FlexRay is using TDMA, providing deterministic data transmissions with a bounded delay. For the asynchronous traffic mini-slotting is used. Compared with CAN, FlexRay is more suitable for the dependable application domain, by including support for redundant transmission channels, bus guardians, and fast error detection and signaling.

ARINC 629. For avionic and aerospace communication systems, the ARINC 429 [ARI99] standard and its newer ARINC 629 [ARI99] successor are the most commonly used communication systems used

© 2005 by CRC Press LLC

today. ARINC 629 supports both periodic and sporadic communication. The bus is scheduled in bus cycles, which in turn are divided into two parts. In the first part, periodic traffic is sent, and in the second part the sporadic traffic is sent. The arbitration of messages is based on collision avoidance (i.e., CSMA/CA) using mini-slotting. Network speeds are as high as 2 Mbps.

Profibus. Profibus [PRO] is used in process automation and robotics. There are three different versions of Profibus: (1) Profibus-DP is optimized for speed and low cost. (2) Profibus-PA is designed for process automation. (3) Profibus-FMS is a general-purpose version of Profibus. Profibus provides master–slave communication together with token mechanisms. Profibus is available with data rates up to 12 Mbps.

Train Communication Network (TCN). The TCN [KZ01] is widely used in trains, and it is implementing the IEC 61275 standard as well as the IEEE 1473 standard. TCN is composed of two networks: the Wire Train Bus (WTB) and the Multifunction Vehicle Bus (MVB). The WTB is the network used to connect the whole train, that is, all vehicles of the train. Network data rate is up to 1 Mbps. The MVB is the network used within one vehicle. Here, the maximum data rate is 1.5 Mbps.

Both the WTB and the MVB are scheduled in cycles called basic periods. Each basic period consists of a periodic phase and a sporadic phase. Hence, there is a support for both periodic and sporadic type of traffic. The difference between the WTB and the MVB (apart from the data rate) is the length of the basic periods (1 or 2 msec for the MVB and 25 msec for the WTB).

WorldFIP. The WorldFIP [Wor] is a very popular communication network in train control systems. WorldFIP is based on the producer–distributor–consumers (PDC) communication model. Currently, network speeds are as high as 5 Mbps. The WorldFIP protocol defines an application layer that includes PDC- and messaging-services.

Ethernet for Real-Time Communication

In parallel with the search for the holy grail of real-time communication, Ethernet has established itself as the *de facto* standard for non-real-time communication. Comparing networking solutions for automation networks and office networks, fieldbuses were the choice for the former. At the same time, Ethernet developed as the standard for office automation, and due to its popularity, prices on networking solutions dropped. Ethernet is not originally developed for real-time communication since the original intention with Ethernet was to maximize throughput (bandwidth). However, nowadays, due to its popularity, a large effort is being made in order to provide real-time communication using Ethernet. The biggest challenge is to provide real-time guarantees using standard Ethernet components.

The reason why Ethernet is not very suitable for real-time communication is its handling of collisions on the network. Several proposals to minimize or eliminate the occurrence of collisions on Ethernet have been proposed. Below, we present some of these proposals.

TDMA. A simple solution would be to eliminate the occurrence of collisions on the network. This has been explored by, for example, Kopetz et al. [KDKM89], using a TDMA protocol on top of Ethernet.

Usage of tokens. Another solution to eliminate the occurrence of collisions is the usage of tokens. Token-based solutions [VC94, PMBL95] on the Ethernet also eliminate collisions, but is not compatible with standard hardware.

A token-based communication protocol is a way to provide real-time guarantees on most types of networks. This is because they are deterministic in their behavior, although a dedicated network is required. That is, all nodes sharing the network must obey the token protocol. Examples of token-based protocols are the Timed Token Protocol (TTP) [MZ94] and the IEEE 802.5 Token Ring Protocol.

Modified collision resolution algorithm. A different approach is to modify the collision resolution algorithm [RY94, Mol94]. Using standard Ethernet controllers, the modified collision resolution algorithm is nondeterministic. In order to make a deterministic modified collision resolution algorithm, a major modification of the Ethernet controllers is required [LR93].

Virtual time and window protocols. Another solution to real-time communication using Ethernet is the usage of the Virtual Time CSMA (VTCSMA) [MK85, ZR86, EDES90] protocol, where packets are delayed in a deterministic way in order to eliminate the occurrence of collisions. Moreover, Window

© 2005 by CRC Press LLC

Protocols [ZSR90] are using a global window (synchronized time interval) that also remove collisions. The window protocol is more dynamic and somewhat more efficient in its behavior compared to the VTCSMA approach.

Master/slave. A fairly straightforward way of providing real-time traffic on Ethernet is by using a master/slave approach. As part of the Flexible Time-Triggered (FTT) framework [APF02], FTT-Ethernet [PAG02] is proposed as a master/multislave protocol. At the cost of some computational overhead at each node in the system, timely delivery of messages on Ethernet is provided.

Traffic smoothing. The most recent work, without modifications to the hardware or networking topology (infrastructure) is the usage of traffic smoothing. Traffic smoothing can be used to eliminate bursts of traffic [KSW00, CCLM02], which have a severe impact on the timely delivery of message packets on the Ethernet. By keeping the network load below a given threshold, a probabilistic guarantee of message delivery can be provided. Hence, traffic smoothing could be a solution for soft RTSs.

Black bursts. Black Burst [SK98] is using the fact that if a transmitting station is detecting a collision on the bus, the station will wait some time before retransmitting its message again (based on the collision resolution algorithm). However, suppose a station is jamming the network, causing stations to wait for retransmission. What the jamming station does is that it will send its message right after it has stopped the jamming. If all stations are using unique length jamming signals, then there will always be a unique winner. This is what the black burst approach is using.

Switches. Finally, a completely different approach to achieve real-time communication using Ethernet is by changing the infrastructure. One way of doing this is to construct the Ethernet using switches to separate collision domains. By using these switches, a collision-free network is provided. However, this requires new hardware supporting the IEEE 802. 1p standard. Therefore, it is not as attractive a solution for existing networks as, for example, traffic smoothing.

Wireless Communication

There are no commercially available wireless communication protocols providing real-time guarantees.[3] Two of the more common wireless protocols used today are the IEEE 802.11 (WLAN) and Bluetooth. However, these protocols are not providing the temporal guarantees needed for hard real-time communication. Today, a large effort is being made (as with Ethernet) to provide real-time guarantees for wireless communication, possibly by using either WLAN or Bluetooth.

81.6 Analysis of RTSs

Analysis techniques are techniques that are used to investigate what properties a component, or a system of components, exhibit. Of particular interest when dealing with RTSs is the issue of *temporal correctness,* that is, that actions are performed at the right time (i.e., we are not concerned with the actual values of an action, only the timing of the action).

Classical program-analysis techniques that focus on functional and structural correctness are well developed. However, to validate the correctness of an RTS, analysis techniques to validate the temporal correctness must be used *in addition to* other analysis techniques. In this section, we focus on techniques to analyze the temporal behavior of RTSs.

Timing Properties

Timing analysis is a complex problem. Not only are the used techniques sometimes complicated but also the problem itself is elusive; for instance, what is the meaning of the term "program execution-time?" Is it the average time to execute the program, or the worst possible time, or does it mean some form of "normal" Execution time? Under what conditions does a statement regarding program execution times

[3] Bluetooth provides real-time guarantees limited to streaming voice traffic.

© 2005 by CRC Press LLC

apply? Is the program delayed by interrupts or higher priority tasks? Does the time include waiting for shared resources?, etc.

To straighten out some of these question marks, and to be able to study some existing techniques for timing analysis, we structure timing analysis into three major types. Each type has its own purpose, benefits, and limitations. The types are listed below.

Execution time. This refers to the execution time of a singe task (or program, or function, or any other unit of single threaded sequential code). The result of an execution-time analysis is the time (i.e., the number of clock cycles) the task takes to execute, when executing undisturbed on a single CPU, that is, the result should not account for interrupts, preemption, background DMA transfers, DRAM refresh delays, or any other types of interfering background activities.

At first glance, leaving out all types of interference from the execution-time analysis would give us unrealistic results. However, the purpose of the execution-time analysis is *not* to deliver estimates on "real-world" timing when executing the task. Instead, the role of execution-time analysis is to find out how much computing resources is needed to execute the task. (Hence, background activities that are not related to the task should not be accounted for.)

There are some different types of execution-times that can be of interest:

- Worst-Case Execution-Time (WCET). This is the worst possible execution time a task could exhibit, or equivalently, the maximum amount of computing resources required to execute the task. The WCET should include any possible atypical task execution such as exception handling or cleanup after abnormal task termination.
- Best-Case Execution-Time (BCET). During some types of real-time analysis, not only the WCET is used, but as we will describe later, having knowledge about the BCET of tasks is useful.
- Average Execution-Time (AET). The AET can be useful in calculating throughput figures for a system. However, for most RTS analysis, the AET is of less importance, simply since a reasonable approximation of the average case is easy to obtain during testing (where typically, the average system behavior is studied). Also, only knowing the average and not knowing any other statistical parameters such as standard deviation or distribution function makes statistical analysis difficult. For analysis purposes, a more pessimistic metric such as the 95%-quartile would be more useful. However, analytical techniques using statistical metrics of execution time are scarce and not very well developed.

Response time. The response time of a task is the time it takes from the *invocation* of the task to the *completion* of the task. In other words, the time from when the task first is placed in the operating-system's ready queue to the time when it is removed from the running state and placed in the idle or sleeping state.

Typically, for analysis purposes, it is assumed that a task does not voluntarily suspend itself during its execution. That is, the task may not call primitives such as `sleep()` or `delay()`. However, involuntarily suspension, such as blocking on shared resources, is allowed. That is, primitives such as `get_semaphore()` and `lock_database_tuple()` are allowed. When a program voluntarily suspends itself, then that program should be broken down into two (or more) analysis tasks.

The response-time is typically a *system level property,* in that it includes interference from other, unrelated, tasks and parts of the system. The response-time also includes delays caused by contention on shared resources. Hence, the response-time is only meaningful when considering a complete system, or in distributed systems, a complete node.

End-to-end delay. The above-described "execution time" and "response time" are useful concepts since they are relatively easy to understand and have well-defined scopes. However, when trying to establish the temporal correctness of a system, knowing the WCET and/or the response-times of tasks is often not enough. Typically, the correctness criterion is stated using *end-to-end* latency timing requirements, for instance, an upper bound on the delay between the input of a signal and the output of a response.

In a given implementation, there may be a chain of events taking place between the input of a signal and the output of a response. For instance, one task may be in charge of reading the input and another task for generating the response, and the two tasks may have to exchange messages on a communications

© 2005 by CRC Press LLC

link before the response can be generated. The end-to-end timing denotes the timing of externally visible events.

Jitter. The term *jitter* is used as a metric for variability in time. For instance, the jitter in execution time of a task is the difference between the task's BCET and WCET. Similarly, the response-time jitter of a task is the difference between its best-case response-time and its worst-case response-time. Often, control algorithms have requirements that the jitter of the output should be limited. Hence, the jitter is sometimes a metric equally important as the end-to-end delay.

Also, input to the system can have jitter. For instance, an interrupt that is expected to be periodic may have a jitter (due to some imperfection in the process generating the interrupt). In this case, the jitter-value is used as a bound on the maximum deviation from the ideal period of the interrupt. Figure 81.3 illustrates the relation between the period and the jitter for this example.

Note that jitter should not accumulate over time. For our example, even though two successive interrupts could arrive closer than one period, in the long run, the average interrupt interarrival time will be that of the period.

In the above list of types of time, we only mentioned time to execute programs. However, in many RTSs, other timing properties may also exist. Most typical are delays on a communications network, but also other resources such as hard disk drives may be causing delays and need to be analyzed. The above-introduced times can all be mapped to different types of resources, for instance, the WCET of a task corresponds the maximum size of a message to be transmitted, and the response time of message is defined analogous to the response time of a task.

Methods for Timing Analysis

When analyzing hard RTSs, it is essential that the estimates obtained during timing analysis are *safe.* An estimate is considered safe if it is guaranteed that it is not an underestimation of the actual worst-case time. It is also important that the estimate is *tight,* meaning that the estimated time is close to the actual worst-case time.

For the previously defined types of timings (section Timing properties), there are different methods available:

Execution-time estimation. For real-time tasks, the WCET is the most important execution time measure to obtain. Unfortunately, however, it is also often the most difficult measure to obtain.

Methods to obtain the WCET of a task can be divided into two categories: (1) static analysis and (2) dynamic analysis. Dynamic analysis is essentially equivalent to testing (i.e., executing the task on the target hardware) and has all the drawbacks/problems that testing exhibit (such as being tedious and error prone). One major problem with dynamic analysis is that it does not produce safe results. In fact, the result can never exceed the true WCET and it is very difficult to be sure that the estimated WCET is actually the true WCET.

Static analysis, on the other hand, can give guaranteed safe results. Static analysis is performed by analyzing the code (source and/or object code is used) and basically counting the number of clock cycles that the task may use to execute (in the worst possible case). Static analysis uses models of the hardware to predict execution times for each instruction. Hence, for modern hardware it may be very difficult to

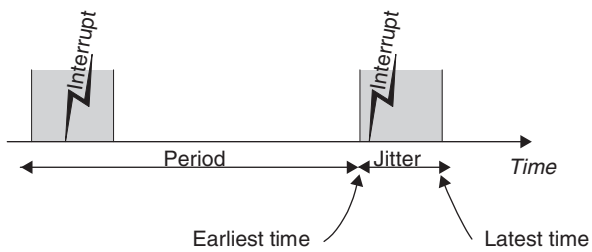

FIGURE 81.3 Jitter used as a bound on variability in periodicity.

© 2005 by CRC Press LLC

produce static analyzers that give good results. One source of pessimism in the analysis (i.e., overestimation) is hardware caches; whenever an instruction or data-item cannot be guaranteed to reside in the cache, a static analyzer must assume a cache miss. And since modeling the exact state of caches (sometimes of multiple levels), branch predictors, etc., is very difficult and time consuming, few tools that give adequate results for advanced architectures exist. Also, to perform a program flow and data analysis that exactly calculates, for example, the number of times a loop iterates or the input parameters for procedures is difficult.

Methods for good hardware and software modeling do exist in the research community; however, combining these methods into good quality tools has proved to be tedious.

Schedulability analysis. The goal of schedulability analysis is to whether or not a system is *schedulable.* A system is deemed schedulable if it is guaranteed that all task deadlines will always be met. For statically scheduled (table driven) systems, calculation of response-times is trivially given from the static schedule. However, for dynamically scheduled systems (such as fixed priority or deadline scheduling), more advanced techniques have to be used.

There are two main classes of schedulability analysis techniques: (1) response-time analysis and (2) utilization analysis. As the name suggests, a response-time analysis calculates a (safe) estimate of the worst-case response-time of a task. That estimate can then be compared to the deadline of the task and if it does not exceed the deadline, then the task is schedulable. Utilization analysis, in contrast, does not directly derive the response-times for tasks; rather, they give a boolean result for each task, stating whether or not the task is schedulable. This result is based on the fraction of utilization of the CPU for a relevant subset of the tasks, hence the term utilization analysis.

Both types of analysis are based on similar types of task models. However, typically the task models used for analysis are not the task models provided by commercial RTOSes. This problem can be resolved by mapping one or more OS-tasks to one or more analysis tasks. However, this mapping has to be performed manually and requires an understanding of the limitations of the analysis task model and the analysis technique used.

End-to-end delay estimation. The typical way to obtain end-to-end delay estimations is to calculate the response time for each task/message in the end-to-end chain and to summarize these response times to obtain an end-to-end estimate. When using a utilization-based analysis technique (in which no response time is calculated), one has to resort to using the task/message deadlines as safe upper bounds on the response times.

However, when analyzing distributed RTSs, it may not be possible to calculate all response times in one pass. The reason for this is that delays on one node will lead to jitter on another node, and that this jitter may in turn affect the response times on that node. Since jitter can propagate in several steps between nodes, in both directions, there may not exist a right order to analyze the nodes. (If A sends a message to B, and B sends a message to A, which node should one analyze first?) Solutions to this type of problems are called *holistic* schedulability analysis methods (since they consider the whole system). The standard method for holistic response-time analysis is to repeatedly calculate response-times for each node (and update jitter values in the nodes affected by the node just analysed) until response-times do not change (i.e., a fix-point is reached).

Jitter estimation. To calculate the jitter, one need not only perform a worst-case analysis (of, for instance, response-time or end-to-end delay). It is also necessary to perform a best-case analysis.

However, even though best-case analysis techniques are often conceptually similar to worst-case analysis techniques, little attention has been paid to best-case analysis. One reason for not spending too much time on best-case analysis is that it is quite easy to make a conservative estimate of the best-case: the best-case time is never less than zero (0). Hence, in many tools it is simply assumed that the BCET (for instance) is zero, whereas great efforts can be spent in analyzing the WCET.

However, it is important to have tight estimates of the jitter, and to keep the jitter as low as possible. It has been shown that the number of *execution paths* a multitasking RTS can take dramatically increases if jitter increases [TH99]. Unless the number of possible execution paths is kept as low as possible, it becomes very difficult to achieve good coverage during testing.

© 2005 by CRC Press LLC

Example of Analysis

In this section, we give simple examples of schedulability analysis. We show a very simple example of how a set of tasks running on a single CPU can be analyzed, and we also give an example of how the response-times for a set of messages sent on a CAN-bus can be calculated.

Analysis of tasks. This example is based on some 30-year-old task models and is intended to give the reader a feel for how these types of analysis work. Present-day methods allow for far richer and more realistic task models, with a resulting increase in the complexity of the equations used (hence, they are not suitable for use in our simple example).

In the first example, we will analyze a small task set described in Table 81.2, where T, C, and D denote the tasks' period, WCET and deadline, respectively. In this example, $T = D$ for all tasks and priorities have been assigned in *rate monotonic* order, that is, the highest rate gives the highest priority.

For the task set in Table 81.2 original analysis techniques of Liu and Layland [LL73] and Joseph and Pandya [JP86] are applicable, and we can perform both utilization-based and response-time-based schedulability analysis.

We start with the utilization-based analysis; for this task model, Liu and Layland's result is that a task set of n tasks is schedulable if its total utilization, U_{tot}, is bounded by the following equation:

$$U_{tot} \leq n(2^{1/n}-1)$$

Table 81.3 shows the utilization calculations performed for the schedulability analysis. For our example task set $n = 3$ and the bound is approximately 0.78. However, the utilization ($U_{tot} = \sum_{i=1}^{n}(C_i/T_i)$) for our task set is 0.81, which exceeds the bound. Hence, the task set fails the *rate monotonic test* and cannot be deemed schedulable.

Joseph and Pandya's response-time analysis allows us to calculate worst-case response-time, R_i, for each task i in our example (Table 81.2). This is done using the following formula:

$$R_i = C_i + \sum_{j \in hp(i)} \left\lceil \frac{R_i}{T_j} \right\rceil C_j \tag{81.1}$$

where $hp(i)$ denotes the set of tasks with priority higher than i.

The observant reader may have noticed that Equation (81.1) is not in closed form, in that R_i is not isolated on the left-hand side of the equality. As a matter of fact, R_i cannot be isolated on the left-hand side of the equality; instead, Equation (81.1) has to be solved using *fix-point iteration.* This is done with the recursive formula in Equation (81.1), starting with $R_i^0 = 0$ and terminating when a fix-point has been reached (i.e., when $R_i^{m+1} = R_i^m$).

$$R_i^{m+1} = C_i + \sum_{j \in hp(i)} \left\lceil \frac{R_i^m}{T_j} \right\rceil C_j \tag{81.2}$$

For our example task-set, Table 81.4 shows the results of calculating Equation (81.1). From the table, we can conclude that no deadlines will be missed and that the system is schedulable.

Remarks. As we could see for our example task-set in Table 81.2, the utilization-based test could not deem the task-set as schedulable, whereas the response-time-based test could. This situation is symptomatic for the relation between utilization-based and response-time-based schedulability tests. That is, the response-time-based tests find more task-sets schedulable than does the utilization-based tests.

TABLE 81.2 Example Task-Set for Analysis

Task	T	C	D	Prio
X	301	0	30	High
Y	401	0	40	Medium
Z	521	0	52	Low

© 2005 by CRC Press LLC

TABLE 81.3 Result of Rate Monotonic Test

Task	T	C	D	Prio	U
X	301	0	30	High	0.33
Y	401	0	40	Medium	0.25
Z	521	0	52	Low	0.23
				Total:	0.81
				Bound:	0.78

TABLE 81.4 Result of Response-Time Analysis for Tasks

Task	T	C	D	Prio	R	$R \leq D$
X	301	0	30	High	10	Yes
Y	401	0	40	Medium	20	Yes
Z	521	0	52	Low	52	Yes

However, also as shown by the example, the response-time-based test needs to perform more calculations than the utilization-based tests does. For this simple example, the extracomputational complexity of the response-time test is insignificant. However, when using modern task-models (which are capable of modelling realistic systems), the computational complexity of response-time-based tests is significant. Unfortunately, for these advanced models, utilization-based tests are not always available.

Analysis of messages. In our second example, we show how to calculate the worst-case response-times for a set of periodic messages sent over the CAN-bus (CAN is described in the section Fieldbuses). We use a response-time analysis technique similar to the one we used when we analyzed the task set in Table 81.2. In this example, our message set is given in Table 81.5, where T, S, D, and Id denote the messages' period, data size (in bytes), deadline, and CAN-identifier, respectively. (The time-unit used in this example is "bit-time," that is, the time it takes to send one bit. For a 1 Mbit CAN this means that 1 time-unit is 10^{-6} sec.)

Before we discuss the problem of calculating response-times, we extend Table 81.5 by two columns. First, we need the priority of each message; in CAN, this is given by the identifier; the lower the numerical value, the higher the priority. Second, we need to know the worst-case transmission time of each message. The transmission time is given partly by the message data-size but we also need to add time for the frame-header and for any *stuff bits.*[4] The formula to calculate the transmission time, C_i for a message i is given below:

$$C_i = S_i + 47 + \left\lfloor \frac{34 + 8S_i + 1}{5} \right\rfloor$$

In Table 81.6, the two columns Prio and C show the priority assignment and the transmission times for our example message set.

Now we have all the data needed to perform the response-time analysis. However, since CAN is a non-preemptive resource, the structure of the equation is slightly different from Equation (81.1), which we used for analysis of tasks. The response-time equation for CAN is given as

$$R_i = w_i + C_i$$

$$w_i = 130 + \sum_{\forall j \in hp(i)} \left\lceil \frac{w_i + 1}{T_j} \right\rceil C_j \tag{81.3}$$

In Equation (81.3), $hp(i)$ denotes the set of messages with a priority higher than message i. Note that (similar to equation 1) w_i is not isolated on the left-hand side of the equation, and its value has to be calculated using fix-point iteration (compare to Equation [81.2]).

[4] CAN adds stuff bits, if necessary, to avoid the two reserved bit patterns 000000 and 111111. These stuff bits are never seen by the CAN-user but have to be accounted for in the timing analysis.

© 2005 by CRC Press LLC

TABLE 81.5 Example CAN-Message Set

Message	T	S	D	Id
X	350	8	300	00010
Y	500	6	400	00100
Z	1000	5	800	00110

TABLE 81.6 Result of Response-Time Analysis for CAN

Message	T	S	D	Id	Prio	C	w	R	$R \leq D$
X	350	8	300	00010	High	130	130	260	Yes
Y	500	6	400	00100	Medium	111	260	371	Yes
Z	1000	5	800	00110	Low	102	612	714	Yes

Applying Equation (81.3), we can now calculate the worst-case response-time for our example messages. In Table 81.6, the two columns w and R show the the results of the calculations, and the final column shows the schedulablilty verdict for each message.

As we can see from Table 81.6, our example message set is schedulable, meaning that the messages will always be transmitted before their deadlines. Note that this analysis was carried out assuming that there will not be any retransmission of broken messages. CAN normally automatically retransmits any message that has been broken due to interference on the bus. To account for such automatic retransmissions, an *error model* needs to be adopted and the response-time equation adjusted accordingly, see, for example, [THW94].

Trends and Tools

As pointed our earlier, and also illustrated by our example in Table 81.2, there is a mismatch between the analytical task-models and the task-models provided by commonly used RTOSes. One of the basic problems is that there is no one-to-one mapping between analysis tasks and RTOS tasks. In fact, for many systems there is an N-to-N mapping between the task types. For instance, an interrupt handler may have to be modeled as several different analysis tasks (one analysis task for each type of interrupt it handles), and one OS task may have to be modeled as several analysis tasks (for instance, one analysis task per call to `sleep()` primitives).

Also, current schedulability analysis techniques cannot adequately model task synchronization other than locking/blocking on shared resources. Abstractions such as message queues are difficult to include in the schedulability analysis.[5] Furthermore, tools to estimate the WCET are also scarce. Currently, only two tools that give safe WCET estimates are commercially available [Abs, Bou].

These problems have led to low penetration of schedulability analysis in industrial software-development processes. However, in isolated domains, such real-time networks, some commercial tools that are based on real-time analysis do exist. For instance, Volcano [CRTM98, Vol] provides tools for the CAN bus that allow system designers to specify signals on and abstract level (giving signal attributes such as size, period, and deadline) and automatically derive a mapping of signals to CAN-messages where all deadlines are guaranteed to be met.

On the software side tools provided by, for instance, TimeSys [Timb], Arcticus Systems [Arc], and TTTech [TTT] can provide system development environments with timing analysis as an integrated part of the tool suite. However, these tools all require that the software development processes be under complete control of the respective tool. This requirement has limited the widespread use of these tools.

[5] Techniques to handle more advanced models include timed logic and model checking. However, the computational and conceptual complexity of these techniques has limited their industrial impact. There are, however, examples of commercial tools for this type of verification, for example, [Tima].

© 2005 by CRC Press LLC

The widespread use of UML [OMG03b] in software design has led to some specialized UML-products for real-time engineering [Rat, IL]. However, these products, as of today, do support timing analysis of the designed systems. There is, however, recent work within the OMG that specifies a *profile* "Schedulability, Performance and Time" (SPT) [OMG03a], which allows specification of both timing properties and requirement in a standardized way. This will in turn lead to products that can analyze UML-models conforming to the SPT-profile.

The SPT-profile has, however, not been received without criticism. Critique has mainly come from researchers active in the timing analysis field, claiming both that the profile is not precise enough and that some important concepts are missing. For instance, the Universidad de Cantabria has instead developed the MAST-UML profile and an associated MAST-tool for analyzing MAST-UML models [MHD01, MAS]. MAST allows modeling of advanced timing properties and requirement, and the tool also provides state-of-the-art timing analysis techniques.

81.7 Testing and Debugging of RTSs

According to a recent study by NIST [U.S02], up to 80% of the life cycle cost for software is spent on testing and debugging. Despite the importance, there are few results on RTSs testing and debugging.

The main reason for this is that it is actually quite difficult to test and debug RTS. Remember that RTSs are timing critical and that they interact with the real world. Since testing and debugging typically involve some instrumentation of the code, the timing behavior of the system will be different when testing/debugging compared to when executing the deployed system. Hence, the test-cases that were passed during testing may very well lead to failures in the deployed system, and tests that failed may very well not cause any problem at all in the deployed system. For debugging, the situation is possibly even worse, since in addition to a similar effect when running the system in a debugger, entering a breakpoint will stop the execution for an unspecified time. The problem with this is that the controlled external process will continue to evolve (e.g., a car will not momentarily stop by stopping the execution of the controlling software). The result of this is that we obtain a behavior of the debugged system that will not be possible in the real system. Also, it is often the case that the external process cannot be completely controlled, which means that we cannot reproduce the observed behavior, indicating that it will be difficult to use (cyclic) debugging to track down an error that caused a failure.

The following are two possible solutions to the above-presented problems:

- To build a simulator that faithfully captures the functional as well as timing behavior of both the RTS and the environment that it is controlling. Since this is both time consuming and costly, this approach is only feasible in very special situations. Since such situations are rare, we will not further consider this alternative here.
- To record the RTS's behavior during testing or execution, and then if a failure is detected replay the execution in a controlled way. For this to work, it is essential that the timing behavior is the same during testing as in the deployed system. This can either be achieved by using nonintrusive hardware recorders, or by leaving the software used for instrumentation in the deployed system. The latter comes at a cost in memory space and execution time, but gives the additional benefit that it becomes possible to also debug the deployed system in case of a failure [RDBC+03].

An additional problem for most RTSs is that the system consists of several concurrently executing threads. This is also the case for the majority of non-real-time systems. This concurrency will *per se* lead to a problematic nondeterminism, since due to race conditions caused by slight variations in execution time, the exact preemtion points will vary, causing unpredictability, both in terms of the number of scenarios and in terms of being able to predict which scenario will actually be executed in a specific situation.

In conclusion, testing and debugging of RTSs are difficult and challenging tasks.

© 2005 by CRC Press LLC

The following is a brief account of some of the results on testing of RTSs reported in the literature:

- Thane et al. [TH99] propose a method for deterministic testing of distributed RTSs. The key element here is to identify the different execution orderings (serializations of the concurrent system) and treat each of these orderings as a sequential program. The main weakness of this approach is the potentially exponential blowup of the number of execution orderings.
- For testing of temporal correctness, Tsai et al. [TFB90] provide a monitoring technique that records run-time information. This information is then used to analyze if temporal constraints are violated.
- Schütz [Sch94] have proposed testing a strategy for testing distributed RTSs. The strategy is tailored for the time-triggered MARS system [KDKM89].
- Zhu et al. [ZHM97] have proposed a framework for regression testing of real-time software in distributed systems. The framework is based on the Onomas [OTPS98] regression testing process.

When it comes to RTS debugging, the most promising approach is record/replay [CAN+01, MCL89, TCO91, TH00, ZN99] as mentioned above. Using record/replay, first, a reference execution of the system is executed and observed; second, a replay execution is performed based on the observations made during the reference execution. Observations are made by instrumenting the system, in order to extract information about the execution.

The industrial practice for testing and debugging of multitasking RTS is a time-consuming activity. At best, hardware emulators, for example, [Lau], are used to obtain some level of observability without interfering with the observed system. More often, it is an *ad hoc* activity, using intrusive instrumentations of the code to observe test results or try to track down intricate timing errors. However, some tools using the above record/replay method are now emerging on the market, for example, [Zea].

82.1 The Embedded System Revolution

The world of electronics has witnessed a dramatic growth in its applications in the last few decades. From telecommunications to entertainment, from automotive to banking, almost any aspect of our everyday life uses some kind of electronic components. In most cases, these components are computer-based systems, which are not, however, used or perceived as computers. For instance, they often do not have a keyboard or a display to interact with the user, and they do not run standard operating systems and applications. Sometimes, these systems constitute a self-contained product themselves (e.g., a mobile phone), but they are frequently embedded inside another system, for which they provide better functionalities and performance (e.g., the engine control unit of a motor vehicle). We call these computer-based systems *embedded systems.*

The huge success of embedded electronics has several causes. The main one in our opinion is that embedded systems bring the advantages of Moore's Law into everyday life, that is, an exponential increase in performance and functionality at an ever decreasing cost. This is possible because of the capabilities of integrated circuit technology and manufacturing, which allow one to build more and more complex devices, and because of the development of new design methodologies, which allow one to efficiently and cleverly use those devices. Traditional steel-based mechanical development, on the other hand, reached a plateau near the middle of the 20th century, and thus it is not a significant source of innovation any longer, unless coupled to electronic manufacturing technologies (MEMS) or embedded systems, as argued above.

There are many examples of embedded systems in the real world. For instance, a modern car contains tens of electronic components (control units, sensors, and actuators) that perform very different tasks. The first embedded systems that appeared in a car were related to the control of mechanical aspects, such as the control of the engine, the antilock brake system, and the control of suspension and transmission. However, nowadays, cars also have a number of components that are not directly related to mechanical aspects, but are mostly related to the use of the car as a vehicle for moving around, or the communication needs of the passengers: navigation systems, digital audio and video players, and phones are just a

© 2005 by CRC Press LLC

few examples. Moreover, many of these embedded systems are connected together using a network, because they need to share information regarding the state of the car.

Other examples come from the communication industry: a cellular phone is an embedded system whose environment is the mobile network. These are very sophisticated computers, whose main task is to send and receive voice, but are also currently used as personal digital assistants, for games, to send and receive images and multimedia messages, and to wirelessly browse the Internet. They have been so successful and pervasive that in just a decade they became essential in our life. Other kinds of embedded systems significantly changed our life as well: for instance, ATM and Point-of-Sale (POS) machines modified the way we make payments, and multimedia digital players changed how we listen to music and watch videos.

We are just at the beginning of a revolution that will have an impact on every other industrial sector. Special-purpose embedded systems will proliferate and will be found in almost any object that we use. They will be optimized for the application and show a natural user interface. They will be flexible, in order to adapt to a changing environment. Most of them will also be wireless, in order to follow us wherever we go and keep us constantly connected with the information we need and the people we care for. Even the role of computers will have to be reconsidered, as many of the applications for which they are used today will be performed by specially designed embedded systems.

What are the consequences of this revolution in the industry? Modern car manufacturers today need to acquire a significant amount of skills in hardware and software design, in addition to the mechanical skills that they already had in-house, or they should outsource the requirements they have to an external supplier. In either case, a broad variety of skills need to be mastered, from the design of software architectures for implementing the functionality, to being able to model the performance, because real-time aspects are extremely important in embedded systems, especially those related to safety-critical applications. Embedded system designers must also be able to architect and analyze the performance of networks, as well as validate the functionality that has been implemented over a particular architecture and the communication protocols that are used.

A similar revolution has taken place or is about to take place to other industrial and socio-economical areas as well, such as entertainment, tourism, education, agriculture, government, and so on. It is therefore clear that new, more efficient, and easy-to-use embedded electronics design methodologies need to be developed, in order to enable the industry to make use of the available technology.

82.2 Design of Embedded Systems

Embedded systems are informally defined as a collection of programmable parts surrounded by Application-Specific Integrated Circuits (ASICs) and other standard components (Application-Specific Standard Parts, ASSPs), which interact continuously with an environment through sensors and actuators. The collection can be physically a set of chips on a board, or a set of modules on an integrated circuit. Software is used for features and flexibility, while dedicated hardware is used for increased performance and reduced power consumption. An example of an architecture of an embedded system is shown in Figure 82.1. The main programmable components are microprocessors and DSPs, which implement the software partition of the system. One can view reconfigurable components, especially if they can be reconfigured at runtime, as programmable components in this respect. They exhibit area, cost, performance, and power characteristics that are intermediate between dedicated hardware and processors. Custom and programmable hardware components, on the other hand, implement application-specific blocks and peripherals. All components are connected through standard and/or dedicated buses and networks, and data are stored on a set of memories. Often, several smaller subsystems are networked together to control, for example, an entire car, or to constitute a cellular or wireless network.

We can identify a set of typical characteristics that are commonly found in embedded systems. For instance, they are usually not very flexible and are designed to always perform the same task: if you buy an engine control embedded system, you cannot use it to control the brakes of your car, or to play games. A PC, on the other hand, is much more flexible because it can perform several very different tasks. An embedded system is often part of a larger controlled system. Moreover, cost, reliability, and safety are

© 2005 by CRC Press LLC

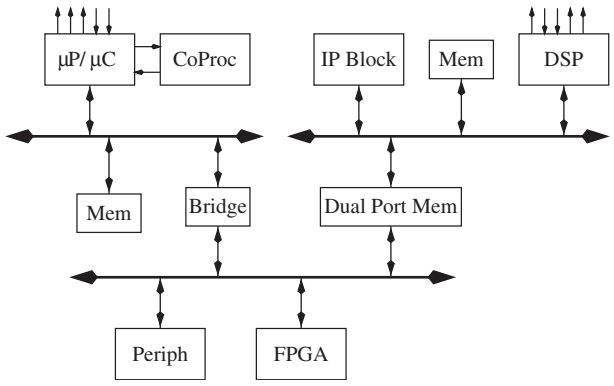

FIGURE 82.1 A reactive real-time embedded system architecture.

often more important criteria than performance, because the customer may not even be aware of the presence of the embedded system, and so he looks at other characteristics, such as the cost, the ease of use, or the lifetime of a product.

Another common characteristic of many embedded systems is that they need to be designed in an extremely short time to meet their time-to-market. Only a few months should elapse from conception of a consumer product to the first working prototypes. If these deadlines are not met, the result is a concurrent increase in design costs and decrease of the profits, because fewer items will be sold. Thus, delays in the design cycle may make a huge difference between a successful product and an unsuccessful one.

In the current state of the art, embedded systems are designed with an *ad hoc* approach that is heavily based on earlier experience with similar products and on manual design. Often, the design process requires several iterations to obtain convergence, because the system is not specified in a rigorous and unambiguous manner, and the level of abstraction, details, and design style in various parts are likely to be different. But as the complexity of embedded systems scales up, this approach is showing its limits, especially regarding design and verification time.

New methodologies are being developed to cope with the increased complexity and enhance designers' productivity. In the past, a sequence of two steps has always been used to reach this goal: *abstraction* and *clustering*. Abstraction means describing an object (i.e., a logic gate made of MOS transistors) using a model where some of the low-level details are ignored (i.e., the Boolean expression representing that logic gate). Clustering means connecting a set of models at the same level of abstraction, to obtain a new object, which usually shows new properties that are not part of the isolated models that constitute it. By successively applying these two steps, digital electronic design went from drawing layouts, to transistor schematics, to logic gate netlists, to register transfer level descriptions, as shown in Figure 82.2.

The notion of *platform* is key to the efficient use of abstraction and clustering. A platform is a single abstract model that hides the details of a set of different possible implementations as clusters of lower-level components. The platform, for example, a family of microprocessors, peripherals, and bus protocol, allows developers of designs at the higher level (generically called "applications" in the following) to operate without detailed knowledge of the implementation (e.g., the pipelining of the processor or the internal implementation of the UART). At the same time, it allows platform implementors to share design and fabrication costs among a broad range of potential users, broader than if each design was a one-of-a-kind type.

Today, we are witnessing the appearance of a new higher level of abstraction, as a response to the growing complexity of integrated circuits. Objects can be functional descriptions of complex behaviors, or architectural specifications of complete hardware platforms. They make use of formal high-level models that can be used to perform an early and fast validation of the final system implementation, although with reduced details with respect to a lower-level description.

The relationship between an "application" and elements of a platform is called a *mapping*. This exists, for example, between logic gates and geometric patterns of a layout, as well as between register transfer-level

© 2005 by CRC Press LLC

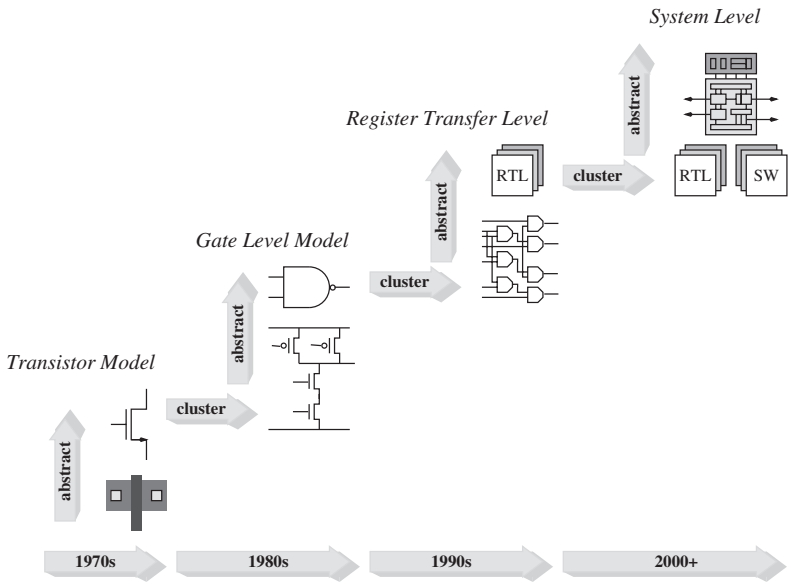

FIGURE 82.2 Abstraction and clustering levels in hardware design.

statements and gates. At the system level, the mapping is between functional objects with their communication links, and platform elements with their communication paths. Mapping at the system level means associating a functional behavior (e.g., an FFT or a filter) to an architectural element that can implement that behavior (e.g., a CPU or DSP or piece of dedicated hardware). It can also associate a communication link (e.g., an abstract FIFO) to some communication services available in the architecture (e.g., a driver, a bus, and some interfaces). The mapping step may also need to specify parameters for these associations (e.g., the priority of a software task or the size of a FIFO), in order to completely describe it. The object that we obtain after mapping shows properties that were not directly exposed in the separate descriptions, such as the performance of the selected system implementation. Performance is not just timing, but any other quantity that can be defined to characterize an embedded system, either physical (area, power consumption, etc.) or logical (quality of service, fault tolerance, etc.).

Since the system-level mapping operates on heterogeneous objects, it also allows one to elegantly separate different and orthogonal aspects such as:

1. Computation and communication. This separation is important because refinement of computation is generally done by hand, or by compilation and scheduling, while communication makes use of patterns.
2. Application and platform implementation (also called functionality and architecture, e.g., in [5]), because they are often defined and designed independently by different groups or companies.
3. Behavior and performance, which should be kept separate because performance information can either represent nonfunctional requirements (e.g., maximum response time of an embedded controller), or the result of an implementation choice (e.g., the worst-case execution time of a task). Nonfunctional constraint verification can be performed traditionally, by simulation and prototyping, or with static formal checks, such as schedulability analysis.

All these separations result in better *reuse,* because they decouple independent aspects, which would otherwise tie, for example, a given functional specification to low-level implementation details, by modeling it as assembler or Verilog code. This in turn allows one to reduce design time, by increasing the productivity and decreasing the time needed to verify the system.

© 2005 by CRC Press LLC

A schematic representation of a methodology that can be derived from these abstraction and clustering steps is shown in Figure 82.3. At the functional level, a behavior for the system to be implemented is specified, designed, and analyzed, either through simulation or by proving that certain properties are satisfied (the algorithm always terminates, the computation performed satisfies a set of specifications, the complexity of the algorithm is polynomial, etc.). In parallel, a set of architectures are composed from a clustering of platform elements, and selected as candidates for the implementation of the behavior. These components may come from an existing library or may be specifications of components that will be designed later.

Now, functional operations are assigned to the various architecture components, and patterns provided by the architecture are selected for the defined communications. At this level, we are now able to verify the performance of the selected implementation, with much richer details than at the pure functional level. Different mappings to the same architecture, or mapping to different architectures, allow one to explore the design space to find the best solutions to important design challenges. These analyses allow the designer to identify and correct possible problems early in the design cycle, thus reducing drastically the time to explore the design space and weed out potentially catastrophic mistakes and bugs. At this stage, it is also very important to define the organization of the data storage units for the system. Various kinds of memories (e.g., ROM, SRAM, DRAM, Flash, etc.) have different performance and data persistency characteristics, and must be used judiciously to balance cost and performance. Mapping data structures to different memories, and even changing the organization and layout of arrays can have a dramatic impact on the satisfaction of a given latency in the execution of an algorithm, for example. In particular, a System-On-Chip designer can afford to do a very fine tuning of the number and sizes of embedded memories (especially SRAM, but now also Flash) to be connected to processors and dedicated hardware [11].

Finally, at the implementation level, the reverse transformation of abstraction and clustering occurs, that is, a lower-level specification of the embedded system is generated. This is obtained through a series of manual or automatic refinements and modifications that successively add more details, while checking their compliance with the higher-level requirements. This step does not need to generate directly a manufacturable final implementation, but rather produces a new description that in turn constitutes the input for another (recursive) application of the same overall methodology at a lower level of abstraction (e.g., synthesis, placement and routing for hardware, compilation, and linking for software). Moreover, the results obtained by these refinements can be back-annotated to the higher level, to perform a better and more accurate verification.

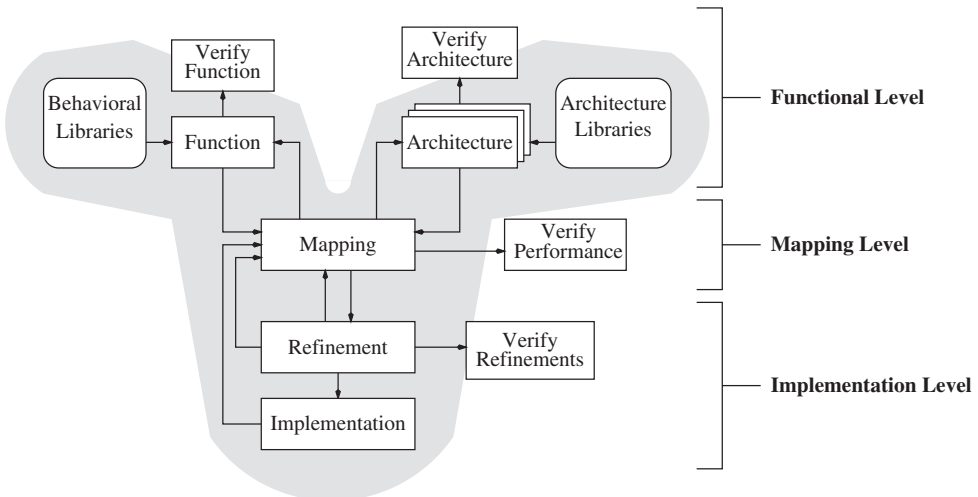

FIGURE 82.3 Design methodology for an embedded system.

82.3 Functional Design

As discussed in the previous section, system-level design of embedded electronics requires two distinct phases. In the first phase, functional and nonfunctional constraints are the key aspects. In the second phase, the available architectural platforms are taken into account, and detailed implementation can proceed after a mapping phase that defines the architectural component on which every functional model is implemented. This second phase requires a careful analysis of the trade-offs between algorithmic complexity, functional flexibility, and implementation costs.

In this section, we describe some of the tools that are used for requirements capture, focusing especially on those that permit *executable* specification. Such tools generally belong to two broad classes.

The first class is represented, for example, by Simulink [45], MATRIXx [33], Ascet-SD [2], SPW [54], SCADE [48], and SystemStudio [51]. It includes block-level editors and *libraries* using which the designer composes *data-dominated* digital signal processing and embedded control systems. The libraries include simple blocks, such as multiplication, addition, and multiplexing, as well as more complex ones, such as FIR filters, FFTs, and so on.

The second class is represented by tools such as Tau [52], StateMate [46], Esterel Studio [48], and StateFlow [45]. It is oriented to *control-dominated* embedded systems. In this case, the emphasis is placed on the decisions that must be taken by the embedded system in response to environment and user inputs, rather than on numerical computations. The notation is generally some form of Har'el's statecharts [24].

The Unified Modeling Language (UML), as standardized by the Object Management Group [53], is in a class by itself, since it focused historically more on general-purpose software (e.g., enterprise and commercial software), rather than on embedded real-time software. Only recently some embedded aspects such as performance and time have been incorporated in UML 2.0 [53,30] and emphasis has been placed on model-based software generation. However, tool support for UML 2.0 is still limited (Tau [52], Real Time Studio [47], and Rose RealTime [41] provide some), and UML-based hardware design is still in its infancy. Furthermore, the UML is a collection of notations, some of which (especially statecharts) are supported by several of the tools listed above in the control-dominated class.

Simulink and its related tools and toolboxes, both from Mathworks and from third parties such as dSPACE [16], are the workhorses of modern *model-based embedded system design.* In model-based design, a functional executable model is used for algorithm development. This is made easier in the case of Simulink by its tight integration with Matlab, the standard tool in DSP algorithm development. The same functional model, with added annotations such as bit widths and execution priorities, is then used for algorithmic refinements such as floating-point to fixed-point conversion and real-time task generation.

Then automated software generators such as Real-Time Workshop, Embedded Coder [45], and TargetLink [16] are used to generate task code and sometimes to customize a real-time operating system on which the tasks will run. Ascet-SD, for example, automatically generates a customization of the OSEK automotive real-time operating system [39] for the tasks that are generated from a functional model. In all these cases, a task is typically generated from a set of blocks that are executed at the same rate or triggered by the same event in the functional model.

Task formation algorithms can use either direct user input (e.g., the execution rate of each block in discrete time portions of a Simulink or Ascet-SD design) or static scheduling algorithms for dataflow models (e.g., based on relative block-to-block rate specifications in SPW or SystemStudio [31,7]).

Simulink is also tightly integrated with StateFlow, a design tool for control-dominated applications, in order to ease the integration of decision-making and computation code. It also allows one to smoothly generate both hardware and software from the very same specification. This capability, as well as the integration with some sort of statechart-based Finite State Machine editor, is available from most tools in the first class above. The difference in market share can be attributed to the availability of Simulink "toolboxes" for numerous embedded system design tasks (from fixed-point optimization to FPGA-based implementation) and its widespread adoption in undergraduate university courses, which makes it well known to most of today's engineers.

© 2005 by CRC Press LLC

The second class of tools either plays an ancillary role in the design of embedded control systems (e.g., as StateFlow and EsterelStudio) or is devoted to inherently control-dominated application areas, such as telecommunication protocols. In the latter market, the clear dominator today is Tau. The underlying languages, SDL and Message Sequence Charts, are standardized by the International Telecommunication Union (ITU). They are commonly used to describe in a tool-independent way protocol standards; thus, modeling in SDL is quite natural in this application domain, since validation and refinement can proceed formally within a unified environment. Tau also has code generation capabilities for both application code and customization of real-time kernels on which the FSM-generated code will run. The use of Tau for embedded code generation (model-based design) significantly predates that of Simulink-based code generators, mostly due to the highly complex nature of telecom protocols and the less demanding memory and computing power constraints that switches and other networking equipment have.

Tau has links to the requirements capture tool Doors [52], also from Telelogic, which allows one to trace dependencies between multiple requirements written in English, and connect them to aspects of the embedded system design files that implement these requirements. The state of the art of such requirement tracing, however, is far from satisfactory, since there is no formal means in Doors to automatically check for violations. Similar capabilities are provided by Reqtify [42].

Techniques for automated functional constraint validation, starting from formal languages, are described in several books, for example, [35,29]. Deadline, latency, and throughput constraints are a special kind of nonfunctional requirements that have received extensive treatment in the Real-Time scheduling community. They are also covered in several books, for example, [9,22].

While model-based functional verification is quite attractive, due to its high abstraction level, it ignores cost and performance implications of algorithmic decisions. These are taken into account by the tools described in the next section.

82.4 Function/Architecture and Hardware/Software Codesign

In this section, we describe some of the tools that are available to help embedded system designers optimally architect the implementation of the system, and choose the best solution for each functional component. After these decisions have been made, detailed design can proceed using the languages, tools, and methods described in the following chapters in this book.

This step of the design process, whose general structure has been outlined in Section 82.2 by using the platform-based design paradigm, has received various names in the past. Early work [18,23] called it hardware/software codesign (or cosynthesis), because one of the key decisions at this level is what functionality has to be implemented in software and in dedicated hardware, and how the two partitions of the design interact together with minimum cost and maximum performance.

Later on, people came to realize that hardware/software was too coarse a granularity, and that more implementation choices had to be taken into account. For example, one could trade off single vs. multiple processors, general-purpose CPUs vs. specialized DSPs, and Application-Specific Instruction-set Processors (ASIPs), dedicated ASIC vs. ASSP (e.g., an MPEG coprocessor or an Ethernet Medium Access Controller), standard cells vs. FPGA. Thus, the term function/architecture codesign was coined [5], to refer to the more complex partitioning problem of a given functionality onto a heterogeneous architecture such as the one in Figure 82.1.

The term system-level design also had some popularity in the industry [54,36], to indicate "the level of design above Register Transfer, at which software and hardware interact." Other terms, such as timed functional model, have also been used [26].

The key problems that are tackled by tools acting as a bridge between the system-level application and the architectural platform are:

1. how to model the performance impact of making mapping decisions from a virtually "implementation-independent" functional specification to an architectural model, and

© 2005 by CRC Press LLC

2. how to efficiently drive downstream code generation, synthesis, and validation tools to avoid redoing the modeling effort from scratch at the RTL, C, or assembly code levels, respectively. The notion of automated implementation generation from a high-level functional model is called "model-based design" in the software world.

In both cases, the notion of what is an "implementation-independent" functional specification, which can be retargeted indifferently to hardware and software implementations, must be carefully evaluated and considered. Taken in its most literal terms, this idea has often been taunted as a myth. However, current practice shows that it is already a reality, at least for some application domains (automotive electronics and telecommunication protocols). It is intuitively very appealing, since it can be considered as a high-level application of the platform-based design principle, by using a formal *system-level platform.* Such a platform, embodied in one of the several models of computation that are used in embedded system design, is a perfect candidate to maximize design reuse, and to optimally exploit different implementation options.

In particular, several of the tools that have been mentioned in the previous section (e.g., Simulink, TargetLink, StateFlow, SPW, System Studio, Tau, Ascet-SD, StateMate, Esterel Studio) have code generation capabilities that are considered good enough for *implementation* and not just for rapid prototyping and simulation acceleration. Moreover, several of them (e.g., Simulink, StateFlow, SPW, System Studio, StateMate, Esterel Studio) can generate indifferently C for software implementation, and synthesizable VHDL or Verilog for hardware implementation. Unfortunately, these code generation capabilities often require the laborious creation of implementation models for each target platform (e.g., software in C or assembler for a given DSP, synthesizable VHDL, or macro-block netlist for ASIC or FPGA, etc.). However, since these careful implementations are instances of the system-level platform mentioned above, their development cost can be shared among a multitude of designs performed using the tool.

Most block diagram-or statechart-based code generators work in a syntax-directed manner. A piece of C or synthesizable VHDL code is generated for each block and connection, or for each hierarchical state and transition. Thus, the designer has tight control over the complexity of the generated software or hardware. While this is a convenient means to bring manual optimization capabilities within the model-based design flow, it has a potentially significant disadvantage in terms of cost and performance (like disabling optimizations in the case of a C compiler). On the other hand, more recent tools like EsterelStudio and SystemStudio take a more radical approach to code generation, based on aggressive optimizations [6]. These optimizations, based on logic synthesis techniques also in the case of software implementation, destroy the original model structure, and thus make debugging and maintenance much harder. However, they can result in an order of magnitude improvement in terms of cost (memory size) and performance (execution speed) with respect to their syntax-directed counterparts [17].

Assuming that good automated code generation, or manual design, is available for each block in the functional model of the application, we are now facing the function-architecture codesign problem. This essentially means tuning the functional decomposition, as well as the algorithms used by the overall functional model and each block within it, to the available architecture, and vice versa.

Several design environments, for example:

- POLIS [5], COSYMA [18], Vulcan [23], COSMOS [28], and Roses [12] in the academic world, as well as
- VCC [54], Real Time Studio [47], Foresight [50], and CARDtools [10] in the commercial world,

help the designer in this task by somehow using the notion of independence between functional specification on the one hand, and hardware/software partitioning or architecture mapping choices on the other.

The step of performance evaluation is performed in an abstract, approximate manner by the tools listed above. Some of them use estimators to evaluate the cost and performance of mapping a functional block to an architectural block. Others (e.g., POLIS and VCC) rely on cycle-approximate simulation to perform the same task in a manner that better reflects real-life effects, such as burstiness of resource occupation and so on. Techniques for deriving both abstract static performance models (e.g., the Worst-Case Execution Time of a software task) and performance simulation models are discussed below.

© 2005 by CRC Press LLC

In all cases, both the cost of computation and that of communication must be taken into account. This is because the best implementation, especially in the case of multimedia systems that manipulate large amounts of image and sound data, is often one that reduces the amount of transferred data between multiple memory locations, rather than one that finds the absolute best trade-off between software flexibility and hardware efficiency. In this area, the Atomium project at IMEC [11,3] has focused on finding the best memory architecture and schedule of memory transfers for data-dominated applications on mixed hardware/software platforms. By exploiting array access models based on polyhedra, they identify the best reorganization of inner loops of DSP kernels and the best embedded memory architecture. The goal is to reduce memory traffic due to register spills, and maximize the overall performance by accessing several memories in parallel (many DSPs offer this opportunity even in the embedded software domain). A very interesting aspect of Atomium, which distinguishes it from most other optimization tools for embedded systems, is the ability to return *a set of Pareto-optimal* solutions (i.e., solutions that are not strictly better than one another in at least one aspect of the cost function), rather than a single solution. This allows the designer to pick the best point based on the various aspects of cost and performance (e.g., silicon area vs. power and performance), rather than forcing him to "abstract" optimality into a single number.

Performance analysis can be based on simulation, as mentioned above, or rely on automatically constructed models that reflect the Worst-Case Execution Time (WCET) of pieces of software (e.g., RTOS tasks) running on an embedded processor. Such models, which must be both provably conservative and reasonably accurate, can be constructed using an execution model called *abstract interpretation* [15]. This technique traverses the software code, while building a symbolic model, often in the form of linear inequalities [32,1], which represents the requests that the software makes to the underlying hardware (e.g., code fetches, data loads and stores, code execution). A solution to those inequalities then represents the total "cost" of one execution of the given task. It can then be combined with processor, bus, cache, and main memory models that in turn compute the cost of each of these requests in terms of time (clock cycles) or energy. This finally results in a complete model for the cost of mapping that task to those architectural resources.

Another technique for software performance analysis, which does not require detailed models of the hardware, uses an approximate compilation step from the functional model to an executable model (rather than a set of inequalities as above) annotated with the same set of fetch, load, store, and execute requests. Then, simulation is used, in a more traditional setting, to analyze the cost of implementing that functionality on a given processor, bus, cache, and memory configuration. Simulation is more effective than WCET analysis in handling multiprocessor implementations, in which bus conflicts and cache pollution can be difficult, if not utterly impossible, to predict statically in a manner that is not too conservative. However, its success in identifying the true worst-case depends on the designer ability to provide the appropriate simulation scenarios. Coverage enhancement techniques from the hardware verification world [4,27] can be extended to also help in this case.

Similar abstract models can be constructed in the case of implementation as dedicated hardware, by using high-level synthesis techniques. Such techniques are not yet good enough to generate production-quality RTL code, but can be considered as a reasonable estimator of area, timing, and energy costs for both ASIC and FPGA implementations [49,55,14,51].

SystemC [26] and SpecC [19,20], on the other hand, are more traditional modeling and simulation languages, for which the design flow is based on successive refinement rather than codesign or mapping. Finally, OPNET [38] and NS [37] are simulators with a rich modeling library specialized for wireline and wireless networking applications. They help the designer in the more abstract task of generic performance analysis, without the notion of function/architecture separation and codesign.

Communication performance analysis, on the other hand, is generally not done using approximate compilation or WCET analysis techniques like those outlined above. Communication is generally implemented not by synthesis but by *refinement* using patterns and "recipes," such as interrupt-based, DMA-based, and so on. Thus, several design environments and languages at the function/architecture level, such as POLIS, COSMOS, Roses, VCC, SystemC and SpecC, as well as N2C [36], provide mechanisms to replace abstract communication, for example, FIFO-based or discrete event-based, with detailed protocol stacks using buses, interrupt controllers, memories, drivers, and so on. These refinements can then be

© 2005 by CRC Press LLC

estimated either using a library-based approach (they are generally part of a library of implementation choices anyway), or sometimes using the approaches described above for computation. Their cost and performance can thus be combined in an overall system-level performance analysis.

However, approximate performance analysis is often not good enough, and a more detailed simulation step is required. This can be achieved by using tools such as Seamless [44], CoMET [13], MaxSim [34], and N2C [36]. They work at a lower abstraction level, by cosimulating software running on Instruction Set Simulators and hardware running in a Verilog or VHDL simulator. While the simulation is often slower than with more abstract models, and dramatically slower than with static estimators, the precision can now be at the cycle level. Thus, it permits close investigation of detailed communication aspects, such as interrupt handling and cache behavior. These approaches are further discussed in the next section.

The key advantage of using the mapping-based approach over the traditional design–evaluate–redesign one is the speed with which design space exploration can be performed. This is done by setting up experiments that change either mapping choices or parameters of the architecture (e.g., cache size, processor speed, or bus bandwidth). Key decisions, such as the number of processors and the organization of the bus hierarchy, can thus be based on quantitative application-dependent data, rather than on past experience.

If mapping can then be used to drive synthesis, in addition to simulation and formal verification, advantages in terms of time-to-market and reduction of design effort are even more significant. Model-based code generation, as we mentioned in the previous section, is reasonably mature, especially for embedded software in application areas, such as avionics, automotive electronics, and telecommunications. In these areas, considerations other than absolute minimum memory footprint and execution time, for example, safety, sheer complexity, and time-to-market, dominate the design criteria.

At the very least, if some form of automated model-based synthesis is available, it can be used to rapidly generate FPGA - and processor-based prototypes of the embedded system. This significantly speeds up verification, with respect to workstation-based simulation. It permits even some hardware-in-the-loop validation for cases (e.g., the notion of "driveability" of a car) in which no formalization or simulation is possible, but a real physical experiment is required.

82.5 Hardware/Software Coverification and Hardware Simulation

Traditionally, the term "hardware/software codesign" has been identified with the ability to execute a simulation of the hardware and software at the same time. We prefer to use the term "hardware/software coverification" for this task, and leave codesign for the synthesis- and mapping-oriented approaches outlined in the previous section. In the form of simultaneously running an Instruction Set Simulator (ISS) and a Hardware Description Language (HDL) simulator, while keeping the timing of the two synchronized, the area is not new [43]. In recent years, however, we have seen a number of approaches to speeding up the task, in order to tackle platforms with several processors, and the need, for example, to boot an operating system in order to coverify a platform with a processor and its peripherals.

Recent techniques have been devoted to the three main ways in which cosimulation speed can be increased:

1. *Accelerate the hardware simulator*. Coverification generally works at the "clock cycle accurate" level, meaning that both the hardware simulator and the ISS view time as a sequence of discrete clock cycles, ignoring finer aspects of timing (sometimes clock phases are considered, e.g., for DSP systems, in which different memory banks are accessed in different phases of the same cycle). This allows one to speed up simulation with respect to traditional event-driven logic simulation, and yet retain enough precision to identify, for example, bottlenecks such as interrupt service latency or bus arbitration overhead.
   Native-code hardware simulation (e.g., NCSim[54]) and emulation (e.g., Quick-Turn [54] and Mentor Emulation [44]) can be used to further speed up hardware simulation, at the expense of longer compilation times and much higher costs, respectively.
2. *Accelerate the instruction set simulator*. Compiled-code simulation has been a popular topic in this area as well [56]. The technique compiles a piece of assembler or C code for a target processor into

© 2005 by CRC Press LLC

object code that can be run on a host workstation. This code generally also contains annotations counting clock cycles by modeling the processor pipeline. The speedup that can be achieved with this technique over a traditional ISS, which fetches, decodes, and executes each target instruction individually, is significant (at least one order of magnitude). Unfortunately, this technique is not suitable for self-modifying code, such as that of a Real-Time Operating System (RTOS). This means that it is difficult to adapt to modern embedded software, which almost invariably runs under RTOS control, rather than on the bare CPU. However, hybrid techniques involving partial compilation on the fly are reportedly used by companies selling fast ISSs [13,34].

3. *Accelerate the interface between the two simulators.* This is the area where the earliest work has been performed. For example, Seamless [44] uses sophisticated filters to avoid sending requests for memory accesses over the CPU bus. This allows the bus to be used only for peripheral access, while memory data are provided to the processor directly by a "memory server," which is a simulation filter sitting in between the ISS and the HDL simulator. The filter reduces stimulation of the HDL simulator, and thus can result in speedups of one or more orders of magnitude, when most of the bus traffic consists of filtered memory accesses. Of course, also, precision of analysis drops, since, for example, it becomes harder to identify an overload in the processor bus due to a combination of memory and peripheral accesses, since no simulator component sees both.

In the HDL domain, as mentioned above, progress in the levels of performance has been achieved essentially by raising the level of abstraction. A "cycle-based" simulator, that is, one that ignores the timing information within a clock cycle, can be dramatically faster than one that requires the use of a timing queue to manage time-tagged events. This is due to mainly two reasons. The first one is that now most of the simulation can be executed always, at every simulation clock cycle. This means that it is much more parallelizable, while event-driven simulators do not fit well over a parallel machine due to the presence of the centralized timing queue. Of course, there is a penalty if most of the hardware is generally idle, since it has to be evaluated anyway, but clock gating techniques developed for low power consumption can obviously be applied here. The second one is that the overhead of managing the time queue, which often accounts for 50–90% of the event-driven simulation time, can now be completely eliminated.

Modern HDLs either are totally cycle-based (e.g., SystemC 1.0 [26]) or have a "synthesizable subset," which is fully synchronous and thus fully compilable to cycle-based simulation. The same synthesizable subset, by the way, is also supported by hardware emulation techniques, for obvious reasons.

Another interesting area of cosimulation in embedded system design is analog–digital cosimulation. This is because such systems quite often include analog components (amplifiers, filters, A/D and D/A converters, demodulators, oscillators, PLLs, etc.), and models of the environment quite often involve only continuous variables (distance, time, voltage, etc.). Simulink includes a component for simulating continuous-time models, using a variety of numerical integration methods, which can be freely mixed with discrete-time sampled-data subsystems. This is very useful when modeling and simulating, for example, a control algorithm for automotive electronics, in which the engine dynamics are modeled with differential equations, while the controller is described as a set of blocks implementing a sampled-time subsystem.

Simulink is still mostly used to drive software design, despite good toolkits implementing it in reconfigurable hardware [21,8]. Simulators in the hardware design domain, on the other hand, generally use HDLs as their input languages. Analog extensions of both VHDL [25] and Verilog [40] are available. In both cases, one can represent quantities that satisfy either of Kirchhoff's laws (i.e., conserved over cycles or nodes). Thus, one can easily build netlists of analog components interfacing with the digital portion, modeled using traditional Boolean or multivalued signals. The simulation environment will then take care of synchronizing the event-driven portion and the continuous time portion. A key problem here is to avoid causality errors, when an event that occurs later in "host workstation" time (because the simulator takes care of it later) has an effect on events that preceded it in "simulated time." In this case, one of the simulators has to "roll back" in time, undoing any potential changes in the state of the simulation, and restart with the new information that something has happened in the past (generally the analog simulator does it, since it is easier to reverse time in that case).

© 2005 by CRC Press LLC

Also, in this case, as we have seen for hardware/software cosimulation, execution is much slower than in the pure event-driven or cycle-based case, due to the need to take small simulation steps in the analog part. There is only one case in which the performance of the interface between the two domains or of the continuous time simulator is not problematic. This occurs when the continuous time part is much slower in reality than the digital part. A classical example is automotive electronics, in which mechanical time constants are larger by several orders of magnitude than the clock period of a modern integrated circuit. Thus, the performance of continuous time electronics and mechanical cosimulation may not be the bottleneck, except in the case of extremely complex environment models with huge systems of differential equations (e.g., accurate combustion engine models). In that case, hardware emulation of the differential equation solver is the only option (see, e.g., [16]).

82.6 Conclusions

This chapter discussed several aspects of embedded system design, including both methodologies that allow one to perform judicious algorithmic and architectural decisions, and tools supporting various steps of these methodologies. One must not forget, however, that often embedded systems are complex compositions of parts that have been implemented by various parties, and thus the task of physical board or chip integration can be as difficult as, and much more expensive than, the initial architectural decisions.

In order to support the integration and system testing tasks, one must use formal models throughout the design process, and if possible perform early evaluation of the difficulties of integration, by virtual integration and rapid prototyping techniques. These allow one to find or avoid completely subtle bugs and inconsistencies earlier in the design cycle, and thus reduce overall design time and cost.

Thus, the flow and tools that we described in this chapter help not only with the initial design but also with the final integration. This is because they are based on executable specifications of the whole system (including models of its environment), early virtual integration, and systematic (often automated) refinement toward implementation.

83.1 Introduction
83.2 Notions of Time
83.3 Communication Support
83.4 Common Models of Computation
Dataflow Models • Discrete Event • Finite State Machines • Codesign Finite State Machines • Synchronous/reactive Models • Statecharts • Petri nets • The Tagged Signal Model

83.1 Introduction

Embedded systems complexity has been continuously increasing and the embedded system requirements have been more and more demanding, trying to cope with different aspects, ranging from complexity management, heterogeneous platforms, design correctness, to costs, power consumption, time-to-market, and other issues.

The specification process is a key aspect in embedded system design. At that stage, a model of the system has to be built and it is described using some specific formalism. Formalisms should be selected to unambiguously describe design specifications. These formalisms are also called *models of computation*. A model of computation (MoC) is composed by a notation and by the rules for computation of the behavior. Instead of notation, we talk about the *syntax* of the model; the rules define the model *semantics*.

Different kinds of graphs are often used as an abstract syntax for MoC representation. Examples of graph-based MoC include Finite State Machines (with different "flavors" and expressiveness capabilities), Data flow, Petri nets, and networks of processes. With respect to semantics associated with a specific MoC, different notions of time and modes of concurrency and communication, within the model or among components, are commonly considered.

Depending on the selected MoC to represent system behavior, it will be possible to perform propriety verification through specific analysis methods.

There are many models of computation ready to be used by embedded system designers, and most of them use a graphical representation. The first task is to choose the right one either to be used for a specific system, or for describing subbehaviors of the system. This is a difficult task, as different embedded systems can emphasize different aspects. For instance, some models of computation for embedded systems are control-dominated (data processing and computation are minimal), while others emphasize data processing, containing complex data transformations, normally described by data flows. For example, in the first group, we found *reactive control systems*, and in the second one we found *digital signal processing applications*. As

© 2005 by CRC Press LLC

examples, we may say that for digital signal processing applications, it is common to select data flow models; on the other hand, finite state machine are usually used for control-intensive applications. The selection of the right formalism should match the specific system characteristics. Some MoCs were specifically defined for describing complex data processing functions, but completely inadequate for modeling complex control; others have complex control in mind, but lack good support for data transfer functions. Also, the need to handle different notions of time, or different modes of communication among components, may further complicate the search for the right model of computation.

The goal is to pick up the right formalism for the different subbehaviors specifications, and, afterwards, to be able to integrate all those models in a coherent way [22]. Several MoCs allow the modeler to describe the system as a collection of communicating modules. In this sense, modeling of behavior and communication among components often presents interdependencies. Yet, separating behavior and communication is a sound attitude as it allows handling system design complexity and reusability of components.

These aspects of time representation and communication support are addressed in the following sections. Later, several selected models of computation are presented.

83.2 Notions of Time

The notion of time is of major importance for many models of computation for embedded systems. Embedded systems are mostly regarded as real-time systems, where the time at which a computation takes place is typically critical.

Roughly speaking, we may identify three groups of attitudes:

- continuous time and differential equations;
- discrete time and difference equations; and
- discrete events.

The first group (see Figure 83.1(a)) uses continuous time functions, which are then expressed by differential equations. These are mostly used in embedded system design for modeling of some interface components. Application areas include modeling of analog circuits and physical systems in a broad sense.

In the second group (Figure 83.1(b)), time is made discrete, and differential equations become difference equations. A global clock (the tick) defines the specific points in time at which the signals have values. For some applications, involving heterogeneous components, it is useful to consider also multirate difference equations. Application areas include digital signal processing.

Finally, in the third group (see Figure 83.1(c)), a signal is seen as a sequence of events. Each event has associated value and time tags. The component will process events in a chronological order, based on a predefined precedence between events.

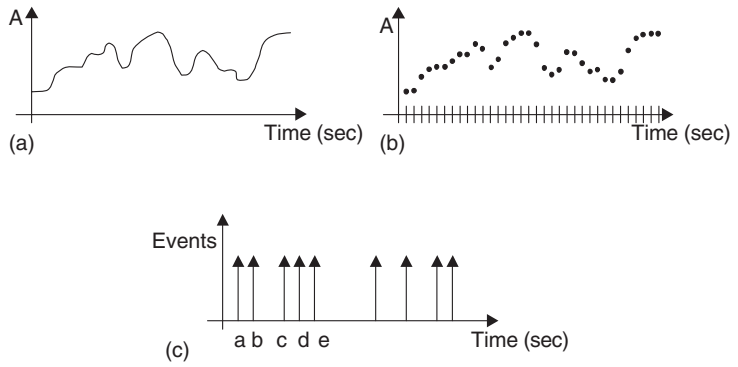

FIGURE 83.1 Time representations.

© 2005 by CRC Press LLC

If the time tags are totally ordered [13], we are in the presence of a *timed system*. This means that, for any distinct t_1 and t_2, either $t_1 < t_2$ or $t_2 < t_1$ (this is called a *total order*). It is possible to define an associated metric, for instance, $f(t_1, t_2) = | t_1 - t_2 |$.

A *continuous time system* is a metric time system where the metric is a continuum. *A discrete-event system* is a timed system where the time tags are order-isomorphic to a subset of the integers; hence, they are totally ordered.

Two events are synchronous if they have the same time tag attached (they occur simultaneously). Similarly, two signals are synchronous if for each event in one signal, there is a synchronous event in the other signal, and vice versa. A system is synchronous if every signal in the system is synchronous with every other signal in the system. In this sense, a discrete-time system is a synchronous discrete-event system.

Totally ordered events are used with digital hardware simulators, namely the ones associated with VHDL and Verilog hardware description languages.

Any two events are either simultaneous, which means that they have the same time tag, or any one of them can precede the other. Events can be considered partially ordered in the sense that the order does not include all the events in the system. When tags are partially ordered instead of totally ordered, the system is *untimed*. This means we can build several event sequences that do not contain all the system events. These missing events are included in other completely ordered event sequences. It is known [26] that totally order of the events cannot be maintained in distributed systems, where a partial order is sufficient to analyze system behavior. Partial orders have also been used to analyze Petri nets [37].

An asynchronous system is a system in which no two events can have the same tag [27]. If tags are totally ordered, the system is *asynchronous interleaved*, while if tags are partially ordered, the system is *asynchronous concurrent*.

As time is intrinsically continuous, real systems are asynchronous by nature. Yet, synchronicity is a very convenient abstraction, allowing efficient and robust implementations, through the use of a reference "clock" signal.

83.3 Communication Support

Due to complexity reasons, or reusability of already available components, it is common to decompose an embedded system into several components, which will interact with one another. Communication between processes is, in this sense, a key issue for embedded system design. It can be implicit or explicit [36]:

- Implicit communication generally requires totally ordered tag events, normally associated with physical time. In order to support this form of communication, it is necessary to have a physically shared signal (for instance, a clock signal), whose availability may be difficult or unfeasible in a large number of embedded system applications.
- Explicit communication imposes an order on the events, in the sense that the sender process will guarantee that the receiver process(es) is(are) informed about some part of its internal state.

Several modes of communication have been described in the literature, namely:

- *Handshake*, using a synchronization mechanism, where all parties are blocked, waiting for the conclusion;
- *Message passing*, using a send–receive scheme, where the receiver will wait for the message;
- *Shared variables*, where the blocking is decided by the control part of the memory where the shared variable is stored.

The referred communication modes are supported by a set of communication primitives (or by a combination of some of them), namely [36]:

Unsynchronized: producer and consumer(s) are not synchronized. There are no guarantees that the producer does not overwrite previously produced data, or that the consumer(s) will receive all produced data.

Read–modify–write: this is the common way to gain access to shared data structures from different processes in software. Access to the data structure is locked during a data access (either read–write or read–modify–write), which means that it is an atomic action (indivisible, and thus uninterruptible).

© 2005 by CRC Press LLC

Unbounded FIFO buffered: the producer generates a sequence of data tokens and the consumer will read those tokens using a FIFO discipline.

Bounded FIFO buffered: also in this case, considering the simplest case of one producer and one consumer, the producer generates a sequence of data tokens and the consumer will also read those tokens using a FIFO discipline. Yet, here the buffer size is limited, so the difference between writings and readings will be bounded by some value. This means that writings can be blocked if the buffer is full.

Petri net places: producers generate sequences of data tokens and consumers will read those tokens.

Rendezvous: the writing and reading processes must simultaneously be at the point where the write and the read occur.

83.4 Common Models of Computation

In this section, we will present and compare some of the main MoCs that have been used for embedded system's design.

Dataflow Models

Dataflow models are graphs where nodes represent operations (also called *actors*) and arcs represent data paths (also called *channels*). These data paths contain totally ordered sequences of data (also called *tokens*). A Dataflow is a distributed MoC, in the sense that there is no single locus of control. Yet, the conventional dataflow model is not suitable for representing the control part of the system (only what is implied by the graph structure). With respect to time handling, dataflow systems are asynchronous concurrent.

Dataflow graphs have been extensively used in modeling data-dominated systems, namely digital signal processing applications, and applications dealing with streams of periodic/regular data samples. Computationally intensive systems, carrying complex data transformation, can be conveniently represented by a directed graph where the nodes represent computation and the arcs represent the order in which the computations are performed. Typically, signal-processing algorithms (encode/decode, filtering, convolution, compression, etc.) are expressed as block diagrams and coded in a specific programming language, like C, whose computation blocks match exactly the dataflow semantics.

Several dataflow graph-based MoCs have been referred in the literature, each one with its specific semantics, namely:

- Kahn Process Network [18];
- Dataflow Process Networks [11];
- Synchronous DataFlow Graphs [14].

In a Kahn Process Networks, and also in Dataflow Process Networks (which constitute a special case of Kahn Process Network), processes communicate by passing data tokens through unidirectional unbounded FIFO channels. A process can fire according to a set of firing rules. During each atomic firing, the actor consumes tokens from input channels, executes some behavior using a selected programming language, and produces tokens that are placed on output channels. Writing to the channel is nonblocking, although reading from the channel blocks the process until there is sufficient data in it. Kahn Process Networks have guaranteed deterministic behavior, in the sense that for a certain sequence of inputs, there is only one possible sequence of outputs. This is independent from the computation and communication durations, and also from the actors' firing order. The dataflow process analysis can be based only on graph inspection. Also, implementation can be very efficient, due to the freedom of choosing the actors' firing order. In fact, one common goal in many signal-processing applications is to schedule the actor firings, at compile time. This results in an interleaved implementation for the concurrent model, represented by a list of processes to be executed, allowing its implementation in single-processor architecture. Accordingly, for multiprocessor architectures, a list per processor is obtained. Kahn Process Networks cannot be schedule statically, as their firing rules do not allow us to build, at compile time, a firing sequence such that the system does not block under any circumstances. For this kind of MoC, one must use dynamic scheduling

© 2005 by CRC Press LLC

(with associated implementation overhead). Another disadvantage of Kahn Process Networks is associated with unbounded FIFO buffers, and the potentially growth of memory needs. In this sense, and without considering some limitations, Kahn Process Networks cannot be efficiently implemented.

Synchronous dataflow graphs are a kind of Kahn process networks with additional restrictions, namely:

- At each firing, a process consumes and produces a fixed amount of tokens on its incoming and outgoing channels, respectively.
- For a process to fire, it must have at least as many tokens on its input channels as it has to consume.
- Arcs are marked with the number of tokens produced or consumed.

Figure 83.2 shows a simple dataflow model and associated static scheduling list. This scheduling is a list of firings that can be repeated indefinitely. One cycle through the schedule should return the graph to its original state (by state, we mean the number of tokens in every arc).

This static schedule can be determined through the analysis of the graph in order to find the paths of firing sequences that satisfy, on each arc, the same amount of tokens to be produced and consumed. One balance equation is built per arc, considering that

$$\text{outgoing_weight} * \text{origin_node} = \text{incoming_weight} * \text{destination node}$$

For the referred example, the following balance equations can be obtained (one per arc):

$$2a - 4b = 0$$

$$b - 2c = 0$$

$$2c - d = 0$$

$$2b - 2d = 0$$

$$2d - a = 0$$

The root of the set of presented equations is ($a = 4$, $b = 2$, $c = 1$, $d = 2$), which gives information about the firing vector associated with the static scheduling list. Yet, in other cases, it is possible that the mentioned balance equations do not have a root, implying that no static schedule is possible.

Many possible variants of data flow models have been explored. Specially interesting, among them, is an extension to Synchronous dataflow networks allowing *dynamic dataflow actors* [10]; dynamic actors are actors with at least one conditional input or output port. The canonical dynamic actors are "switch" and "selector," enabling the test of tokens on one specific incoming arc, and the consumption and production of tokens in a data-dependent way. A "Switch" process, for example, has one regular incoming arc, one control incoming

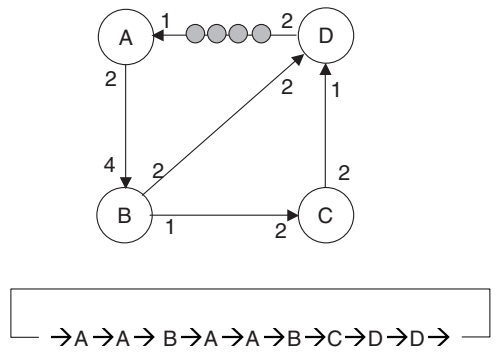

FIGURE 83.2 Simple dataflow model and associated static schedule list.

© 2005 by CRC Press LLC

arc, and two outgoing arcs; whenever tokens are presented in the incoming arcs, the value carried by the token presented in the control arc will dynamically select the active outgoing arc: the process firing will produce one single token at the selected outgoing arc. Figure 83.3 illustrates dynamic dataflow actor behavior before and after firing. It has to be noted that control ports are never conditional ports. More complex dynamic actors can be used, namely dynamic actors with integer control (instead of Boolean control), giving rise to CASE and ENDCASE actors (generalizations of the SWITCH and SELECT actors, respectively).

Aggregation of the referred actors using specific patterns is commonly applied. For instance, integer-controlled dataflow graphs can result from cascading a CASE actor, a set of mutually exclusive processing nodes, and an ENDCASE actor; control ports of the CASE and ENDCASE actors receive the same value; only one of the processing nodes is executed at a time depending on the value presented at the control port.

Most simulation environments targeted for signal processing, like Matlab-Simulink or Khoros (for image processing), use dataflow models.

Discrete Event

In the discrete-event MoC, events carry a totally ordered time stamp, referring to the time at which the event occurs. The events are sorted by time stamp and they are analyzed in chronological order. A discrete-event

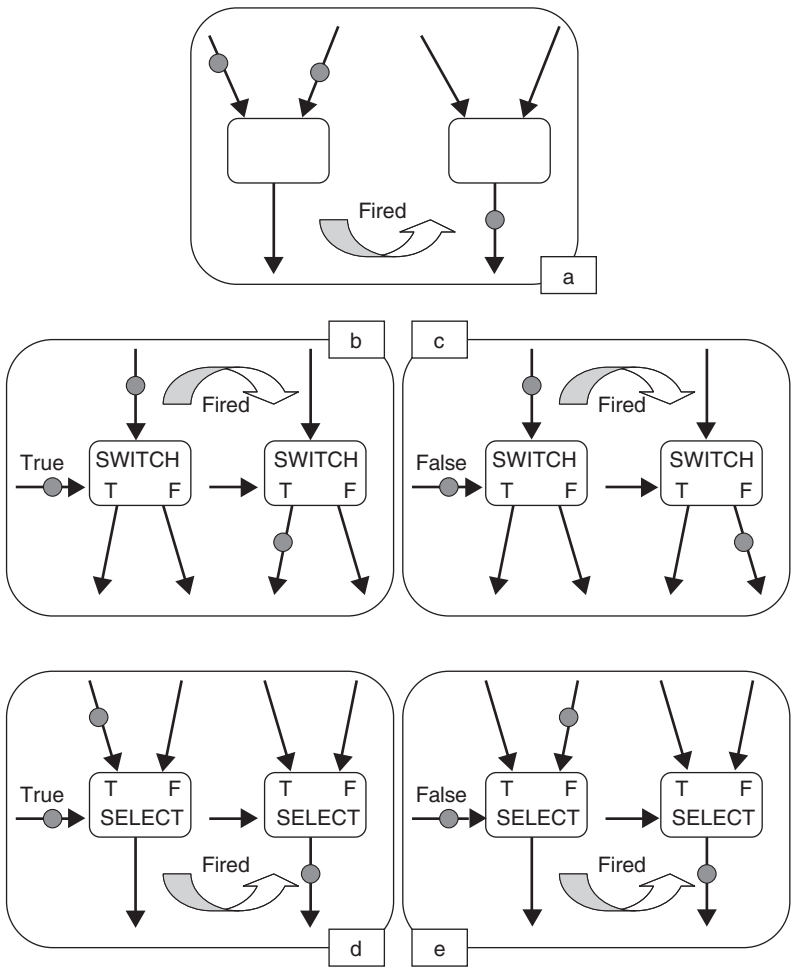

FIGURE 83.3 Dynamic dataflow actors and dataflow firings.

© 2005 by CRC Press LLC

simulator usually maintains a global event queue. This can be computationally expensive, as it is necessary to maintain a sorted queue of all the occurred events, according to the respective time of occurrence.

The operational semantics of a discrete event system consists in the sequential firing of the processes according to the chronological time stamps of queued events. For each specific queued event, the processes, that have it as an input, will be fired and the event will be removed from the queue. New events will be produced due to the previous firing and should be added to the event queue, according to its time tag.

Hardware description languages, like VHDL and Verilog, as most digital hardware simulation engines, use a discrete-event based simulation approach.

Simultaneous events, especially those arising from zero-time delay, can cause some problems, due to the ambiguity resulting from equal time tags (they cannot be ordered). Figure 83.4 illustrates one simple situation.

Considering that *X*, *Y* and *Z* represent some processing modules/processes/components, and that module *Y* has zero-time delay, it will produce output events with the same time stamp as input events. If module *X* produces an event with time stamp *t* (Figure 83.4 (a)), both modules *Y* and Z will receive that event; there is ambiguity about whether *Y* or *Z* should be executed first. If *Z* is executed first, the event presented at its input will be consumed; afterwards, *Y* will be executed and will produce an event that will be consumed in turn by *Z*.

On the other hand, if *Y* is executed first, an event will be produced with the same time stamp, because module *Y* has zero-time delay (Figure 83.4 (b)). At this point, execution of *Z* can be accomplished in several ways: taking both events at the same invocation step, or taking one of the events first and the other afterwards (it is also not clear as to which should be processed first). In order to enable a coherent system simulation (producing the same result even if *Y* or *Z* are executed first), the concept of delta delay is introduced. Events with the same time stamp are ordered according to the delta value. Now, the event produced by module *Y* will have a time stamp of $t+\Delta$ (Figure 83.4 (c)), resulting in an execution of *Z* first consuming the event arising from *X* with time stamp *t*, and afterwards (in the next delta step) consuming the event arising from *Y*, with time stamp $t+\Delta$ (Figure 83.4 (d)). If a different zero-time delay process receives the event with time stamp $t+\Delta$, it will generate a further event with time stamp $t+2\Delta$. All events with the same (time tag, delta tag) will be consumed at the same time.

This means a two-level model of time was introduced: on top of the totally ordered events, each time instant can be further decomposed into (totally ordered) delta steps applicable to generated events. However, from the point of view of the simulated time reported to the user, no delta information is included. In this sense, delta steps do not relate to time as perceived by the observer. They are simply a mechanism to compute the behavior of the system at a point in time. Similar mechanisms can also be used in synchronous/reactive models. These are analyzed in the next section.

Finite State Machines

Finite State Machines (FSMs) are a common computational model used by system designers for decades. They are commonly represented in different ways. In this chapter, state diagrams are used. The modeling

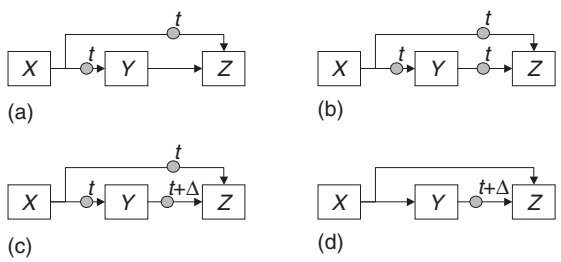

FIGURE 83.4 Handling of simultaneous events in a discrete-event system.

© 2005 by CRC Press LLC

attitude is based on the characterization of the system in terms of the global states that it can exhibit, and also in terms of the conditions that can cause a change in those states. An FSM consists of a set of input signals, a set of output signals, a finite set of states (with a specified initial state), an output function, and a next-state function.

Figure 83.5 illustrates a basic notation for a state diagram. Circles or ellipses represent states; transitions between states use a directed arc. Each arc has an attached expression, potentially containing reference to the input event and/or to an external condition that will cause the change of state. Two basic models can be considered for output modeling: Moore-type machine [12], where outputs are associated with state activation, and Mealy-type machine [17], where outputs are associated with transition arcs. Both models have the same modeling capabilities.

They also have well-known strengths and weaknesses. Among the strengths, we should mention that they are simple and intuitive to understand. This is one of the reasons why designers have extensively used them in the past, and continue to use them. Unfortunately, several weaknesses prevent their usage for complex systems modeling. Namely, FSMs do not provide data processing capabilities, support for concurrency modeling, (practical) support for data memory, and hierarchical constructs.

FSMs are a control-dominated model of computation. We will use an FSM model to introduce a running example, inspired by the one in [30]. It has to do with the control of an electric car that should carry goods from one point to another, and come back. The order to start movement is specified by actuation on key "GO," while the command to return is specified through the actuation on the key "BACK." After receiving an order, the car motor is adequately activated, while the initial, or the final, position is not reached; there are two sensors available for this purpose. Figure 83.6(a) represents the external view of the controller in terms of inputs and outputs, and Figure 83.6(b) illustrates the layout of the plant.

Figure 83.6(c) and (d) present two possible (and equivalent) models for the control of the referred system. The first relies on the evaluation of external conditions (signal values are explicitly checked), while the second relies on events. It is clear that events usage will produce a lighter model, with less arcs and inscriptions (it is assumed in this representation that an event associated with a signal is generated when the signal changes its state from '0' to '1').

From the execution semantics point of view, we can find two attitudes (which correspond to different models of computation) [31]:

1. Synchronous FSMs;
2. Asynchronous FSMs.

In Synchronous FSMs, both computation and communication occur instantaneously at discrete time instants (under the control of clock ticks). One strong aspect in favor of Synchronous FSMs is its implementation robustness, especially when using synchronous hardware. However, when heterogeneous implementations are foreseen, some difficulties or inefficiencies may arise. Anyway, within a synchronous

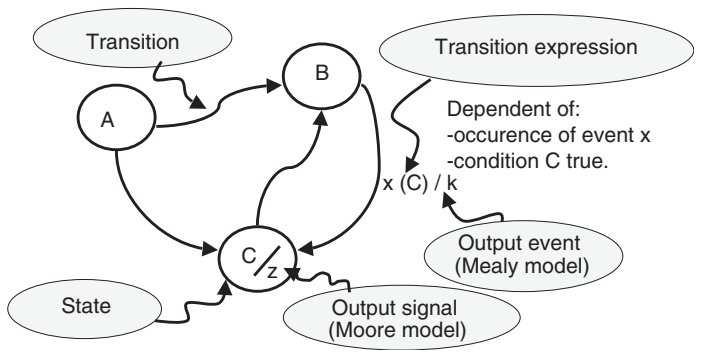

FIGURE 83.5 State diagram basic notation.

© 2005 by CRC Press LLC

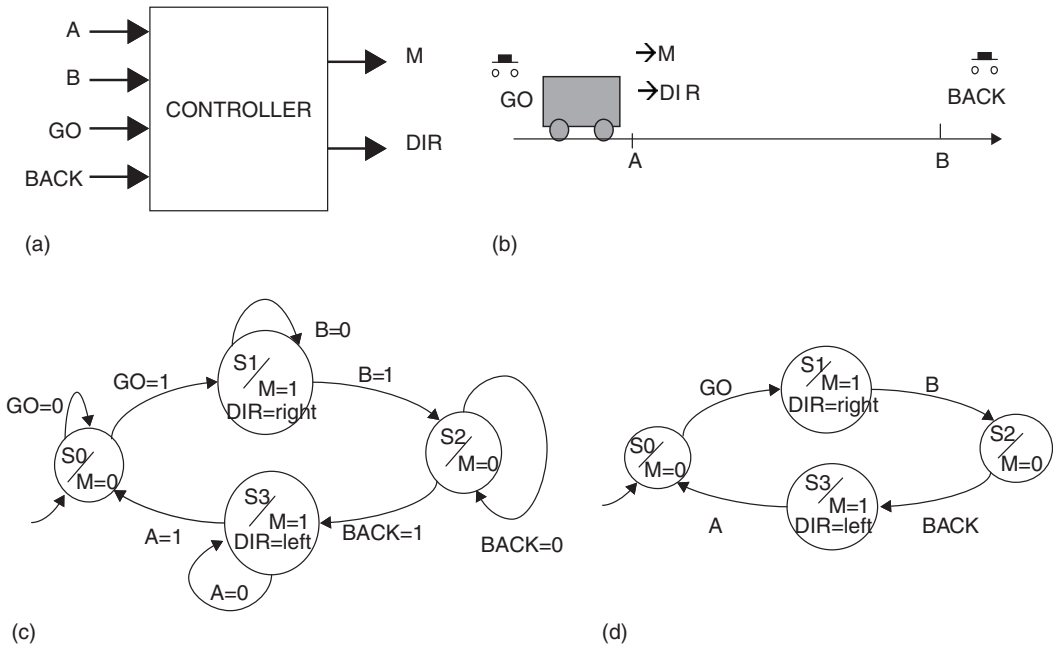

FIGURE 83.6 State diagram models of an electric car.

implementation island, it is possible to rely on robust compilation techniques, either to optimally map FSMs onto Boolean and sequential circuits (hardware) or to software code.

In Asynchronous FSMs, process behavior is similar to the one on synchronous FSMs, but without dependency on a clock tick. As already referred, an asynchronous system is a system in which two events cannot have the same time tag. In this sense, two asynchronous FSMs never execute a transition at the same time (asynchronous interleaving). For heterogeneous architectures or for multirate specifications, implementation can be easier than in the synchronous case, however, still somehow problematic. The difficulties come from the need to atomically synchronize communicating transitions, which can make a correct implementation of rendezvous on a distributed architecture very difficult to achieve.

Codesign Finite State Machines

Most MoCs are control-dominated or data-dominated. However, embedded systems are composed of a mixture of reactive behavior, control functions, and data processing, especially those targeted for networking and multimedia applications. Considering FSMs as the starting point, which proved to be adequate for low-to medium-complexity control-dominated system modeling, we can find in the literature numerous proposals extending FSMs in several directions. Each extension tries to overcome one or more intrinsic FSMs shortages, from concurrency modeling inability and the associated state space explosion problem, to data processing modeling and the absence of hierarchical structuring mechanisms (supporting specification at different levels of abstraction).

One line of thought is targeted to overcome the lack of modeling ability regarding data representation. For instance, to model an 8-bit variable with 256 possible values through an FSM, it is necessary to use 256 states, which is not manageable for the designer as the model loses its expressiveness. This problem can be eased through the use of FSM with data paths, where data-processing capabilities are added to FSM intrinsic characteristics: the system is decomposed into a control part and a data part. On the one hand, the control part is efficiently specified and synthesized using an FSM model, easier to understand if considered in synchronous terms. On the other hand, data computation can be efficiently specified and synthesized using data flow graphs (as usually found in digital signal processing and associated code generation tools).

© 2005 by CRC Press LLC

Codesign Finite State Machines (*CFSMs*) are another MoC for embedded system design [29] [36] obtained in this line of thought. They extend *Finite State Machines* with support for data handling and asynchronous communication. Data handling is associated with transitions and these are associated with external instantaneous functions. This implies that data manipulation should typically exhibit a low algorithmic complexity.

In this sense, CFSMs supports the specification of embedded systems, involving both control and data flow aspects, and having the following key characteristics:

- Are composed by FSMs components.
- Support a data computation part.
- Use a Globally Asynchronous Locally Synchronous (GALS) reference model, where
  - Local behavior is synchronous (as seen inside each component), and
  - Global behavior is asynchronous (as seen by the rest of the system).

Any high-level language with precise semantics based on extended FSMs can be used to model individual CFSMs (currently, Esterel is directly supported).

Synchronous/reactive Models

Reactive systems are those that interact continuously with their environment. David Harel and Amir Pnueli gave the name in the early 1980s. In the synchronous model of computation, all events are synchronous. This means that all signals have events with equal tags to other events in other signals. The tags are totally ordered. In this computational model, the output responses are produced simultaneously with the input stimuli. Conceptually, Synchrony means that reactions take no time; thus, there is no observable time delay in the reaction (outputs become available as inputs become available). Unlike the discrete event model, all signals have events at all clock ticks, simplifying the simulator. Simulators that exploit this characterization are called cycle-based (as opposed to the so-called discrete-event simulators). A cycle is the processing of all events at a given clock tick. Cycle-based simulation is excellent for clocked synchronous circuits. It is also possible to consider, for some applications, a multirate cycle-based model, where every *n*th event in one signal aligns with the events in another signal.

Synchronous languages [34, 1], like Esterel [16], Lustre [33], and Signal [2], use the synchronous/reactive model of computation. Statecharts graphical formalism belongs to the same language family and is sometimes referred as quasi-synchronous; statecharts will be presented in a separated section.

Esterel is a language for describing a collection of interacting synchronous FSMs. Esterel supports the description of concurrent and sequential statements. ***S1;S2*** represents the sequential execution of S1 followed by S2, while ***S1||S2*** represents the parallel execution of S1 and S2; ***[S1||S2]*** executes until S1 and S2 terminate. The synchronized modules communicate through signals, using an instantaneous broadcast mechanism.

As an introductory example, we consider an FSM that implements the following behavior [19]: "Emit an output *O* as soon as two inputs *A* and *B* have occurred. Reset this behavior each time the input *R* occurs."

Figure 83.7 presents the associated state diagram. The associated Esterel representation is presented below:

```
module SMSM:
input A, B, R;
output O;
loop
  [ await A || await B ];
  emit O
each R
end module
```

The declaration part is trivial. Waiting for the occurrences of A and B is accomplished through "[await A || await B]." The "emit O" statement emits the signal *O* and terminates at the time it starts. Hence, *O* is

© 2005 by CRC Press LLC

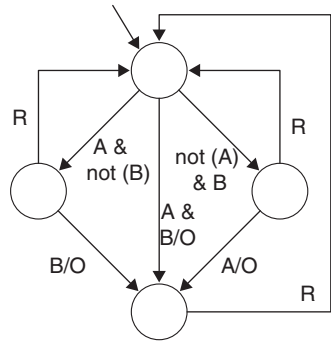

FIGURE 83.7 A simple Mealy state machine.

emitted exactly at the time where the last of *A* and *B* occurs. The handling of the reset condition is accomplished by the loop "loop p each R." When the loop starts, its body *p* runs freely until the occurrence of R. At that time, the body is aborted and it is immediately restarted. If the body terminates before the occurrence of R, one simply waits for R to restart the body.

It has to be noted that Esterel code grows linearly with the size of the specification (while FSM complexity grows exponentially). For instance, if we want to wait for the occurrence of three events, A, B, and C, the code change is minimal: "[await A || await B || await C]."

Esterel is a control flow-oriented language. On the other hand, Lustre is a language that adopts a data-oriented flavor. It follows a synchronous dataflow approach and supports multi-rate clocking mechanism.

In addition to the ability to translate these languages into finite-state descriptions, it is possible to compile these languages directly into hardware (execution in software of these languages is also achieved through the simulation of the generated circuit).

Statecharts

Statecharts [7, 6] provide a model of computation to specify complex reactive systems. They are based on state diagrams, plus the notions of hierarchy, parallelism, and communication between parallel subsystems. The main advantage of Statecharts over FSMs is the structuring of the specification, magnifying the legibility, and improving the system maintenance. These characteristics were key points that supported its adoption as one of the specification formalisms within the Unified Modeling Language (UML) [3, 4, 20].

Statecharts define three types of state instances: the set (implementing the AND refinement mechanism), the cluster (implementing the XOR refinement mechanism), and the simple state. The cluster supports the hierarchy concept, through encapsulation of state machines. The set supports the concurrency concept, through parallel execution of clusters. Figure 83.8(a) illustrates the usage of the cluster mechanism; the state diagram composed of states C, D, and associated arcs is encapsulated by the state A. This provides us with a top-level view of the model composed only of states A and B, but complemented by the inner level if one wishes to obtain further details regarding the system behavior. Figure 83.8(b) presents a simple model containing a set A composed of three AND components (B, C, and D); whenever A is activated/deactivated, the associated components B, C, and D will also be activated/deactivated, The reader should refer to [6, 7, 9] for further details regarding the Statecharts formalism.

Apart from the referred main characteristics, the Statecharts formalism presents some interesting features, such as:

- The default state that defines which state will take control in the case where a transition reaches a cluster state. In Figure 83.8(a), the system initial state is state B, and, after the occurrence of *w,* states A and C will become active.
- The notion of history, simple or deep, can be associated with cluster state instances. When the system enters a cluster with history property, the state that will be active upon entrance will be the

© 2005 by CRC Press LLC

one that was active upon the last exit from that cluster. In the case of the first entrance in the cluster, the active state will be the default one. This is the case for cluster C of Figure 83.8(b), which holds the "*H*" attribute inside a circle. The history property, can also be deep, meaning that, all the clusters inside the cluster with the history property also have that property; this is the case for cluster B in Figure 83.8(b), which holds the "*H**" attribute inside a circle.

- The activation expressions present in transitions can also have special events, special conditions, and special actions. Special events can be the *entered(state)* event and the *exited(state)* event, which are generated whenever the system, respectively, enters or exits some state. One special condition is the *in(state)*, which indicates if the system is currently in the specified state. Examples of special actions are *clear history(state)* and *deep clear history(state)*. These initialize a cluster history state to the default state.

So far, we have only characterized syntactic issues for the Statecharts formalism. Its semantic characterization includes, among other things, the characterization of the *step algorithm* and the definition of the *criteria for solving conflicts* (which set of triggering transitions to choose among a set of conflicting transitions).

The step algorithm is of fundamental importance as it dictates the way the system evolves from one global state to another. The triggering of a finite set of transitions causes the evolution of the system. In [9], the trigger of this set of transitions is called microstep (conceptually it can be seen as equivalent to the delta concept, already introduced when presenting the discrete event MoC). Transitions fired in a microstep can generate internal events that, in turn, can fire other transitions. Thus, a step is defined as a finite sequence of microsteps. This means that, after all the microsteps have taken place, there will be no more active transitions and the system will remain in a stable state. External events are not considered during a step; hence, one must assume that a system can completely react to an external event before the occurrence of the next external event. According to many authors, the initial Statechart proposal [8] left their semantics partially open. As a consequence, different semantics associated with the handling of broadcasted event have been considered possible. Statechart semantics proposals are discussed in [32]. Yet, as pointed out by Harel in [8], that survey does not mention the semantics implemented in the STATEMATE tool (in the following citation, the original reference citations were replaced by the citation numbering used in this chapter): "the survey [32] does not mention the STATEMATE implementation of statecharts or the semantics adopted for it at all, although this semantics is different from the ones surveyed therein (and was developed earlier than all of them except for [8])" [8].

Even so, most common semantics consider that a generated event will only be valid during the next microstep (more used) or for the remaining microsteps within the same step (persistent events).

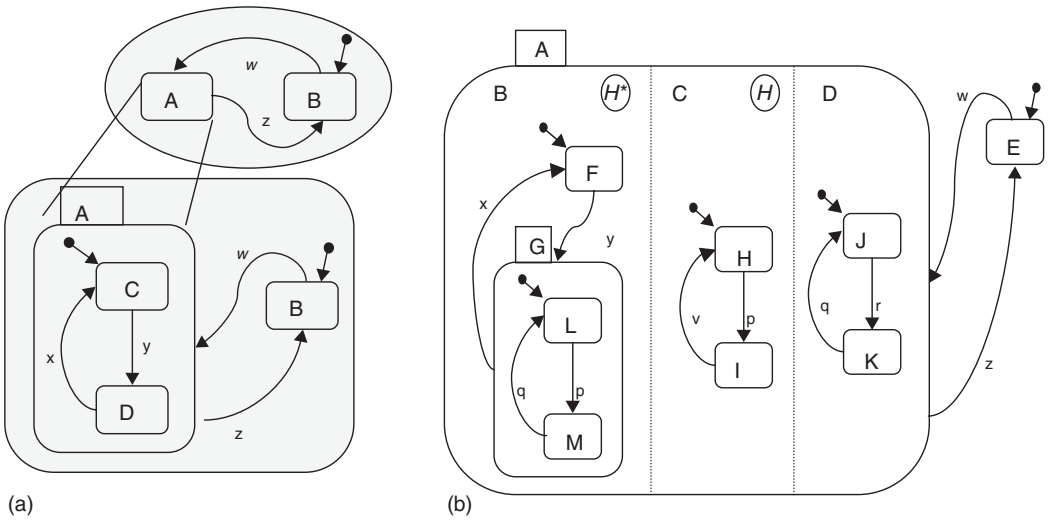

FIGURE 83.8 Statecharts basic models.

© 2005 by CRC Press LLC

Coming back to the example of the electric car, if one considers controlling two or three of those cars using the same controller, and tries to use a state diagram to model the whole system, he/she will encounter the well-known problem of state explosion, due to the orthogonal composition of state diagrams: if we have two independent state diagrams with N1 and N2 states, the composed state diagram will contain N1 × N2, as for each state of machine 1, one may have machine 2 in any of its states. This illustrates the already presented weakness resulting from the lack of support for concurrency modeling of FSM.

Now consider that we want to keep the cars synchronized at both ends, which means that we will wait for all cars at each end, before launching them in the opposite direction. Figure 83.9 presents a statechart model enabling a compact modeling of the referred system. Those additional constraints associated with global start and global return are explicitly modeled through specific arc inscriptions; for instance, arc expression leaving state S01 is augmented with the condition [in(S02)], imposing that car 1 only starts its travel if car 2 is also in its original position (identical constraint for car 2).

Petri nets

Carl Adam Petri proposed Petri nets in 1962 [5]. They can be viewed as a generalization of a state machine where several states can be active simultaneously and transitions can start at a set of "states" and end in another set of "states." More formally, Petri nets are directed graphs with two distinct sets of nodes: places, drawn as circles or ellipses, are the passive entities, and transitions, drawn as bars, rectangles or squares, are the active entities. Arcs connect them in an alternate way: places can only be connected to transitions and transitions can only be connected to places. Places can contain tokens, also called marks. Small circles, inside places, specify these tokens. Figure 83.10 shows two nets, each with one transition (t_1), five places (p_1 to p_5), and five arcs. The nets have distinct markings: the net (b) corresponds to the net (a) marking after the transition firing. A transition can only fire if all its input places contain at least one token. From the transition point of view, one token is taken from each input place and one token is placed in each output place; this destruction and creation of tokens is an atomic operation, in the sense that it cannot be decomposed. Notice that a transition can have only input arcs (*sink transition*) or only output arcs (*source transition*).

More exactly, this Petri net model is a Place/Transition net [37, 24]. They are the most well-known and best-studied class of Petri nets. In fact, this class is sometimes just called Petri nets. Generalized Petri nets simply add the possibility of weights in arcs with the expected change in the semantics: each arc must now take or deposit the specified number of tokens.

It is important to note that, contrary to state machines, the number of places grows linearly with the size of the modeled system as not all the states have to be represented explicitly but can result from the combination of several already existent "states" (modeled by places). This implies that Petri nets models

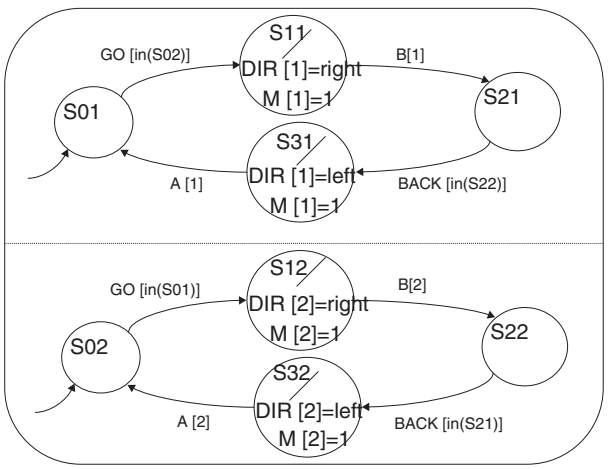

FIGURE 83.9 Simple statechart model for electric cars example.

© 2005 by CRC Press LLC

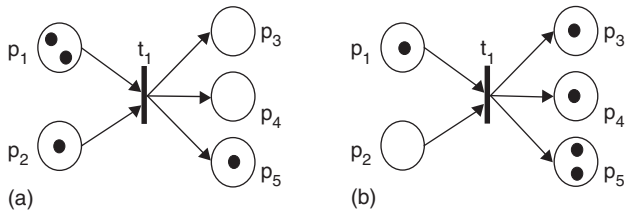

FIGURE 83.10 Transition t_1 firing: (a) before, and (b) after.

"scale better" that state machines (including statecharts). Even so, model growth is still a significant problem for Petri net models due to their graphical nature and low-level concepts. To minimize this, several abstraction and composition mechanisms exist.

Petri nets are well known for their inherent simplicity due to the small number of elementary concepts. Yet, Petri nets' simplicity is a two-edged sword [15]: on the one hand, it avoids the addition of further complications in the model resulting from the language complexity; on the other, it invariably implies that some desired feature is missing. As such, this basic type of Petri net has been modified in numerous ways to the point that *Petri nets* is actually a general name for a large group of different definitions and extensions, although all claim some close relation to the seminal work by Carl Petri [5]. A very readable, and informal, discussion about the existence of many different Petri nets classes can be found in the paper by Desel and Juhás [23]. This evidence has its origins in the fact, easily confirmed by experience, that conventional Petri nets, also known as low-level Petri nets, are sometimes difficult to use in practice not only due to the problem of rapid model growth, but also due to the lack of more specific constructions. Namely, time modeling, interface with the environment, and structuring mechanisms are frequent causes for extensions. While the former two are specific to some types of systems, structuring mechanisms are useful for even the simplest system model.

Coming back to our electric cars example, Figure 83.11(a) presents a Petri net model suitable for the modeling of a system with three electric cars, maintaining the constraint of synchronized starts and returns (in order to improve legibility, annotations associated with outputs are omitted, but can be associated with different places, or transitions, as well in state diagrams). It should be noted that transitions have the dynamics of the model associated with them, while places hold the current states of each car. Figure 83.11(b) uses a generalized Petri net model (arcs have weights associated with them), enabling a more compact representation of the system. Considering introducing more cars into our system (scability problem), it is clear that, considering this last model, it is only necessary to change the initial marking of the net: the left-most place should contain as many tokens as the number of electric cars in the system.

As even this simple example shows, Petri nets do not give special emphasis to states, as state diagrams, nor to actions, as data flows: states and actions are both "first-class citizens." In other words, Petri nets provide a *pure dual interpretation of the modeled world*: each entity is either passive or active. As already stated, passive entities (e.g., states, resources, buffers, channels, conditions) are modeled by places, and active entities (e.g., actions, events, signals, execution of procedures) are modeled as transitions. Another fundamental characteristic of Petri nets is their *locality of cause and effect*. More concretely, this means transitions are only red based on their vicinity, namely their input places and, possibly (for some classes of Petri nets), in their output places.

Two other fundamental aspects of Petri nets are their c*oncurrent and distributed execution*, and the *instantaneous firing* of transitions. The concurrent and distributed execution results from the locality of cause and effect: all transitions with no input or output places in common fire independently. This implies that the model is intrinsically distributed, as all transitions with disjoint locality do not depend on other transitions. The instantaneous firing means that each transition fires instantaneously: there are no intermediate states between token destruction in input places and token creation in output places.

In general terms, Petri nets structuring mechanisms can be classified into two groups: refinement/abstraction and composition mechanisms.

© 2005 by CRC Press LLC

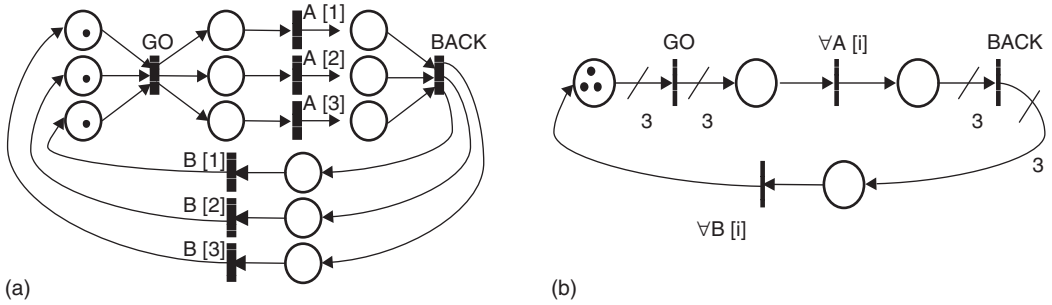

FIGURE 83.11 Petri net models for our electric cars example.

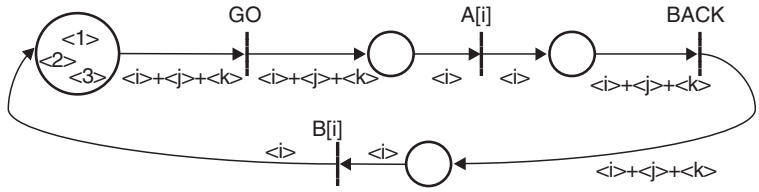

FIGURE 83.12 High-level Petri net models for our electric cars example.

Refinement/abstraction constructs correspond, roughly, to the programming languages concepts of macros or procedure invocation. Intuitively, macroexpansion is an "internal" composition where we get nets inside nets through the use of nodes (places or transitions). The use of places and transitions as encapsulated Petri nets goes back to the works of Carl Adam Petri [5] and was extensively presented in [30]. They are usually named macros (or macronodes) [28]. These constructs support hierarchical specification of systems, in the traditional sense of module decomposition/aggregation and "divide to conquer" attitude.

A common compositional mechanism is the *folding* of nets found in *high-level nets*. High-level nets can be seen as an internal composition made possible by structural symmetries inside a low-level net model. This is achieved by the use of high-level tokens. These tokens are no longer undistinguishable, but have data structures attached to them. Figure 83.12 shows the high-level Petri net model associated with our three electric cars system. Tokens presented at the left-most place (initial marking) now contain integer values, which enable the identification of a specific car status inside the model.

As tokens can carry data, it is necessary to add some inscriptions to the arcs, in order to properly select the right token to involve in a specific transition firing. For some classes of high-level nets, it is also possible to add within those arc inscriptions references to functions that support token attribute transformation. This is the case for Colored Petri nets [25]. In this way, data processing capabilities can also be embedded in the model.

It is important to note that many Petri net classes use several structuring mechanisms in an orthogonal way. For example, Hierarchical Colored Petri nets [25, 35] use abstraction in the form of macrotransitions, and composition by net folding and place fusion. Several proposals have even added object-oriented features to Petri nets (see [21] for an up-to-date detailed survey of some approaches).

The Tagged Signal Model

The Tagged-Signal Model is a denotational formalism that was defined as a meta-model for other MoCs [13, 36]. As such, it should not be seen as another MoC but as a very abstract framework within which different models of computation can be expressed and compared. The abstract nature of the Tagged-Signal Model also implies that the MoCs are expressed by imposing additional specific constraints on it.

The Tagged-Signal Model is also based on the notion of *event*. An event is a pair composed of a *value* and a *tag*. Tags are typically used to specify temporal behavior. A *signal* is a set of events. A functional or

© 2005 by CRC Press LLC

deterministic signal is defined as not containing two pairs with the same tag and a different value. The same is to say that a deterministic signal is a function from tags to values. The function can be partial, as not all tags have to be associated to values.

A process with *n* signals is a set of sequences of *n* signals. Processes operate concurrently. The synchronization among processes is defined by constraints imposed on their signal tags.

Functions are specified by the way events are related around a particular tag, or how inputs are used to compute outputs. Time is specified by the assignment of tags to events.

In [36], most significant models of computation are compared using the Tagged-Signal Model, where special attention is devoted to *Co-design Finite State Machines.*

84.1 Introduction

Digital circuit design has experienced a very rapid evolution during the last decades. Integrated circuits have become more and more complex. The number of gates in a single chip has been continuously increasing, from a few hundreds in Small Scale Integration (SSI) chips to thousands or millions in latest devices. At this point, the design process became very difficult to manage and Computer-Aided Design (CAD) tools became invaluable for chip designers. Some parts of the process began to be supported by computer tools.

With the advent of Very Large Scale Integration (VLSI) chips, with hundreds of thousands of transistors in a single chip, circuit complexity imposes a different role for CAD tools; it is no longer possible to have reliable test through breadboarding. Consequently, CAD tools became very popular, from logic simulators (supporting circuit functionality verification) to automatic placement and routing of circuit layout.

The role of logic simulation became more and more important, in direct correspondence with the circuit complexity (in terms of gate count). Designers felt the necessity to describe the circuit through the use of a neutral representation amenable to be used by them and by computer tools. This was the motivation leading to hardware description languages (HDLs).

To support circuit functionality description, designers have three major choices:

- Boolean equations.
- Schematics.
- Hardware description languages.

© 2005 by CRC Press LLC

Boolean equations are interesting for small circuits. For complex circuits, only schematics and hardware description languages are widely used.

During the 1970s, the so-called Computer Hardware Description Languages were very popular enabling a compact representation of the large mainframe computers in use at the time. Designers used HDLs mostly for simulation and verification purposes and manually translated the circuit to schematics in order to produce the circuit.

Meanwhile, logic synthesis tools came into play and the process changed radically. Designers start with an HDL description, most of the time at the register transfer level (RTL), specifying how the data flow between registers and which transformations are required; afterwards, logic synthesis tools automatically generate the circuit description, in terms of a netlist (gates and interconnections).

84.2 What to Expect from Hardware Description Languages

Thus, by using HDLs, designers can produce a neutral representation of the hardware, amenable to represent the circuit structure (schematics) or the circuit behavior. The circuit representation should include the following facets:

- Project documentation, to support exchange of information among designers
- Modeling of the circuit, in order to support simulation
- Synthesis support
- Module representation, enabling reusage of predefined modules.

In the initial design attitude, schematics played a fundamental role in data exchange among designers, but, nowadays, automatic synthesis is fundamental to cope with system complexity. This means a shift from schematics to hardware description languages. In this sense, designers moved from describing the circuit from their structure perspective (gates, modules, and interconnections) to their behavior.

Emphasis on HDL-based synthesis tools received an additional significant push with the advent of *Programmable Logic Devices* (PLDs), from the "old" *Programmable Array Logic* (PALs), to *Complex Programmable Logic Devices* (CPLDs) and "recent" *Field Programmable Gate Arrays* (FPGAs). For these user-programmable platforms, the module concept plays a major role as it allows the reusability of predefined modules. Those modules range from user-defined modules to complex IPs (Intellectual Property), ready to implement functions for specific applications. These include signal processing (DCT, FFT), multimedia (MPEG, JPEG), and telecommunications (Viterbi), among others.

As already argued [1], compared to traditional schematic-based design, HDLs have many advantages:

- Designs can be described at several abstraction levels, independent of the technology to be used. HDLs support reusability, in the sense that logic synthesis tools can automatically convert the design to a specific implementation technology (thus, logic synthesis tools are responsible for the technology shifts).
- Functional verification of the design can be done early in the design cycle, using verification through simulation, minimizing risks associated with finding a bug in a later point in time at the gate-level netlist.
- Compared with gate-level schematics, which is difficult to use for complex designs, a textual description with comments is an easier way to develop and debug circuits.

Also, the usage of HDLs easily accommodates changes in the circuit. Consider a small example of a multiplexer of 3 inputs (A, B, C) and 1 output (Z), using two selection signals (X and Y). For a multiplexer implementation, we may have a circuit with a few OR gates, one three-input AND gate, and interconnecting nets; alternatively, we can describe this dependency using the associated Boolean equation:

$$Z = (A \text{ and } (X = 0 \text{ and } Y = 0)) \text{ or } (B \text{ and } (X = 0 \text{ and } Y = 1)) \text{ or } (C \text{ and } (X = 1 \text{ and } Y = 0)).$$

© 2005 by CRC Press LLC

Consider, now, that we need to face a change in the specification, for instance, that we need to add an extra input (D) to the multiplexer. It is clear that we need to change significantly the schematic, even changing the supporting gate types (e.g., from three-input AND gate to four-input AND gate, if available, or to a composition of gates to support its implementation). On the other hand, textual description of the new multiplexer is close to the initial one:

$$Z = (A \text{ and } (X = 0 \text{ and } Y = 0)) \text{ or } (B \text{ and } (X = 0 \text{ and } Y = 1)) \text{ or}$$

$$(C \text{ and } (X = 1 \text{ and } Y = 0)) \text{ or } (D \text{ and } (X = 1 \text{ and } Y = 1))$$

An HDL description imposes a smaller change penalty.

On the one hand, a hardware description language can be characterized in a manner similar to a high-level programming language [2], and the main features should include:

- Describe the digital system in a precise way and as succinctly as possible.
- Support generation of associated documentation.
- Support hierarchical decomposition and multi-level simulation of the system.
- Shortening development time, accommodating time-to-market restrictions.
- Support earlier development of software parts of the system, as hardware interface and functionality can be described by blocks in advance.
- Reduce costs associated with changes.
- Detecting and reducing errors at earlier stages of the process, through support for system analysis at different complexity levels.
- Enabling comparison of different solutions for the same system, trying to reach specific goals in terms of power, performance, costs, or other features.
- Make available new technologies for integrated circuits to a broader range of persons, taking advantage of the fact that most of the technology-dependent tasks were transferred to the tools.

On the other hand, a hardware description language has to exhibit some hardware-intrinsic features in order to be a valuable tool supporting digital system development process, namely [3]:

- Describe the intrinsic parallel execution of hardware.
- Support separated description of architecture and control parts of the system, enabling different views of the system, namely structured- and behavior-dominated views.
- Support representation at several levels.
- Easy to learn and memorize.
- Support module representation, namely LSI and MSI modules commonly in use, and complex blocks, including IPs.
- Support for different approaches, namely top-down and bottom-up approaches, allowing the designer to define the adequate level of detail for the different components.

Several hardware description languages have been proposed during the last decades to reach these objectives. Yet, mainly due to the industry drive, it seems that "academic" or "experimental" languages do not seem to have a significant number of users. Currently, only VHDL and Verilog seem to survive in the hardware-level description languages arena. As such, and also due to time and space limitations, we will restrict our presentation to those two languages.

84.3 Levels for Digital System's Representation

The abstraction level in which a digital system can be described ranges from the physical level till the system level.

© 2005 by CRC Press LLC

Figure 84.1 presents a common characterization of the reference abstraction levels. For each level, one can focus on two types of views. The first one emphasizes the structural view of the system: it is the "schematics" view of the system, with modules and interconnections between them. The second one emphasizes the behavioral view of the system: it is the "algorithm" view of the system, where, instead of specifying how the system is composed, as in the structural view, the designer specifies what should be implemented.

The "Physical" level gives the maximum system detail, containing information associated either with the layout of the circuit for discrete components-based implementation or with the geometric description associated with masks for integrated circuits production. This level is not covered by the techniques for digital circuit representation referred so far, namely schematics and hardware description languages.

At the "Circuits" level, we can find the traditional representation of electronic circuits, based on transistors and resistors interconnected by nets (wires). At this level, the building blocks (at the structural view) are transistors and resistors, which have an associated model amenable to be used for adequate simulators (within the behavioral view). The system model uses differential equations; SPICE is a common simulator for this description level. As the complexity of the circuit increases, simulation at this level starts becoming too expensive and time consuming. This abstraction level is also not associated with the digital circuits design.

The "Logic" level is the traditional representation level for digital circuits. From the structural point of view, the basic building blocks include gates and flip-flops. From the behavioral point of view, Boolean equations are used. Higher granularity blocks can also be included, like multiplexers and other modules. Each block has an associated model, normally expressed as a Boolean equation, and including time dependencies associated with delays between inputs and outputs. It is possible to simulate the circuit and determine some of its characteristics, namely typical delay times.

The next level, referred to as "Register transfer," can be seen as a generalization of the previous one. Here, the fundamental building block is the register, complemented by processing blocks, like arithmetic and logic units (ALUs), interconnected through buses. From the behavioral point of view, at this level, the circuit characterization is based on truth tables, state transition tables, and the way in which the operations on data are performed (namely how data are transferred among registers and which transformations on data are required). Also at this level, the notion of control part appears. It is a common level for usage of hardware description languages like VHDL and Verilog.

At the "Device" level, systems are decomposed into two interactive blocks: control and data parts. The data part is composed of register transfer architecture. The control part is responsible for the sequential configuration of the data part in order to accomplish a specific processing result or behavior; it is commonly characterized through a state machine like formalism. It is probably the most used abstraction level for digital circuit representation.

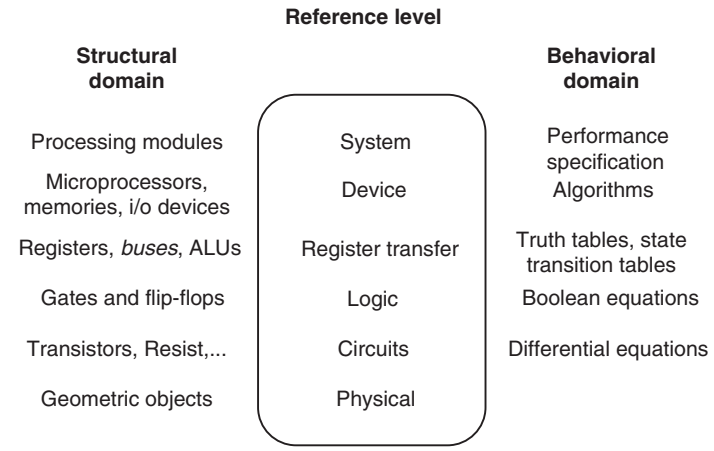

FIGURE 84.1 Levels of abstraction in digital systems.

© 2005 by CRC Press LLC

The top abstraction level is the "System" level. Here, the system is decomposed into interconnected subsystems. Each subsystem is described from an external point of view and global reasoning about the behavior of the system is possible. Results on performance analysis and global proprieties can be obtained.

84.4 Hierarchical Design: A Key Concept

Complementing the reference abstraction levels, presented in the previous section, hierarchies are used for complexity management. It is a common way of structuring the system description, already started with the schematic representation. It is also a key concept in hardware description languages, like VHDL and Verilog.

Two main approaches can be followed for hierarchically structuring digital designs:

1. top-down design methodology;
2. bottom-up design methodology.

In the top-down approach, we start with the top-level system characterization. This block is decomposed in terms of the subblocks necessary to build the top-level block functionality. Each of the subblocks can be further decomposed until a representation amenable for implementation is reached.

In the bottom-up approach, we start by identifying the building blocks available for the task. Later, we build larger blocks using those available blocks. Further aggregations with other blocks will allow us to obtain the top-level block of the system.

Typically, in most designs we will use a mixed approach. Architectural design will define top-level goals that will be decomposed into blocks and subblocks according to functionality. At the same time, circuit designers will design or verify the viability to design-specific leaf-level blocks (starting by the critical blocks that will compromise overall performance or cost). In some way, analysis is top-down first, while circuit design is bottom-up first.

84.5 Verilog

The Verilog HDL was launched in early 1984 at Gateway Design Automation, and evolved to become a current industry standard. It started as a proprietary language supported by a simulation environment, which was the first environment supporting mixed-level design representations containing switches, gates, RTL, and a higher level of abstractions of digital circuits. In 1995, Verilog found a way to become an IEEE Standard, already updated to the IEEE Standard 1364-2001 [4]. Before, Verilog had been put in the public domain (as a response to VHDL also being an IEEE Standard).

Verilog offers many useful features for hardware design [1]:

- It is a general-purpose hardware description language that is easy to learn and use. It has a syntax similar to the C programming language. This allows an easy migration for designers with C programming experience.
- Allows different levels of abstractions to be mixed in the same model (from switches, gates, or RTL to behavioral code).
- Most logic synthesis tools support Verilog.
- Fabrication vendors provide Verilog libraries for postlogic synthesis simulation.
- Offers the Programming Language Interface (PLI) that allows the user to write custom C code and embedded it in the Verilog simulator, according to her/his needs.

The module is the basic building block in Verilog. A module can be an element or an aggregation of lower-level design blocks. It supports reusability of a predefined, already implemented, functionality. A module is described in upper levels by its interface ports (inputs and outputs), concealings internal implementation. This means that, from upper levels, it is seen as a black box. In this sense, it is possible to compare or test the usage of different implementations for a specific block without imposing changes at the upper levels. In Verilog, the keyword *module* declares a module. All interface ports have to be

© 2005 by CRC Press LLC

declared as *input* for input port, *output* for output port, or *inout* for bidirectional port. A module definition always ends with the *endmodule* keyword.

Verilog supports both behavioral and structural descriptions. Each model can be described at four levels of abstraction:

- *Behavioral or algorithmic level*: This is the highest level provided by Verilog. Hardware implementation details are omitted. Also, due to the C-like syntax of Verilog, descriptions at this level are similar to C programs.
- *Dataflow level*: At this level, emphasis is placed on how data flow between registers and how data are processed.
- *Gate level*: Design at this level is similar to describing a design in terms of "Logic" level, based on gates and interconnections between those gates.
- *Switch level*: This is the lowest level provided by Verilog, and requires that the designer master technological implementation details.

From the point of view of the circuit simulation, Verilog allows signals to have four logic values and eight strength levels. Possible logic values are: ***0*** (logic zero), ***1*** (logic one), ***x*** (unknown value), and ***z*** (high impedance). Verilog supports basic logic gates as predefined primitive modules. There are two classes of basic gates: and/or gates (composed by *and*, *nand*, *or*, *nor*, *xor*, and *xnor*) and buf/not gates (composed by *buf*, *not*, *bufif1*, *bufif0*, *notif1*, and *notif0*). For each basic gate, associated truth table is defined, considering the possible four logic values. Considering a 2-input AND gate as an example, the associated truth table is presented in Table 84.1.

In addition to logic values, the eight possible strength levels can be used for conflict resolution between drivers of different strengths. Possible strength levels are the following: *supply* (strongest), *strong*, *pull*, *large*, *weak*, *medium*, *small*, and *highz* (weakest). Considering the example of having two (or more) signals driving the same net with different values and strengths, the signal with stronger strength prevails; if several signals with incompatible values and with same strength are present, the result is *x* (unknown). For instance, if two signals with *strong1* and *weak0* are tied in the same net, the result will be *strong1* (stronger strength prevails); as a second example, if two signals with *strong1* and *strong0* are tied in the same wire, the result will be *strongx* (resulting unknown value).

84.6 VHDL

VHDL stands for **V**HSIC **H**ardware **D**escription **L**anguage (and VHSIC stands for Very High Speed Integrated Circuit). The development of the language started in the beginning of 1980s by the United States Department of Defense with the purpose of obtaining a standardized method for describing electronic circuits. In 1987, the IEEE adopted VHDL as IEEE Standard 1076-1987. In 1993 and 2000, the standard was revised and established that:

> "The VHSIC Hardware Description Language (VHDL) is a formal notation intended for use in all phases of the creation of electronic systems. Because it is both machine readable and human readable, it supports the development, verification, synthesis, and testing of hardware designs; the communication of hardware design data; and the maintenance, modification, and procurement of hardware" [5].

TABLE 84.1 AND-gate Truth Table

		i1			
	and	0	1	*x*	*z*
	0	0	0	0	0
i2	1	0	1	*x*	*x*
	x	0	*x*	*x*	*x*
	z	0	*x*	*x*	*x*

© 2005 by CRC Press LLC

This means that VHDL can be applied throughout the design process: including capture, simulation, synthesis, and documentation.

Why use VHDL? The answer to this question should not be much different from "why use Verilog?" As a matter of fact, arguments are mostly interchangeable. In [6], the following arguments are presented as answers to the initial question:

- It is standardized; hence it is possible to move code among different development environments (although special attention should be paid to the synthesis of subset constructs supported by each tool).
- It supports top-down, bottom-up, and mixed methodologies.
- It is independent from the technology, as technology change support is transferred to automatic tools.
- It supports hierarchical structures, reusable components, error management, and verification.
- A component can be made in such a way that it can be adapted automatically to different sizes of elements (generic component). As an example, an adder can be defined with the bit size as an attribute; at instantiation time, the size attribute receives a value and the adder will be adjusted accordingly.
- It supports concurrent and sequential constructions.
- It uses the same language for simulation.

VHDL supports both behavioral and structural descriptions. Four abstraction levels are supported, according to [6]:

1. *Functional level*, where algorithms can be described.
2. *Behavioral level*: A behavioral module can be described as interconnected functional modules. The advantage of models at this level is that models for simulation can be built quickly.
3. *RTL (Register Transfer Level)*: At this level, it is possible to describe behaviors in several different ways, namely data flows, asynchronous and synchronous state machines, operations between registers, etc.
4. *Logic or gate levels* use descriptions based on Boolean algebra or associated netlist.

This means that lower levels of abstraction, like circuit level using transistor- and resistor-based descriptions, are not supported by VHDL.

Several criteria should be taken into account in the selection of the abstraction level to be used for the description of a specific circuit. For instance, if a shorter development time is required, then a higher abstraction level should be selected. Also, if the design has restrictive performance requirements, RTL should be selected, or even the gate level, depending on the set of synthesis tools to be used.

In VHDL, a signal has a type, which encapsulates a set of possible values that the signal can take. VHDL intrinsically supports a type known as *bit* (which allows signals to take values "0" and "1"), and also the *integer* type (using a 32-bit representation). Yet, the *bit* type is not a good support for simulation, as, for instance, high-impedance cannot be represented, and neither conflict can be solved. In this sense, it is common to use the *std_logic* type, defined in the IEEE 1164 standard. The *std_logic* type has nine values with the following meanings:

- U, uninitialized
- X, forcing (strong driven) unknown
- 0, forcing (strong driven) 0
- 1, forcing (strong driven) 1
- Z, high impedance
- W, weak (weakly driven) unknown
- L, weak (weakly driven) 0 (supports modeling of pull-downs)
- H, weak (weakly driven) 1 (supports modeling of pull-ups)
- -, don´t care.

Circuit simulation is carried out in a similar way as the one described for Verilog.

84.7 From Boolean Algebra to Sequential Circuits, or How to Get VHDL into Action

In the current and following sections, VHDL code will be used to illustrate code implementations.

In VHDL (as in Verilog and in hardware design, in general), components are a central concept. Components can be used to build up component libraries, supporting reusability. In fact, VHDL is an object-based language, which means that the designer can create instances of the library's components. Additionally, generic components can be defined, enabling some modification before instantiation, for instance, the width of a bus.

A component representation contains two parts:

1. Entity and
2. Architecture.

Entity is responsible for the declaration of input and output ports; it is the black box view. Each entity port can have one of three modes associated with them: *in* for input signals, *out* for output signals, and *inout* for bidirectional signals. Note that the *inout* mode should only be used with bidirectional signals. If we need to read the status of an output signal, we should do it in an indirect way (to be referred later in the section). In this sense, the entity declaration defines the interface between the entity and the environment. The entity name is the same as the component name. Code Fragment 1 presents the definition of the entity interface ports for a component with three input signals (a, b, and c) and one output signal (z), all of type *std_logic*.

```
library IEEE;
use IEEE.STD_LOGIC_1164.ALL;
use IEEE.STD_LOGIC_ARITH.ALL;
use IEEE.STD_LOGIC_UNSIGNED.ALL;
entity logic is
    Port ( a  : in std_logic;
           b  : in std_logic;
           c  : in std_logic;
           z  : out std_logic);
end logic;
```

CODE FRAGMENT 1 — Entity representation.

Architecture contains the structural or behavioral description of the component. It defines the body for the component. The architecture name is different from the component name, although the architecture is tied to a specific entity.

VHDL offers several ways to describe the architecture, associated with the different ways in which one can describe a particular circuit. Here, we will use a multiplexer as an example, and several specifications will be produced.

Figure 84.2 summarizes different circuit modeling attitudes. Figure 84.2 (a) presents the black-box characterization of the component, which means an external view of the interface without knowing functionality. Figure 84.2(b) presents a schematic symbol commonly used to describe MUX functionality. The next step is related to the description of the component, either using a behavioral description or a structural view. Three views are shown: Figure 84.2(c) uses a Boolean expression to represent multiplexer dependencies, while in Figure 84.2(d) the multiplexer module is represented through the associated schematic, and in Figure 84.2(e) a linguistic description is used (algorithmic style).

Starting with the "old-fashioned" schematic style of Figure 84.2(d), we face a pure structural functionality description, based on the usage of the primitive components INV, OR2, and AND2. Each block has its own truth table, known by the simulator engine. The description of the structure is based on the instantiation of the primitive components, referring to how they will be interconnected with the other components. Associated architecture code is presented in Code Fragment 2.

© 2005 by CRC Press LLC

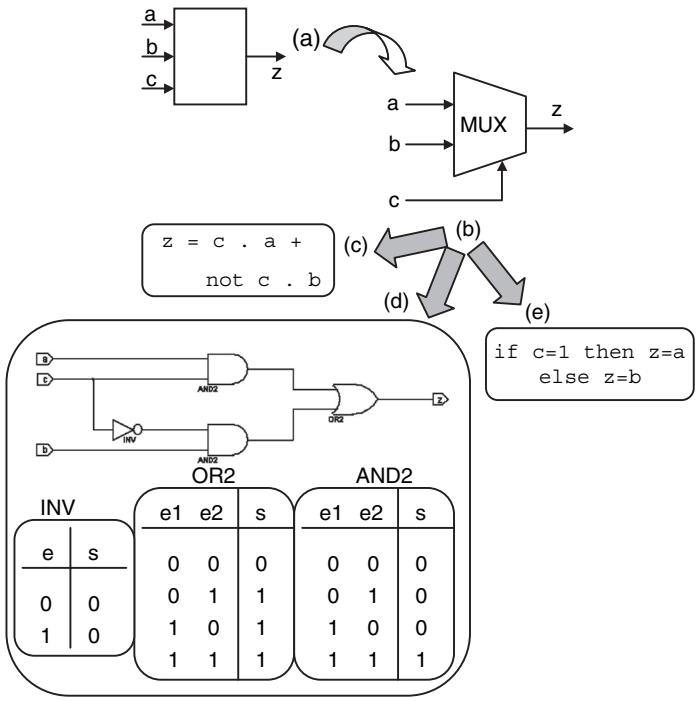

FIGURE 84.2 Equivalent multiplexer descriptions.

```
architecture Structural of logic is
signal node1, node2, node3 : std_logic;
begin
u1: and2 port map (I0    => a,
                   I1    => c,
                   O     => node1);
u2: inv port map (I      => c,
                  O      => node3);
u3: and2 port map (I0    => b,
                   I1    => node3,
                   O     => node2);
u4: or2 port map (I0     => node1,
                  I1     => node2,
                  O      => z);
end Structural;
```

CODE FRAGMENT 2 — Gate-based structure description of a multiplexer.

It has to be noted that internal nets are referred by signals that were declared at the beginning of the architecture body (signals *node1*, *node2*, and *node3* with *std_logic* type associated). This architecture has four modules concurrently running, obtained from the instantiation of primitive components.

An alternative method to describe the multiplexer is through the Boolean equation presented in Figure 84.2(c). In this case, the associated architecture has three statements running concurrently: the first and second ones are responsible for the generation of signals *node1* and *node2*, respectively, and the third one for producing the output. Associated code is presented in Code Fragment 3.

© 2005 by CRC Press LLC

```
architecture Dataflow of logic is
signal node1, node2 : std_logic;
begin
  node1  <= c and a;
  node2  <= not c and b;
  z      <= node1 or node2;
end Dataflow;
```

CODE FRAGMENT 3 — Alternative description for a multiplexer.

It is important to note that in both previous alternative multiplexer representations, the hardware components were represented individually. Thus, as hardware is intrinsically concurrent, so are the statements that describe them. In this sense, the order of the different statements or component instantiation inside architecture is not relevant (we can change the order without consequences).

Coming to Figure 84.2(e), where a behavioral representation is used, it is useful to introduce an alternative language construct: the process. A process is a collection of sequential statements, in the sense that the statements will be evaluated in the order that they appear in the description; hence, for statements inside a process, the order is important. Associated architecture code for the multiplexer example is presented in Code Fragment 4. With this example, we introduce the *if..then..else* statement, which is a basic mechanism for building decision structures. The VHDL syntax is:

IF condition THEN
[{ sequence_of_statements }]
[{ELSIF condition THEN}
[{ sequence_of_statements }]
[ELSE
[{ sequence_of_statements }]
END IF;

A minimum *if..then..else* statement is:

IF condition THEN
sequence_of_statements
END IF;

```
architecture Behavioral of logic is
begin
process (a,b,c) begin
  if c = '1' then z   <= a;
             else z   <= b;
  end if;
end process;
end Behavioral;
```

CODE FRAGMENT 4 — Multiplexer behavioral description.

After the keyword *process*, a list of signals is referred. This is the sensitive list, and whenever an event occurs in one of these signals, the process will be executed. For the present combinatorial function example, whenever any input signal changes its value, it is necessary to recalculate z (which means running the process).

Several ways were already presented enabling the representation of combinatorial logic, using different constructs of the language. Before going into sequential circuits representation, an alternative representation for a multiplexer is presented in Code Fragment 5.

© 2005 by CRC Press LLC

```
architecture Infered of logic is
begin
  z <= a when c='1' else b;
end Infered;
```

CODE FRAGMENT 5 — Multiplexer inferred architecture.

This time, the conditional construct will be recognized by the synthesis tool as amenable to be implemented by a multiplexer (similar to the one already used). This recognition technique is what is commonly known as inferred architecture.

An additional coding example on gate representation is presented in Code Fragment 6, where a tri-state buffer is represented in three alternative types (input signal is *d*, enable signal is *en*, and output signals are *x*, *y*, and *z*). The first representation uses the conditional statement, while the remaining two rely on process constructs, using different statements, namely the *if..then..else* and the *case* statements.

```
architecture Behavioral of tristate is
begin
  x <= d when en='1' else 'Z';
  process (d,en) begin
    if en = '1'
       then y <= d;
       else y <= 'Z';
    end if;
  end process;
  process (d,en) begin
    case en is
       when '1' =>
            z <= d;
       when others =>
            z <= 'Z';
    end case;
  end process;
end Behavioral;
```

CODE FRAGMENT 6 — Alternative representations for tri-state buffers.

Thus, this example is also used to introduce the *case* statement. It can be considered as a switch. An expression is evaluated and a sequence_of_statements associated with the matching choice is executed. The general syntax is:

```
CASE expression IS
WHEN choice => sequence_of_statements
[WHEN choice => sequence_of_statements]
END CASE;
```

The *case* statement (as well the *if..then..else* statement) will be extensively used to implement state machines, as presented later in this chapter.

A concluding coding example on gate-level representation uses the concept of bus. The goal is to connect 8-bit buses *A (7 downto 0)* and *B (7 downto 0)* to an 8-bit bus *Z (7 downto 0)*, through tri-state buffers controlled by the signal C (note that a vector was used to represent the group of signals under the same name). Figure 84.3 presents the associated schematics, and Code Fragment 7 illustrates one possible representation, introducing a new VHDL statement, *generate*.

© 2005 by CRC Press LLC

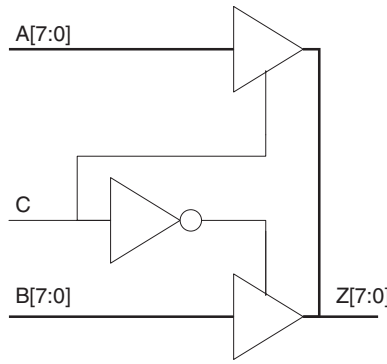

FIGURE 84.3 Bus access.

```
XPTO: for I in 0 to 7 generate
     Z(I) <= A(I) when C = '1' else 'Z';
     Z(I) <= B(I) when C = '0' else 'Z';
end generate;
```

CODE FRAGMENT 7 — Two drivers for one bus.

The *generate* statement generates logic by repeating a slice of logic. It is very useful in creating regular structures and can encapsulate concurrent statements. These concurrent statements can be either concurrent assignments, or component instances.

After presenting common possibilities to represent combinatorial logic functions, either structurally or behaviorally, we will focus on the representation of memory elements and sequential logic. There are two ways for describing memory elements in VHDL:

- Explicitly.
- Using implicit inference.

On the one hand, the explicit method relies on structural instantiation, where the component is already available in some library; its usage is similar to the instantiation of primitive components in Figure 84.2(d). In this situation, it is necessary to include at the beginning of the design the relevant library reference using the statement *use*, as it is not a primitive component.

On the other hand, implicit inference uses behavioral description based on the process construct.

Again, we can find alternative behaviorally equivalent descriptions for describing a memory element. The Code Fragment 8 presents the code for a register with eight D-type flip-flops, with asynchronous reset (*arst* signal) and synchronous reset (*srst* signal). The use of std_logic_vector-type signal allowing compact buses' representation has to be stressed.

```
entity reg is
     Port ( din : in std_logic_vector(7 downto 0);
            dout : out std_logic_vector(7 downto 0);
            arst, srst : in std_logic;
            clk : in std_logic);
end reg;
architecture Behavioral of reg is
begin
    reg : process (clk,arst)
     begin
       if (arst = '1') then
          dout <= "00000000";
```

© 2005 by CRC Press LLC

```
      elsif (clk'event and clk='1') then
        if (srst = '1') then
           dout <= "00000000";
        else
           dout <= din;
        end if;
    end if;
  end process;
end Behavioral;
```

CODE FRAGMENT 8 — 8-bit D flip-flop register with synchronous and asynchronous resets.

```
entity cont1 is
    Port ( clk : in std_logic;
           rst : in std_logic;
           count : out std_logic_vector(7 downto 0));
end cont1;
architecture Behavioral of cont1 is
signal caux : std_logic_vector(7 downto 0);
begin
  process (clk,rst)
    begin
      if (rst = '1') then
         caux <= "00000000";
      elsif (clk'event and clk='1') then
         caux <= caux + 1;
      end if;
  end process;
  count <= caux;
end Behavioral;
```

CODE FRAGMENT 9 — Up-counter with asynchronous reset.

The sequential execution of the process statements starts whenever an event occurs on signals *clk* or *arst* (as the events on synchronous signals will not produce a change in the register status, they are not included in the sensitivity list). First, the asynchronous reset condition is evaluated; if it evaluates to true, register outputs are cleared. If not, a test on the rising edge of the signal *clk* is performed (by clk'event and clk="1"). In the presence of clock rising edge, a further test on synchronous reset condition is performed and the register is cleared or loaded with fresh data, accordingly. The statements, after the clock rising edge test, implement a register with two modes of operation under the control of one external signal (*srst*). It can be seen as a general template for multimode register implementation, for RTL design.

As an example, in Code Fragment 9 the implementation of an up-counter is presented.

```
LIBRARY ieee;
USE ieee.std_logic_1164.all;
ENTITY SM1 IS
     PORT (CLK,a,b,c,RESET: IN std_logic;
           y,z : OUT std_logic);
END;
```

CODE FRAGMENT 10 — Entity interface of the state machine represented in Figure 84.5.

© 2005 by CRC Press LLC

Note that, due to output mode associated with *count*, it is not possible to involve *count* in the next counter state computation. In this sense, one internal signal (*caux*) is used and updated within the process. An additional concurrent statement assures that the value presented in *caux* is propagated to the output *count*.

84.8 State Machine Design

Finite state machines (FSMs) have been used for decades for control function implementation and state diagrams are, probably due to their graphical expressiveness, the most used notation representing FSMs.

Figure 84.4 presents an RTL block diagram associated with state machine implementation after synthesis from a state diagram, considering Moore and Mealy combinatorial outputs. Moore machine's outputs are a function of the current state, while Mealy machine' outputs are a function of the current state and all the inputs. It could also be of interest for some applications to consider registered outputs.

One common attitude to implement the block diagram of Figure 84.4 is to associate one process to each block. More specifically, we may have a process modeling the register that stores state variables, and another process computing the next state function and output functions.

The entity interface associated with the state machine of Figure 84.5 is presented in Code Fragment 10.

Code Fragment 11 implements the state diagram of Figure 84.5. Two processes are used: one for register modeling with reset capability (*sreg*) and another for combinatorial functions' modeling (next state function *next_sreg* and output functions *y* and *z*):

```
ARCHITECTURE BEHAVIOR OF SM1 IS
      SIGNAL sreg : std_logic_vector (1 DOWNTO 0);
      SIGNAL next_sreg : std_logic_vector (1 DOWNTO 0);
      CONSTANT STATE0 : std_logic_vector (1 DOWNTO 0) :="00";
      CONSTANT STATE1 : std_logic_vector (1 DOWNTO 0) :="01";
      CONSTANT STATE2 : std_logic_vector (1 DOWNTO 0) :="10";
BEGIN
      PROCESS (CLK, RESET)
      BEGIN
            IF ( RESET='1' ) THEN sreg <= STATE0;
            ELSIF CLK='1' AND CLK'event THEN
                  sreg <= next_sreg;
            END IF;
      END PROCESS;
      PROCESS (sreg,a,b,c)
      BEGIN
            y <= '0'; z <= '0';
            next_sreg<=STATE0;
            CASE sreg IS
                  WHEN STATE0 =>
                        z<='0'; y<='0';
                        IF ( a='1' ) THEN next_sreg<=STATE1;
                         ELSE next_sreg<=STATE0;
                        END IF;
                  WHEN STATE1 =>
                        y<='0'; z<='1';
```

© 2005 by CRC Press LLC

```
                    IF ( b='1' ) THEN next_sreg<=STATE2;
                     ELSE next_sreg<=STATE1;
                    END IF;
                WHEN STATE2 =>
                    z<='0'; y<='1';
                    IF ( c='1' ) THEN next_sreg<=STATE0;
                     ELSE next_sreg<=STATE2;
                    END IF;
                WHEN OTHERS =>
            END CASE;
        END PROCESS;
END BEHAVIOR;
```

CODE FRAGMENT 11 — State machine representation.

One concept of key importance regarding state machine implementation is state encoding. Several techniques can be used for state encoding, namely sequential, Gray, one-hot, random, including outputs, *ad hoc,* among others. For the above-presented code, sequential coding is used. It is explicitly encoded through the use of the constants STATE0, STATE1, and STATE2.

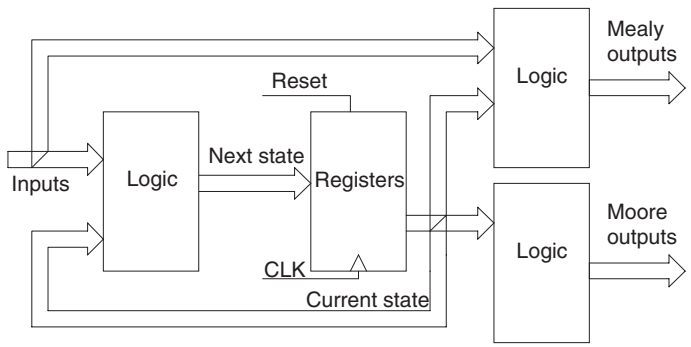

FIGURE 84.4 Block diagram for state machine implementation.

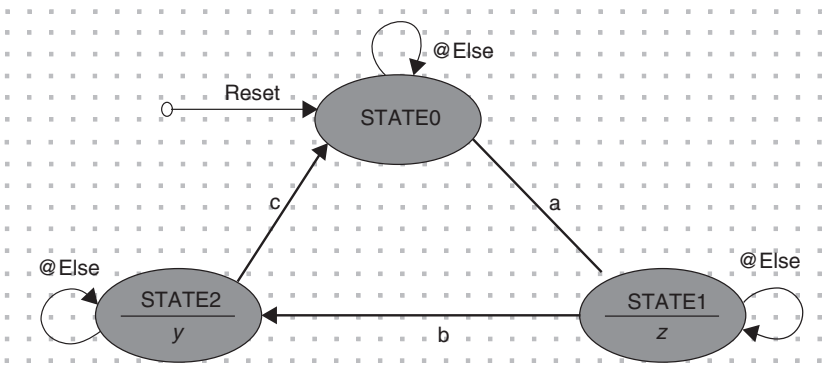

FIGURE 84.5 A simple state diagram.

© 2005 by CRC Press LLC

Code Fragment 12 illustrates a particularly interesting "neutral" encoding scheme. Its is based on an enumerated type that will be defined later considering the synthesis tool active options.

```
ARCHITECTURE BEHAVIOR OF SM1 IS
      TYPE type_sreg IS (STATE0,STATE1,STATE2);
      SIGNAL sreg, next_sreg : type_sreg;
BEGIN …
```

CODE FRAGMENT 12 — Symbolic state encoding scheme.

84.9 Simulation, Testing, and Design Verification

One of the initial goals of hardware description languages was to support simulation of the digital circuit design, and to verify its correctness against the specification document. Earlier design verification was accomplished through experimentation of the prototype, using signal generators, oscilloscopes, and data analyzers. But as circuit complexity increased, the importance of simulation has been proportional to it. VHDL also permits to build up a simulation environment, enabling test vectors generation, response capture, and analysis as well. Figure 84.6 presents the test-bench environment, where a VHDL top-level model represents the circuit under test.

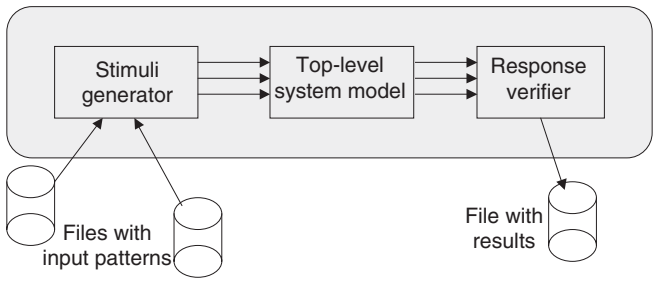

FIGURE 84.6 Test-bench environment.

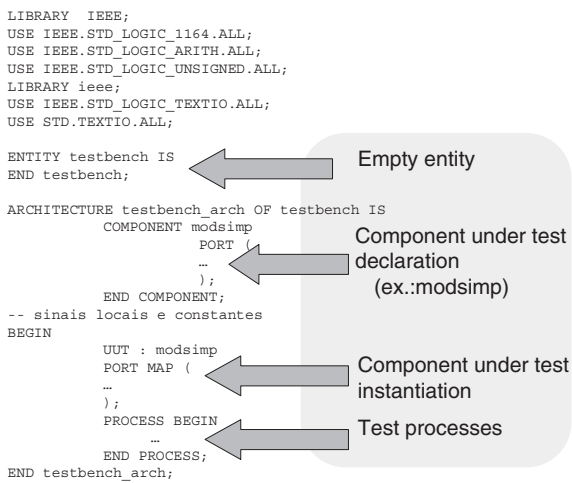

FIGURE 84.7 VHDL test-bench file structure.

© 2005 by CRC Press LLC

Stimuli generator and response verifier are composed of pieces of VHDL code. Stimuli generator can explicitly generate adequate waveforms to exercise the model, or rely on a set of test vectors prestored in an external file. Similarly, verification of response can be accomplished by visual or automatic inspection of the results of the simulation, or stored in files for further analysis.

Anyway, considering that both stimuli generator and response verifier will be coded in VHDL, the test-bench code has no interface ports. Figure 84.7 presents a skeleton of the test-bench file.

The generation of test patterns is straightforward. It is possible to generate periodic or nonperiodic waveforms. Consider the statements contained in Code Fragment 13 as examples.

```
a <= '1', '0' after 150ns, '1' after 777ns, '0' after 2003ns;
databus <= "01010101", "11001100" after 245ns;
z <= x and y after 20ns;
```

CODE FRAGMENT 13 — Waveform generation.

The first one specifies the signal waveform identifying the time points where some change occurs; the second one does a similar job for a vector. The last statement models time delay associated with one *and* gate. It is possible to model inertial and transport delays [7].

```
PROCESS -- clock process for clk,
BEGIN
      clk <= '0';
      WAIT FOR 10 ns;
      clk <= '1';
      WAIT FOR 10 ns;
END PROCESS;
```

CODE FRAGMENT 14 — Clock generation.

Process constructs can also be used for producing periodic and nonperiodic signals. Code Fragment 14 illustrates the generation of a clock signal. Finally, Code Fragment 15 generates a nonperiodic signal, whose evolution depends on the status of some signals. Finally, the *wait* statement imposes waiting for the end of simulation.

```
PROCESS
BEGIN
      d <= '0';
      WAIT UNTIL reset='1';
      d <= '1';
      WAIT UNTIL clk='1';
      d <= '0' AFTER 10 ns;
      WAIT;
END PROCESS;
```

CODE FRAGMENT 15 — Conditional waveform generation.

Languages for Embedded Systems[1]

85.1 Introduction

85.2 Software Languages
Assembly Languages • The C Language • C++ • Java • Real-Time Operating Systems

85.3 Hardware Languages
Verilog • VHDL

85.4 Dataflow Languages
Kahn Process Networks • Synchronous Dataflow

85.5 Hybrid Languages
Esterel • SDL • SystemC

85.6 Summary

Stephen A. Edwards
Columbia University

85.1 Introduction

An embedded system is a computer masquerading as a noncomputer that must perform a small set of tasks cheaply and efficiently. A typical system might have communication, signal processing, and user interface tasks to perform.

Because the tasks must solve diverse problems, a language general-purpose enough to solve them all would be difficult to write, analyze, and compile. Instead, a variety of languages have evolved, each best suited to a particular problem domain. The most obvious divide is between languages for software and hardware, but there are others. For example, a language for signal processing is often more convenient for a particular problem than, say, assembly, but might be poor for control-dominated behavior.

This chapter describes popular hardware, software, dataflow, and hybrid languages, each of which excels certain problems. Dataflow languages are good for signal processing, and hybrid languages combine ideas from the other three classes.

Due to space constraints, this chapter describes only the main features of each language. The author's book on the subject [9] provides many more details on all of these languages.

85.2 Software Languages

Software languages describe sequences of instructions for a processor to execute. As such, most consist of sequences of imperative instructions that communicate through memory: an array of numbers that hold their values until changed.

Each machine instruction typically does little more than, say, add two numbers, thus, high-level languages aim to specify many instructions concisely and intuitively. Arithmetic expressions are typical:

[1]Part of this chapter originally appeared in the Online Symposium for Electrical Engineers (OSEE).

coding an expression such as $ax^2 + bx + c$ in machine code is straightforward, tedious, and best done by a compiler. The C language provides such expressions, control-flow constructs such as loops and conditionals, and recursive functions (See Table 85.1). The C++ language adds classes as a way to build new data types, templates for polymorphic code, exceptions for error handling, and a standard library of common data structures. Java is a still higher-level language that provides automatic garbage collection, threads, and monitors to synchronize them.

Assembly Languages

An assembly language program (Figure 85.1) is a list of processor instructions written in a symbolic, human-readable form. Each instruction consists of an operation such as addition along with some operands. For example, `add r5, r2, r4` might add the contents of registers `r2` and `r4` and write the result to `r5`. Such arithmetic instructions are executed in order, but branch instructions can perform conditionals and loops by changing the processor's program counter — the address of the instruction being executed.

A processor's assembly language is defined by its opcodes, addressing modes, registers, and memories. The opcode distinguishes, say, addition from conditional branch, and an addressing mode defines how and where data are gathered and stored (e.g., from a register or from a particular memory location). Registers can be thought of as small, fast, easy-to-access pieces of memory.

There are roughly four categories of modern assembly languages (Table 85.2). The oldest are those for the so-called complex instruction set computers, or CISC. These are characterized by a rich set of instructions

```
  jmp   L2
L1:
  movl  %ebx, %eax
  movl  %ecx, %ebx
L2:
  xorl  %edx, %edx
  divl  %ebx
  movl  %edx, %ecx
  testl %ecx, %ecx
  jne   L1
```

TABLE 85.2 Typical Modern Processor Architectures

CISC	RISC	DSP	Microcontroller
x86	SPARC	TMS320	8051
68000	MIPS	DSP56000	PIC
	ARM	ASDSP-21xx	AVR

and addressing modes. For example, a single instruction in Intel's x86 family, a typical CISC processor, can add the contents of a register to a memory location whose address is the sum of two other registers and a constant offset. Such instruction sets are usually convenient for human programmers, who are generally fairly skilled at using a heterogeneous set of tools, and the code itself is usually quite compact. Figure 85.1(a) illustrates a small program in x86 assembly.

By contrast, reduced instruction set computers (RISC) tend to have fewer instructions and much simpler addressing modes. The philosophy is that while you generally need more RISC instructions to accomplish something, it is easier for a processor to execute them because it does not need to deal with the complex cases and it is easier for a compiler to produce them because they are simpler and more uniform. Figure 85.1(b) illustrates a small program in SPARC assembly.

The third category of assembly languages arises from more specialized processor architectures such as digital signal processors (DSPs) and very-long instruction word processors (VLIWs). The operations in these instruction sets are simple like those in RISC processors (e.g., add two registers); but they tend to be very irregular (only certain registers may be used with certain operations) and support a much higher degree of instruction-level parallelism. For example, Motorola's DSP56001 can, in a single instruction, multiply two registers, add the result to a third, load two registers from memory, and increase two circular buffer pointers. However, the instruction severely limits which registers (and even which memory) it may use. Figure 85.2(a) shows a filter implemented in 56001 assembly.

The fourth category includes instruction sets on small (4- and 8-bit) microcontrollers. In some sense, these combine the worst of all worlds: there are few instructions and each cannot do much, much like an RISC processor, and there are also significant restrictions on which registers can be used when, much like a CISC processor. The main advantage of such instruction sets is that they can be implemented very cheaply. Figure 85.2(b) shows a routine that writes to a parallel port in 8051 assembly.

```
move #samples, r0
move #coeffs, r4
move #n-1, m0
move m0, m4

The C Language

C is currently the most popular language for embedded system programming. C compilers exist for virtually every general-purpose processor, from the lowliest 4-bit microcontroller to the most powerful 64-bit processor for compute servers.

C was originally designed by Dennis Ritchie [23] as an implementation language for the Unix operating system being developed at Bell Labs for a 24K DEC PDP-11. Because the language was designed for systems programming, it provides very direct access to the processor through such constructs as untyped pointers and bit-manipulation operators, things appreciated today by embedded systems programmers. Unfortunately, the language also has many awkward aspects, such as the need to define everything before it is used, which are holdovers from the cramped execution environment in which it was first implemented.

A C program (Figure 85.3) contains functions built from arithmetic expressions structured with loops and conditionals. Instructions in a C program run sequentially, but control-flow constructs such as loops of conditionals can affect the order in which instructions execute. When control reaches a function call in an expression, control is passed to the called function, which runs until it produces a result, and control returns to continue evaluating the expression that called the function.

C derives its types from those that the processor manipulates directly: signed and unsigned integers ranging from bytes to words, floating point numbers, and pointers. These can be further aggregated into arrays and structures — groups of named fields.

C programs use three types of memory. Space for global data is allocated when the program is compiled, the stack stores automatic variables allocated and released when their function is called and returns, and the heap supplies arbitrarily sized regions of memory that can be deallocated in any order.

The C language is an ISO standard, but most people consult the book by Kernighan and Ritchie [16].

C succeeds because it can be compiled into very efficient code and because it allows the programmer almost arbitrarily low-level access to the processor when necessary. As a result, virtually every function can be written in C (exceptions include those that must manipulate specific processor registers) and can be expected to be fairly efficient. C's simple execution model also makes it fairly easy to estimate the efficiency of a piece of code and improve it if necessary.

While C compilers for workstation-class machines usually comply closely to ANSI/ISO standard C, C compilers for microcontrollers are often much less standard. For example, they often omit support for floating-point arithmetic and certain library functions. Many also provide language extensions that, while often very convenient for the hardware for which they were designed, can make porting the code to a different environment very difficult.

```
#include <stdio.h>

int main(int argc, char *argv[])
{
  char *c;
  while (++argv, --argc > 0) {
    c = argv[0] + strlen(argv[0]);
    while (--c >= argv[0])
      putchar(*c);
    putchar('\n');
  }
  return 0;
}
```

FIGURE 85.3 A C program that prints each of its arguments backwards. The outermost while loop iterates through the arguments (count in argc, array of strings in argv), while the inner loop starts a pointer at the end of the current argument and walks it backwards, printing each character along the way. The ++ and −− prefixes increment the variable they are attached to before returning its value.

C++

C++ (Figure 85.4) [24] extends C with structuring mechanisms for large programs: user-defined data types, a way to reuse code with different types, namespaces to group objects and avoid accidental name collisions when program pieces are assembled, and exceptions to handle errors. The C++ standard library includes a collection of efficient polymorphic data types such as arrays, trees, and strings for which the compiler generates custom implementations.

A class defines a new data type by specifying its representation and the operations that may access and modify it. Classes may be defined by inheritance, which extends and modifies existing classes. For example, a rectangle class might add length and width fields and an area method to a shape class.

A template is a function or class that can work with multiple types. The compiler generates custom code for each different use of the template. For example, the same *min* template could be used for both integers and floating-point numbers.

C++ also provides exceptions, a mechanism intended for error recovery. Normally, each method or function can only return directly to its immediate caller. Throwing an exception, however, allows control to return to an arbitrary caller, usually an error-handling mechanism in the *main* function or similar. Exceptions can be used, for example, to gracefully recover from out-of-memory conditions no matter where they occur, without the tedium of having to check whether every function encountered an out-of-memory condition.

Memory consumption is a disadvantage to C++'s exception mechanism. While most C++ compilers do not generate a slower code when exceptions are enabled, they do generate larger executables by including tables that record the location of the nearest exception handler. For this reason, many compilers, such as GNU's gcc, have a flag that completely disables exceptions.

C++ is being used more and more within embedded systems, but it is sometimes a less suitable choice than C for a number of reasons. First, C++ is a much more complicated language that demands a much larger compiler; hence, C++ has been ported to fewer architectures than C. Second, certain language features such as dynamic dispatch (virtual function calls) and exceptions can be too costly to implement in very small embedded systems. It is a more difficult language to learn and use properly, meaning there may be fewer qualified C++ programmers. Also, it is often more difficult to estimate the cost of a certain construct in C++ because the object-oriented programming style encourages many more function calls than the procedural style of C, and the cost of these is harder to estimate.

```
class Cplx {
  double re, im;
public:
  Cplx(double v) : re(v), im(0) {}
  Cplx(double r, double i)
    : re(r), im(i) {}
  double abs() const {
    return sqrt(re*re + im*im);
  }
  void operator+= (const Cplx& a) {
    re += a.re; im += a.im;
  }
};

int main() {
  Cplx a(5), b(3,4);
  b += a;
  cout << b.abs() << '\n';
  return 0;
}
```

FIGURE 85.4 A C++ fragment illustrating a partial complex number type and how it can be used (the C++ library has a complete version). This class defines how to create a new complex number from either a scalar or by specifying the real and imaginary components, how to compute the absolute value of a complex number, and how to add a complex number to an existing one.

Java

Sun's Java language [1,11,19] resembles C++ but is not a superset. Like C++, Java is object-oriented, providing classes and inheritance. It is a higher-level language than C++ since it uses object references, arrays, and strings instead of pointers. Java's automatic garbage collection frees the programmer from memory management.

Java omits a number of C++'s more complicated features. Templates are absent, although there are plans to include them in a future release of the language because they make it possible to write type-safe container classes. Java also omits operator overloading, which can be a boon to readability (e.g., when performing operations on complex numbers) or a powerful obfuscating force. Java also does not support C++'s complex multiple inheritance mechanism completely. But it does provide the notion of an interface — a set of methods provided by a class — that is equivalent to one of the most common uses of multiple inheritance.

Java provides concurrent threads (Figure 85.5). Creating a thread involves extending the *Thread* class, creating instances of these objects, and calling their *start* methods to start a new thread of control that executes the objects' *run* methods.

Synchronizing a method or block uses a per-object lock to resolve contention when two or more threads attempt to access the same object simultaneously. A thread that attempts to gain a lock owned by another thread will block until the lock is released, which can be used to grant a thread exclusive access to a particular object.

For embedded systems, Java holds promise but also many caveats. On the positive side, it is a simple, powerful language that provides the programmer a convenient set of abstractions. For example, unlike C,

```
import java.io.*;
class Counter {
    int value = 0;
    boolean present = false;
    public synchronized void count() {
        try { while (present) wait(); }
        catch (InterruptedException e) {}
        value++; present = true; notifyAll();
    }
    public synchronized int read() {
        try { while (!present) wait(); }
        catch (InterruptedException e) {}
        present = false; notifyAll();
        return value;
    }
}
class Count extends Thread {
    Counter cnt;
    public Count(Counter c) { cnt = c; start(); }
    public void run() { for (;;) cnt.count(); }
}
class Mod5 {
    public static void main(String args[]) {
        Counter c = new Counter();
        Count count = new Count(c);
        int v;
        for (;;) if ( (v = c.read()) % 5 == 0 )
            System.out.println(v);
    }
}
```

FIGURE 85.5 A contrived Java program that spawns a counting thread to print all numbers divisible by 5. The *main* method in the Mod5 class creates a new Counter, and then a new Count object. The Count class extends the Thread class and spawns a new thread in its constructor by executing *start.* This invokes its *run* method, which calls the method *count.* Both *count* and *read* are synchronized, meaning at most one may run on a particular Count object at once, here guaranteeing the counter is either counting or waiting for its value to be read.

© 2005 by CRC Press LLC

Java provides true strings and variable-sized arrays. On the negative side, Java is a heavyweight language, even more so than C++. Its run-time system is large, consisting of either a bytecode interpreter, a just-in-time compiler, or perhaps both, and its libraries are absolutely vast. While work has been done on paring down these things, Java still requires a much larger footprint than C.

Unpredictable runtimes are a more serious problem for Java. For time-critical embedded systems, Java's automatic garbage collector, bytecode interpreter, or just-in-time compiler make runtimes both unpredictable and variable, making it difficult to assess efficiency both beforehand and in simulation.

The real-time Java specification [6] attempts to address many of these concerns. It introduces mechanisms for more precise control over the scheduling policy for concurrent threads (the standard Java specification is deliberately vague on this point to improve portability), memory regions for which automatic garbage collection can be disabled, synchronization mechanisms for avoiding priority inversion, and various other real-time features such as timers. It remains to be seen, however, whether this specification addresses enough real-time concerns and is sufficiently efficient to be practical. For example, a naive implementation of the memory management policies would be very inefficient.

Real-Time Operating Systems

Many embedded systems use a real-time operating system (RTOS) to simulate concurrency on a single processor. An RTOS manages multiple running processes, each written in sequential language such as C. The processes perform the system's computation and the RTOS schedules them — attempts to meet deadlines by deciding which process runs when. Labrosse [17] describes the implementation of a particular RTOS.

Most RTOSes uses fixed-priority preemptive scheduling in which each process is given a particular priority (a small integer) when the system is designed. At any time, the RTOS runs the highest-priority running process, which is expected to run for a short period of time before suspending itself to wait for more data. Priorities are usually assigned using rate-monotonic analysis [7] (due to Liu and Layland [20]), which assigns higher priorities to processes that must meet more frequent deadlines (Figure 85.6).

Priority inversion is a fundamental problem in fixed-priority preemptive scheduling that can lead to missed deadlines by enabling a lower-priority process to delay indefinitely the execution of a higher-priority one. Figure 85.7 illustrates the typical scenario: a low-priority process L runs and acquires a resource. Shortly thereafter, a high-priority process H preempts L, attempts to acquire the same resource, and blocks waiting for L to release it. This can cause H to miss its deadline even though it is at a higher priority than L. Even worse, if a process M with priority between L and now starts, it can delay the execution of H indefinitely. Process M does not allow L to run since M is at a higher priority; hence, L cannot execute and release the lock and H will continue to block.

Priority inversion is usually solved with priority inheritance. When a process L acquires a lock, its priority is temporarily raised to a level where it will not be preempted by any other process that will also attempt to acquire the lock. Many RTOSes provide a mechanism for doing this automatically.

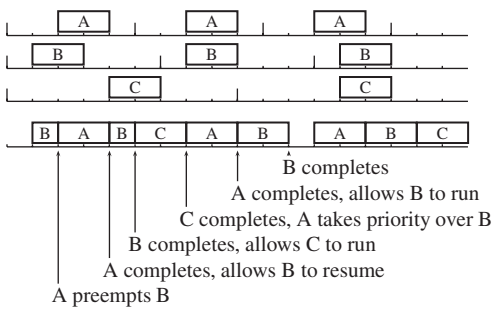

FIGURE 85.6 The behavior of an RTOS with fixed-priority preemptive scheduling. Rate-monotonic analysis gives process A the highest priority since it has the shortest period; C has the lowest.

© 2005 by CRC Press LLC

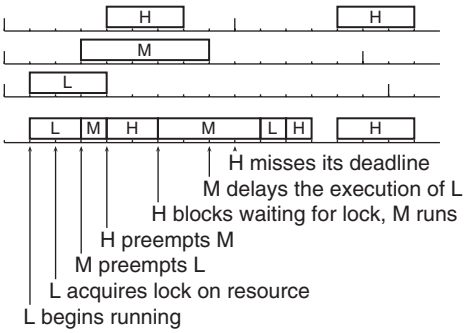

FIGURE 85.7 Priority inversion illustrated. When low-priority process L acquires a lock on a resource needed by process H, it effectively blocks process H, but then intermediate-priority process M preempts L, preventing it from running and releasing the resource needed by H. Priority inheritance, the common solution, temporarily raises the priority of L to that of H when H requests the resource held by L.

85.3 Hardware Languages

Concurrency and the notion of control is the fundamental difference between hardware and software. In hardware, every part of the "program" is always running, but in software, exactly one part of the program is running at any one time. Software languages naturally focus on sequential algorithms, while hardware languages enable concurrent function evaluation, speculation, and concurrency.

Ironically, efficient simulation *in software* is a main focus of the hardware languages presented here; thus, their discrete-event semantics are a compromise between what would be ideal for hardware and what simulates efficiently.

Verilog [13, 25] and VHDL [12, 22, 8, 2] are the most popular languages for hardware description and modeling (Figures 85.8 and 85.9). Both are model systems with discrete-event semantics that ignore idle portions of the design for efficient simulation. Both describe systems with structural hierarchy: a system consists of blocks that contain instances of primitives, other blocks, or concurrent processes. Connections are listed explicitly.

Verilog provides more primitives geared specifically toward hardware simulation. VHDL's primitive are assignments such as $a = b + c$ or procedural code. Verilog adds transistor and logic gate primitives, and allows new ones to be defined with truth tables.

Both languages allow concurrent processes to be described procedurally. Such processes sleep until awakened by an event that causes them to run, read, and write variables, and suspend. Processes may wait for a period of time (e.g., #10 in Verilog, `wait for 10 ns` in VHDL), a value change (`@(a or b)`, `wait on a,b`), or an event (`@(posedge clk)`, `wait on clk until clk='1'`).

VHDL communication is more disciplined and flexible. Verilog communicates through *wires* or *regs*: shared memory locations that can cause race conditions. VHDL's signals behave like wires but the resolution function may be user-defined. VHDL's variables are local to a single process unless declared shared.

Verilog's type system models hardware with four-valued bit vectors and arrays for modeling memory. VHDL does not include four-valued vectors, but its type system allows them to be added. Furthermore, composite types such as C *structs* can be defined.

Overall, Verilog is the leaner language more directly geared toward simulating digital integrated circuits. VHDL is a much larger, more verbose language capable of handing a wider class of simulation and modeling tasks.

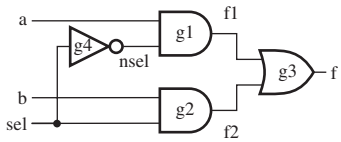
Verilog

Verilog was first devised in 1984 as an input language for a discrete-event simulator for digital hardware design. It was one of the first hardware description languages able to specify both the circuit and a test bench in the same language, which remains one of its strengths.

© 2005 by CRC Press LLC

Verilog has since been pressed into use as both a modeling language and a specification language. Although Verilog is still simulated frequently, it is also frequently fed to a logic synthesis system that translates it into an actual circuit. This is a technically challenging process and not all Verilog constructs can be translated into hardware since Verilog's semantics are nondeterministic and effectively defined by the behavior of an event-driven simulator.

Verilog provides both structural and behavioral modeling styles, and allows them to be combined at will. Consider the simple multiplexer circuit shown in Figure 85.8(a). It can be modeled in Verilog as a schematic



(a)

```
module mux(f,a,b,sel);
output f;
input a, b, sel;

and g1(f1, a, nsel),
    g2(f2, b, sel);
or  g3(f, f1, f2);
not g4(nsel, sel);

endmodule
```

(b)

```
module mux(f,a,b,sel);
output f;
input a, b, sel;

assign f = sel ? a : b;

endmodule
```

(c)

```
primitive
   mux(f,a,b,sel);
output f;
input a, b, sel;

table
  1?0 : 1;
  0?0 : 0;
  ?11 : 1;
  ?01 : 0;
  11? : 1;
  00? : 0;
endtable
endprimitive
```

(d)

```
module mux(f,a,b,sel);
output f;
input a, b, sel;
reg f;

always @(a or b or sel)
  if (sel) f = a;
  else f = b;

endmodule
```

(e)

```
module testbench;
  reg a, b, sel;
  wire f;

mux dut(f, a, b, sel);

  initial begin
    $display("a,b,sel -> f");
    $monitor($time,,
             "%b%b%b -> ",
             a, b, sel, f);
    a = 0; b = 0 ; sel = 0;
    #10 a = 1;
    #10 sel = 1;
    #10 b = 1;
    #10 sel = 0;
  end
endmodule
```

(f)

composed of logic gates (Figure 85.8[b]), with a continuous assignment statement that represents logic using an expression (Figure 85.8[c]), with a truth table as a "user-defined primitive" (Figure 85.8[d]), or with an imperative, event-driven code (Figure 85.8[e]).

The imperative modeling style is particularly useful for creating testbenches: models of an environment that stimulate a particular circuit and check its behavior. Figure 85.8(f) illustrates such a testbench, which instantiates a multiplexer (the instance is called "dut"— device under test) and starts a simple process (the `initial` block) to apply inputs and monitor outputs. Running Figure 85.8(f) in a Verilog simulator gives a partial truth table for the multiplexer.

As these examples illustrate, a Verilog program is composed of *modules.* Each module has an interface with named input and output ports and contains one or more instances of other modules, continuous assignments, and imperative code in *initial* and *always* blocks. Modules perform the same information hiding function as functions in imperative languages: a module's contents is not visible from outside and names for instances, wires, and whatnot inside a module do not have to differ from those in other modules.

Verilog programs manipulate four-valued bit vectors intended to model digital hardware. Each bit is 0, 1, X, representing unknown, or Z, used to represent an undriven tri-state bus. While such vectors are very convenient for modeling circuitry, one of Verilog's shortcomings is the lack of a more complicated type system. It does provide arrays of bit vectors but no other aggregate types.

The plumbing within a module comes in two varieties: one for structural modeling, and the other for behavioral. Structural components, such as instances of primitive logic gates and other modules, communicate through *wires,* each of which may be connected to drivers such as gates or continuous assignments. Conceptually, the value of a wire is computed constantly from whatever drives it. Practically, the simulator evaluates the expression in a continuous assignment whenever any of its inputs changes.

Behavioral components communicate through *regs*, which behave like memory in traditional programming languages. The value of a reg is set by an assignment statement executed within an initial or always block, and that value persists until the next time the reg is assigned. While a reg can be used to model a state-holding element such as a latch or flip-flop, it is important to remember that they are really just memory. Figure 85.8(e) illustrates this: a reg is used to store the output of the mux, even though it is not a state-holding element. This is because imperative code can only change the value of regs, not wires.

Verilog is a large language that contains many now-little-used features such as switch-level transistor models, pure event handling, and complicated delay specifications, all remnants of previous design methodologies. Today, switch-level modeling is rarely used because Verilog's precision is too low for circuits that take advantage of this behavior (a continuous simulator such as SPICE is preferred). Delays are rarely used because static timing analysis has replaced event-driven simulation as the timing analysis method of choice because of its speed and precision. Nevertheless, Verilog remains one of the most commonly used languages for hardware design.

System Verilog, a recently introduced standard (2002), is an extension to the Verilog language designed to aid in the creation of large specifications. It adds a richer set of datatypes, including C-like structures, unions, and multidimensional arrays, a richer set of processes (e.g., an `always_comb` block has an implied sensitivity to all variables it references), the concept of an interface to encapsulate communication and function between blocks, and many other features. Whether System Verilog supplants Verilog as a standard language for hardware specification remains to be seen, but it does have the advantage of being an obvious evolutionary improvement over previous versions of Verilog.

VHDL

The VHDL language (VHDL is a two-level acronym, standing for Very High Speed Integrated Circuit [VHSIC] Hardware Description Language) was designed to be a flexible modeling language for digital systems. It has fewer built-in features such as Verilog's four-valued bit vectors, gate, and transistor-level models. Instead, it has very flexible type and package systems that allow such things to be specified in the language.

Unlike Verilog, VHDL draws a strong distinction between the interface to a hierarchical object and its implementation. VHDL interfaces are called *entities* and their implementations are called *architectures.*

© 2005 by CRC Press LLC

Figure 85.9 illustrates how these are used in a simple model: the entities are essentially named lists of ports and the architectures consist of named lists of component instances. While this increases the verbosity of the language, it makes it possible to use different implementations, perhaps at differing levels of abstraction.

```
entity NAND is
  port (a: in Bit; b: in Bit; y: out Bit);
end NAND;
```

(a)

```
architecture arch1 of mux2 is
  signal cc, ai, bi : Bit; -- internal signals

  component Inverter          -- component interface
    port (a:in Bit; y: out Bit);
  end component;

  component AndGate
    port (a1, a2:in Bit; y: out Bit);
  end component;

  component OrGate
    port (a1, a2:in Bit; y: out Bit);
  end component;

begin
  I1: Inverter port map(c => a, y => cc); -- by name
  A1: AndGate  port map(a, c, ai); -- by position
  A2: AndGate  port map(a1 => b, a2 => cc, y => bi);
  O1: OrGate   port map(a1 => ai, a2 => bi, y => d);
end;
```

(b)

```
architecture arch2 of mux2 is
  signal cc, ai, bi : Bit;
begin
  cc <= not c;
  ai <= a and c;
  bi <= b and cc;
  d  <= ai or bi;
end;
```

(c)

```
architecture arch3 of mux2 is
begin
  process(a, b, c)  -- sensitivity list
  begin
    if c = '1' then
      d <= a;
    else
      d <= b;
    end if;
  end process;
end;
```

(d)

FIGURE 85.9 VHDL examples. Compare with Figure 85.8. (a) The entity declaration for the multiplexer, which defines its interface. (b) A structural description of the multiplexer from Figure 85.8(a). (c) A dataflow description with one equation per gate. (d) An imperative behavioral description.

© 2005 by CRC Press LLC

Like Verilog, VHDL supports structural, dataflow, and behavioral modeling styles, illustrated in Figure 85.9. As in Verilog, they can be mixed. In the three styles, an architecture is specified by listing components and their connections (structural), as a series of equations (dataflow, like Verilog's `assign` declarations), or as a sequence of imperative instructions (behavioral, like Verilog's `always` blocks).

In general, a process runs until it reaches a `wait` statement. This suspends the process until a particular event occurs, which may be an event on a signal, a condition on a signal, a timeout, or any combination of these. By itself, `wait` terminates a process. At the other extreme, `wait on Clk until Clk = "1" for 5 ns;` waits for the clock to rise or for 5 ns, whichever comes first.

Combinational processes, which always run in response to a change on any of their inputs, are common enough to warrant a shorthand. Thus, `process (A,B,C)` effectively executes a `wait on A,B,C` statement at the end.

VHDL's type system is much more elaborate than Verilog's. It provides integers, floating-point numbers, enumerations, and physical quantities. Integers and floating-point numbers include a range specification. For example, a 16-bit integer might be declared as

```
type address is range 16#0000# to 16#FFFF#;
```

Enumerated literals may be single characters or identifiers. Identifiers are useful for FSM states and single characters are useful for Boolean wire values. Typical declarations:

```
type Bit is ('0', '1');
type FourV is ('0', '1', 'X', 'Z');
type State is (Reset, Running, Halted);
```

Objects in VHDL, such as types, variables, and signals, have attributes such as size, base, and range. Such information can be useful for, say, iterating over all elements in an array. For example, if `type Index is range 31 downto 0`, then `Index'LOW` is 0. Access to information about signals can be used for collecting simulation statistics. For example, if `Count` is a signal, then `Count'EVENT` is true when there is an event on the signal.

VHDL has a powerful library and package facility for encapsulating and reusing definitions. For example, the standard logic library for VHDL includes types for representing wire states and standard functions such as AND and OR that operate on these types. Verilog has such facilities built in, but is not powerful enough to allow such functionality to be written as a library.

85.4 Dataflow Languages

The hardware and software languages described earlier have semantics very close to that of their implementations (e.g., as instructions on a sequential processor or as digital logic gates), which makes for efficient realizations, but some problems are better described using different models of computation.

Many embedded systems perform signal processing tasks such as reconstructing a compressed audio signal. While such tasks can be described and implemented using the hardware and software languages described earlier, signal-processing tasks are more conveniently represented with systems of processes that communicate through queues. Although clumsy for general applications, dataflow languages are a perfect fit for signal-processing algorithms, which use vast quantities of arithmetic derived from linear system theory to decode, compress, or filter data streams that represent periodic samples of continuously changing values such as sound or video. Dataflow semantics are natural for expressing the block diagrams typically used to describe signal-processing algorithms, and their regularity makes dataflow implementations very efficient because otherwise costly run-time scheduling decisions can be made at compile time, even in systems containing multiple sampling rates.

Kahn Process Networks

Kahn Process Networks [15] form a formal basis for dataflow computation. Kahn's systems consist of processes that communicate exclusively through unbounded point-to-point first-in, first-out queues

© 2005 by CRC Press LLC

```
process f(in int u, in int v, out int w)
{
  int i; bool b = true;
  for (;;) {
    i = b ? wait(u) : wait(w);
    printf("%i\n", i);
    send(i, w);
    b = !b;
  }
}

process g(in int u, out int v, out int w)
{
  for (;;) {
    send(wait(u), v); send(wait(u), w);
  }
}

process h(in int u, out int v, int init)
{
  send(v, init);
  for(;;)
    send(wait(u), v);
}

channel int X, Y, Z, T1, T2;
f(Y, Z, X);
g(X, T1, T2);
h(T1, Y, 0);
h(T2, Z, 1);
```

FIGURE 85.10 A Kahn Process Network written in a C-like dialect. Here, processes are functions that run continuously, may be attached to communication channels, and may call *wait* to wait for data on a particular port and *send* to write data to a particular port. The f process alternately copies from its u and v ports to its w port; the g process does the opposite, copying its u port to alternately v and w, and h simply copies its input to its output.

(Figure 85.10). Reading from a port makes a process wait until data are available, but writing to a port always completes immediately.

Deterministic behavior is the most unique aspect of Kahn's networks. Processes' blocking read behavior guarantees the overall system behavior (specifically, the sequence of data tokens that flow through each queue) is the same regardless of the relative execution rates of the processes, that is, regardless of the scheduling policy. This is generally a very desirable property because it provides a guarantee about the behavior of the system, ensures that simulation and reality will match, and greatly simplifies the design task since designers are not obligated to ensure this themselves.

Balancing processes' relative execution rates to avoid an unbounded accumulation of tokens is the challenge in scheduling a Kahn network. One general approach, proposed in Parks' thesis [21], places artificial limits on the size of each buffer. Any process that writes to a full buffer blocks until space is available, but if the system deadlocks because all buffers are full, the scheduler increases the capacity of the smallest buffer.

In practice, Kahn networks are rarely used in their pure form since they are fairly costly to schedule and their completely deterministic behavior is sometimes overly restrictive since they cannot easily handle sporadic events (e.g., an occasional change of volume level in a digital volume control) or server-like behavior where the environment may make requests in an unpredictable order. Nevertheless, Kahn's model still has useful properties and forms a starting point for other dataflow models.

Synchronous Dataflow

Lee and Messerschmitt's [18] Synchronous Dataflow (SDF) fixes the communication patterns of the blocks in a Kahn network (Figure 85.11 shows an example after Bhattacharyya et al. [5]). Each time a block runs, it consumes and produces a fixed number of data tokens on each of its ports. Although more

© 2005 by CRC Press LLC

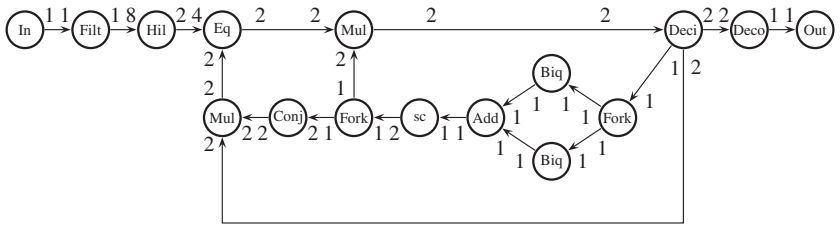

FIGURE 85.11 A modem in SDF. Each node represents a process. The labels on each arc indicate the number of tokens sent or received by a process each time it fires.

restrictive than Kahn networks, SDF's predictability allows it to be scheduled completely at compile time, producing a very efficient code.

Scheduling operates in two steps. First, the rate at which each block fires is established by considering the production and consumption rates of each block at the source and sink of each queue. For example, the arc between the Hil and Eq nodes in Figure 85.11 implies that Hil runs twice as frequently. Once the rates are established, any algorithm that simulates the execution of the network without buffer underflow will produce a correct schedule if one exists. However, more sophisticated techniques reduce generated code and buffer sizes by better ordering the execution of the blocks (see Bhattacharyya et al. [4]).

Synchronous dataflow specifications are built by assembling blocks typically written in an imperative language such as C. The SDF block interface is specific enough to make it easy to create libraries of general-purpose blocks such as adders, multipliers, and even FIR filters.

While SDF is often used as a simulation language, it is also well-suited to code generation. It enables a practical technique for generating code for digital signal processors, for which C compilers often cannot generate efficient code. Assembly code is handcrafted for each block in a library, and code synthesis consists of assembling these handwritten blocks, sometimes generating extra code that handles the interblock buffers. For large, specialized blocks such as fast Fourier transforms, this can be very effective because most of the generated code was carefully optimized by hand.

85.5 Hybrid Languages

The languages in this section use even more novel models of computation than the hardware, software, or dataflow languages presented earlier. While such languages are more restrictive than general-purpose ones, they are much better-suited for certain applications. Esterel excels at discrete control by blending software-like control flow with the synchrony and concurrency of hardware. Communication protocols are SDL's forte; it uses extended finite-state machines with single input queues. SystemC provides a very flexible discrete-event simulation environment built on C++.

Esterel

Intended for specifying control-dominated reactive systems, Esterel [3] combines the control constructs of an imperative software language with concurrency, preemption, and a synchronous model of time like that used in synchronous digital circuits. In each clock cycle, the program awakens, reads its inputs, produces outputs, and suspends (Table 85.3).

An Esterel program communicates through signals that are either present or absent in each cycle. In each cycle, each signal is absent unless an emit statement for the signal runs and makes the signal present for that cycle only. Esterel guarantees determinism by requiring each emitter of a signal to run before any statement that tests the signal.

Esterel is strongest at specifying hierarchical state machines. In addition to sequentially composing statements (separated by a semicolon), it has the ability to compose arbitrary blocks of code in parallel (the double vertical bars) and abort or suspend a block of code when a condition is true. For example, the *every-do* construct in Figure 85.12 effectively wraps a reset statement around two state machines running in parallel.

SDL

SDL is a graphical specification language developed for describing telecommunication protocols defined by the ITU [14] (Ellsberger [10] is more readable). A system consists of concurrently running FSMs, each with a single input queue, connected by channels that define which messages they carry. Each FSM consumes the most recent message in its queue, reacts to it by changing internal state or sending messages to other FSMs, changes to its next state, and repeats the process. Each FSM is deterministic, but because messages from other FSMs may arrive in any order because of varying execution speed and communication delays, an SDL system may behave nondeterministically.

In addition to a fairly standard textual format, SDL has a formalized graphical notation. There are three types of diagrams. Flowcharts define the behavior of state machines at the lowest level (Figure 85.13). Block diagrams illustrating the communication among state machines local to a single processor are at the next level up. Each communication channel is labeled with the set of messages that it conveys. The top level is another block diagram that depicts the communication among processors. The communica-

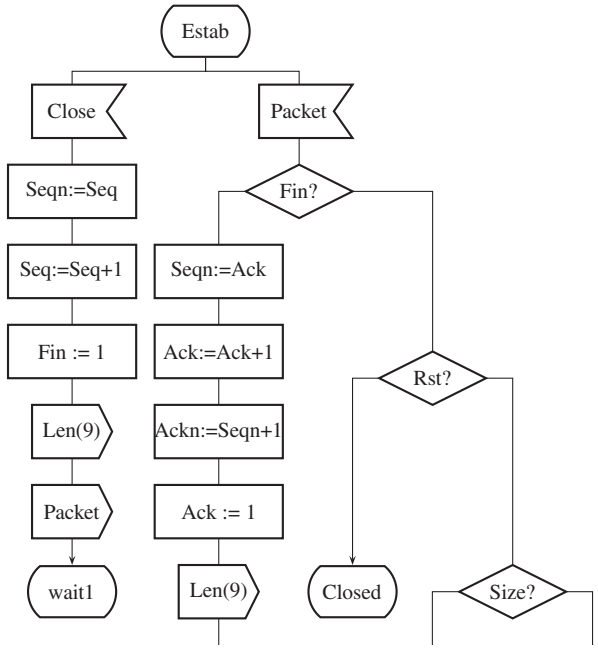

FIGURE 85.13 A fragment of an SDL flowchart specification for a TCP protocol. The rounded boxes denote states (Estab, wait1, and Closed). Immediately below Estab are inward-pointing boxes that receive signals (Close, Packet). The square and diamond boxes below these are actions and decisions. The outward-pointed boxes (e.g., Packet) emit signals.

tion channels in these diagrams are also labeled with the signals they convey, but are assumed to have significant delay, unlike the channels among FSMs in a single processor.

The behavior of an SDL state machine is straightforward. At the beginning of each cycle, it gets the next signal in its input queue and sees if there is a "receive" block for that signal off the current state. If there is, the associated code is executed, possibly emitting other signals and moving to a next state. Otherwise, the signal is simply discarded and the cycle repeats from the same state. By itself, such semantics have a hard time dealing with signals that arrive out-of-order, but SDL has an additional construct for handling this condition. The save construct is like the receive construct, a state appearing immediately and matching a signal, but when it matches it stores the signal in a buffer that holds it until another state has a matching rule.

SystemC

The SystemC language (Figure 85.14) is a C++ subset for system modeling. A SystemC specification is simulated by compiling it with a standard C++ compiler and linking in freely distributed class libraries from www.systemc.org.

The SystemC language builds systems from Verilog- and VHDL-like modules. Each has a collection of I/O ports and may contain instances of other modules or processes defined by a block of C++ code.

SystemC uses a discrete-event simulation model. The SystemC scheduler executes the code in a process in response to an event such as a clock signal, or a delay. This model resembles the one used in Verilog and VHDL, but has the flexibility of operating with a general-purpose programming language.

SystemC began life aiming to replace Verilog or VHDL as a hardware description language (it did not offer designers a sufficiently compelling reason to switch), but has since moved beyond that. Very often in system design, it is desirable to run simulations to estimate such high-level behavior as bus activity or memory accesses. Historically, designers had custom-written simulators in a general-purpose language such as C, but this was time-consuming because of the need to write a new simulation kernel (i.e., something that provided concurrency) for each new simulator.

```
#include "systemc.h"

struct complex_mult : sc_module {
  sc_in<int>  a, b;
  sc_in<int>  c, d;
  sc_out<int> x, y;
  sc_in_clk   clock;

  void do_mult() {
    for (;;) {
      x = a * c - b * d;
      wait();
      y = a * d + b * c;
      wait();
    }
  }

  SC_CTOR(complex_mult) {
    SC_CTHREAD(do_mult, clock.pos());
  }
};
```

FIGURE 85.14 A SystemC model for a complex multiplier.

SystemC is emerging as a standard for writing system-level simulations. While not perfect, it works well enough and makes it fairly easy to glue large pieces of existing software together. Although Verilog has a programming language interface (PLI) that allows arbitrary C/C++ code to be linked and run simultaneously with a simulation, the higher integration of the SystemC approach is more efficient.

SystemC supports transaction-level modeling, in which bus transactions, rather than being modeled on a per-cycle basis as would be done in a language such as Verilog, are modeled as function calls. For example, a burst-mode bus transfer would be modeled with a function that marks the bus as in use, advances simulation time according to the number of bytes to be transferred, actually copies the data in the simulator, and marks the bus as unused. Nowhere in the simulation would the actual sequence of signals and bits transferred over the bus appear.

85.6 Summary

Currently, most embedded systems are programmed using C for software and Verilog, or possibly VHDL, for hardware components such as FPGAs or ASICs, but this will probably change. The increased complexity of such designs makes a compelling case for different, higher-level languages. Years ago, designers made the jump from assembly to C, and the higher-level constructs of Java are growing more attractive despite its performance loss.

Domain-specific languages, especially for signal-processing problems, already have a significant beachhead, and will continue to make inroads. Most signal processing algorithms are already prototyped using a higher-level language (Matlab), but it remains to be seen whether synthesis from Matlab will ever be practical.

For hardware, the direction is less clear. While modeling languages such as SystemC will continue to grow in importance, there is currently no clear winner for the successor to VHDL and Verilog. Roughly a decade ago, a different, high-level subset of VHDL and Verilog was proposed as the new "behavioral" synthesis subset, but did not catch on because it was too limiting, largely because of restrictions placed on it by the synthesis algorithms. Additions such as System Verilog are incremental, if helpful, improvements, but will not provide the quantum leap forward that synthesis from the register-transfer level (RTL) subsets of Verilog and VHDL provided. Perhaps future hardware langauges may contain constructs such as Esterel's.

86.1 Introduction

Verification is the process of checking whether a given design is correct with respect to its specification. The specification itself can be in different forms — it can be a nontangible entity such as a designer's intent, or a document written in a natural language, or expressions written in a formal language. In this chapter, we consider a *verification language* to be a language with a formal syntax, which supports expression of verification-related tasks. While it is useful for a verification language to have a precise unambiguous semantics, we do not regard it as a defining feature. Broadly speaking, we focus on the support it provides for dynamic verification based on simulation, as well as static verification based on formal techniques. Although we discuss some modeling languages also, we highlight their verification-related features. Other details on how they are used for representing higher-level models can be found in the accompanying chapters in this book [1], and a recent survey [2].

Verification is increasingly becoming a bottleneck in the design of embedded systems and system-on-chips (SoCs). The primary reason is the inability of design automation methodologies to keep up with growing design complexity, due to the increasing number of transistors achievable on a chip in accordance with the well-known Moore's Law. The emerging trend toward systematic reuse of design components and platforms can help amortize the verification costs across multiple designs. At the same time, it places an even greater responsibility on the verification methodology, because the correctness of reusable,

© 2005 by CRC Press LLC

parameterized components must be verified in potentially multiple contexts. The cost of detecting bugs late in the design cycle is very high, both in terms of design respins, and in terms of time lost to market.

A verification methodology for system-level design needs to address issues related to component-level verification, as well as system-level integration of these components. For embedded systems, this requires verifying the effects of distributed concurrent computation, not only for hardware but also for the embedded software. Additional complexity arises due to the heterogeneous nature of the components. For example, many embedded applications include digital controllers and analog sensors and actuators. This requires verifying the hybrid systems, where the dynamics consist of discrete as well as continuous behaviors. Another crucial problem for embedded systems is verifying the interfaces for parameterized components, and third-party IP components, mostly without access to the design details. Finally, real-time constraints play an important role in hardware–software partitioning and scheduling (typically implemented in an on-chip real-time operating system kernel). It is important to specify and verify these real-time assumptions and requirements.

Overview

Although there has been progress in verification of embedded systems, there has been relatively little effort at language standardization targeted at verification features described above. At the same time, much of the recent standardization activities for hardware and system-level verification languages (e.g., by Accellera [3], and IEEE [4]) are very much applicable for embedded systems. Therefore, in this chapter, we describe verification languages for hardware, software, and embedded systems. A comprehensive survey in any of these categories is beyond the scope of this chapter. Instead, we focus on representative languages, including language standards where available. Note that many of these languages and standards are still evolving, and are likely to undergo further changes from the details described in this chapter.

For hardware designs, the historic success of logic synthesis technology for register-transfer level (RTL) designs led to the popularity of hardware description languages (HDLs), such as Verilog and VHDL. This in turn has led to the emergence of *hardware verification languages* (HVLs). Examples of these languages, described in Section 86.3, include *e*, OpenVera, Sugar/PSL, and ForSpec. In the area of software verification related to embedded applications, described in Section 86.4, we focus on the use of standard programming languages such as C/C++, Java, and on software modeling languages such as UML, SDL, and Alloy. For embedded systems, described in Section 86.5, we focus on languages for system-level verification, such as SystemC, SpecC, and SystemVerilog. We also describe domain-specific verification efforts, such as those based on Esterel and hybrid systems.

86.2 Background

We start by providing some background for verification methods, in order to provide a sufficient context and terminology for our discussion on verification languages. More details can be found in the references cited.

Simulation-based Verification

Simulation has been, and continues to be, the primary method for functional verification of hardware and system level designs. It consists of providing input stimuli to the *design under verification* (DUV), and checking the correctness of the output response. In this sense, it is a dynamic verification method. The practical success of simulation has largely been due to automation through development of *testbenches*, which provide the verification context for a DUV. (Details of testbench development are described in a recent book [5].)

A typical testbench consists of a *generator* of testcases (input stimuli), a *checker* or *monitor* for checking the output response, and a *coverage analyzer* for reporting how much of the design functionality has been covered by the testcases. Depending on how much of the internal design state is observable and controllable by the generators and checkers, verification can be classified as black-box (none), white-box (full), or gray-box (partial, added to aid verification).

It is impossible to simulate all testcases for designs of modest size. Traditionally, *directed* testbenches are used to generate specific scenarios of interest, especially to nail down designer's intent in the early

© 2005 by CRC Press LLC

phase of the design cycle. In contrast, *constrained random* testbenches are used to generate random stimuli, subject to certain constraints added to the testbench. These are very useful for verifying unexpected scenarios, which help in finding bugs in later phases of the design cycle. In all cases, progress is evaluated in terms of *coverage metrics*, which have been used with varying degrees of success. These include code coverage metrics such as statement/branch/toggle/expression coverage, and functional coverage metrics such as state/transition coverage of the finite state machines (FSMs) in the design description.

As systems become increasingly complex, designs need to be specified at much higher levels of abstraction. A *transaction* is a sequence of lower-level tasks, which implement a logical operation at the higher level. For example, a read transaction by an agent on a shared bus typically consists of transferring the address to the bus, waiting for the data to be ready, and transferring the data from the bus. In complex systems, it is more natural to model intermodule communication at the transaction level, rather than at the signal level. This has led to the development of transaction-based testbenches for system-level verification. These testbenches use adaptors called transactors/bus functional models (BFM) to translate between the higher and lower levels.

Development of testbenches at RTL and system level can be quite tedious. It is useful to have language support for abstraction and object-oriented features, such as abstract data types, data encapsulation, dynamic object creation/destruction, inheritance, and polymorphism. The testbench language must also be able to specify and launch many tasks concurrently, and provide features for synchronization, monitoring multiple in-flight tasks, and reentrancy of tasks. Most of these features were absent from the HDLs, which motivated the emergence of testbench languages, HVLs, and system-level modeling languages, described in Sections 86.3 and 86.5, respectively.

Formal Verification

In contrast to simulation, formal verification methods do not rely on the dynamic response of a DUV to certain testcases. Rather, they perform static analysis on a formal mathematical model of the given DUV, to check its correctness with respect to a given specification under all possible input scenarios. In this section, we briefly describe some of these methods. Successful instances of industry applications have been described in a survey [6].

A popular formal method is *equivalence checking*, where a given DUV is checked for equivalence against a given reference design. Equivalence checking has been applied very successfully in automated hardware design, to check that no errors are introduced during logic synthesis flow from RTL to gate-level design. Since both the reference design and the DUV are adequately represented in standard HDLs, there has been little motivation to develop a special language for equivalence checking.

When reference models are unavailable, or where the correctness of the highest-level model needs to be checked, design requirements are expressed in terms of correctness properties. *Property checking* is used to check whether a given design satisfies a given correctness property, expressed as a formal specification. Most property specification languages are derived from formal logics, or automata theory (described in more detail in the Formal Specification of Properties section).

The two main techniques for property checking are *model checking* and *theorem-proving*. In model checking [7], the DUV is typically modeled as a finite state transition system, the property is specified as a temporal logic formula, and verification consists of checking whether the formula is true in that model.[1] In theorem-proving, both the DUV and the specification are modeled as logic formulas, and the satisfaction relation between them is proved as a theorem, using the deductive proof calculus of a theorem-prover. Model checking techniques have found better acceptance in the industry so far [8, 9], primarily because they can be easily automated for finite state systems, and they provide counterexamples that are useful for debugging. Although theorem-proving techniques [10–12] can handle more general problems, including infinite state systems, they are not as highly automated, and the learning curve for users is steeper.

[1] A related method is called *language containment*, where the specification and DUV are represented as automata, and verification consists of checking that the language of the DUV is contained in the language of the specification.

© 2005 by CRC Press LLC

The practical application of model checking techniques is limited by the state explosion problem, that is, the state space to be searched grows exponentially with the number of state components. *Symbolic model checking* techniques [7, 8] use BDD-based methods [13] to symbolically manipulate sets of states without explicit enumeration. Although this improves scalability to some degree, these techniques can fail due to the memory explosion for BDDs. As an alternative, *Bounded model checking* techniques use SAT-based methods for finding bounded-length counterexamples [14]. These techniques scale better for finding bugs, but they need additional reasoning for obtaining conclusive proofs.

Assertion-Based Verification

Another emerging methodology is assertion-based verification. Although its basic elements have been part of industry practice for a while, it has gained attention more recently as a systematic means of enhancing the benefits of simulation and formal verification, and for combining them effectively. In particular, the Accellera organization [3] has been actively involved in developing and promoting language standards for top-down specification using a formal property language, as well as for bottom-up implementation assertions. (The chosen standards are described in the Property Specification Language, and the SystemVerilog and SystemVerilog Assertions sections. More details can be found in a recent book [15].)

The key ingredient of assertion-based verification is the formal specification of properties to capture designer intent at all levels of the design. Properties can be used as *assertions*, to check for violations of correct behavior or functionality. The checking can be done dynamically during simulation, statically using formal verification techniques, or by a combination of the two. Properties that specify interfaces between modules can also be used as *constraints,* that is, as assumptions on the input interface of a given module. For simulation, these constraints can be translated into stimulus generators, or added to the constraint-solvers for constrained random simulation. For formal verification, these constraints serve the role of an environment, which can be handled explicitly as an abstract module, or implicitly by the verification method.

Assertions and constraints are crucial in exploiting an *assume–guarantee* verification paradigm, whereby assertions (guarantees) on the output interface of a given module, serve as constraints (assumptions) on the input interface of the downstream module. (Care must be exercised in defining interfaces, in order to avoid a circular reasoning.) This allows verification of a large design to be handled modularly by verifying each of its components. Assertions and constraints also help to assess functional coverage achieved by simulation testbenches, for example how many assertions have been checked, what fraction of the constraint space has been covered, etc.

Formal Specification of Properties

Property specification languages are derived mostly from formal logics and automata theory. There are many related theoretical issues — expressiveness (i.e., what kinds of properties a logic can capture), complexity of the related property checking problem, etc. In general, the more expressive a logic, the higher the complexity of the property checking problem. There are also many practical issues — ease of use, available tool support, etc. In this section, we briefly describe some logics that form the basis of languages described in the rest of this chapter.

Propositional Logic: This is essentially the Boolean logic familiar to most hardware designers. Formulas consist of Boolean-valued variables connected using standard Boolean operators (not/and/or). The complexity of checking the satisfiability of a Boolean formula (SAT) is known to be NP-complete [16]. When both universal and existential quantifiers are added, the complexity of checking the satisfiability of a Quantified Boolean Formula (QBF) is PSPACE-complete [16]. The expressiveness of these logics is fairly limited, but they are well-suited for handling bit-level hardware designs.

First-order Predicate Logic: The expressiveness of Boolean logic is extended here by allowing variables to range over elements of an arbitrary set, not necessarily finite. This is very useful for handling higher-level systems and software, for example to reason directly about integers or real numbers. Although the problem of checking the validity of many interesting classes of formulas over these sets is undecidable, automated decision procedures exist for useful subsets of the logic [17, 18], which have been successfully utilized for

© 2005 by CRC Press LLC

verification of microprocessors, and word-level hardware designs. *Higher-order logics*, that is, where quantifiers are allowed to range over subsets of sets, have also been used, but mainly by specialists [10].

Temporal Logics: Temporal logics are used for specification of concurrent reactive systems, which are modeled as state transition systems labeled by propositions [19]. Here, the expressiveness of predicate logic is further extended, such that the interpretation of a proposition can change dynamically over the states. In addition to the standard Boolean operators, there are typically four temporal operators, with the intended semantics as shown below:

- *G p*: *p* is Globally (Always) true
- *F p*: *p* is true some time in the Future (Eventually)
- *X p*: *p* is true at the neXt instant
- *p U q*: *p* is true Until *q* becomes true

Temporal logics are ideally suited for expressing qualitative temporal behavior. The correctness properties are typically categorized as follows:

- *Safety Properties*: nothing bad happens
  for example, *G* (*!p1_critical + !p2_critical*)
  This formula expresses the mutual exclusion property that processes p1 and p2 should never be in the critical section simultaneously.
- *Liveness Properties*: something good eventually happens
  for example, *G* (*request -> F grant*)
  This captures absence of starvation, that is, every request for a resource should be eventually granted.
- *Precedence Properties*: ordering of events
  for example, *G* (*!p2_req U p1_req -> !p2_grant U p1_grant*)
  This expresses an ordering requirement, that is, if process p1 requests a resource before process p2, then it should be granted the resource earlier.

Different kinds of temporal logics have been proposed, depending upon the view of time. Linear Temporal Logic (LTL) [19] takes a linear view, where formulas are interpreted over linear sequences of states. In contrast, Computation Tree Logic (CTL) [7] takes a branching view of time, where formulas are interpreted over a tree of possible computations starting from a state (with additional path quantifiers to denote all/some paths). In terms of expressiveness, LTL and CTL are incomparable, that is, each can express a property that cannot be expressed by the other. In terms of model checking complexity, LTL is linear in the size of the model, but exponential in the size of the specification, while CTL is linear in both. Despite the relative stability of these logics, there is an ongoing debate regarding their suitability for various verification applications [20].

Regular and ω-Regular Languages: Although temporal logics are quite useful, they cannot express regular (or *ω*-regular) properties of sequences. Such properties are easily expressed as languages recognized by finite state automata on finite (infinite) words [21]. Regular expressions are formed by using three basic operations — concatenation (" . "), choice ("|"), and bounded repetition ("*"). For example, a sequence with alternation of a *request* signal with *grant* or *error* signals can be expressed as *(request .(grant | error))**. An *ω*-regular expression consists of the form $U.V^{\omega}$, where *U* and *V* are *-free regular expressions, and V^{ω} denotes an infinite repetition of expression *V*. These are used for specifying properties of systems that do not terminate.

86.3 Languages for Hardware Verification

In this section, we focus on verification languages for hardware RTL designs (system-level hardware designs are covered in Section 86.5).

HDLs and Interfaces to Programming Languages

RTL designs are typically implemented in standard HDLs — Verilog [22], VHDL [23]. However, it is not practical to implement simulation testbenches in HDLs alone. Indeed, the testbench can be purely behav-

© 2005 by CRC Press LLC

ioral, because there are no synthesizability constraints. Furthermore, it can be implemented at levels higher than RTL. Historically, a popular testbench development approach has been to implement some of its parts in a software programming language such as C/C++ or Perl. These parts are integrated with HDL simulators through standard programming language interfaces. Unfortunately, this approach not only slows down the simulator but it also requires significant development effort, such as defining new data types (e.g., 128-bit bus), handling concurrency, dynamic memory objects, etc. [5].

For property specification, VHDL has some support for static assertions, with a variety of different severity levels. Although Verilog lacks such explicit constructs, it is straightforward to use the *if* and *$display* constructs to implement a similar effect.

Example 1: Suppose we need to check that two signals *A* and *B* cannot be high at the same time. The fragment below shows an assertion template and an instance in VHDL. The keyword *assert* specifies a property that must hold during simulation.

```
[label] assert expression
  [report message]
    [severity level]
assert (A NAND B)
  report "oops: A & B cannot both be 1"
    severity 0;
```

A similar effect can be achieved by using Verilog's if/$display combination, which specifies the undesired situation, as shown below:

```
always (A or B) begin
  if (A & B) begin
    $display("oops: A = B = 1");
    $finish; // end simulation
  end
end
```

Open Verification Library

Although simple assertions are quite useful, they do not provide a practical way for specifying properties. Temporal properties can be specified using checkers or monitors in HDLs, but this involves a significant development effort. Therefore, there has been a great deal of interest in developing a library of reusable monitors. An example is the Open Verification Library (OVL), available from Accellera [3]. It is not a stand-alone language, but a set of modules that can be used to check common temporal specifications within Verilog or VHDL design descriptions.

Example 2: As an example [15], consider the following PCI Local Bus Specification: *To prevent **AD, C/BE#,** and **PAR** signals from floating during reset, the central resource may drive these lines during reset (bus parking) but only to a logic low level; they may not be driven high.*

Suppose *ad, cbe_ , par, rst_* are the Verilog signal names corresponding to *AD, C/BE#, PAR,* and *RST#* respectively.[2] The given property can be specified within a Verilog implementation of OVL as follows:

assert_always master_reset (clk, !rst_, ! |(ad ,cbe_ ,par));

Here, *assert-always* is the name of the library monitor, and *master_reset* is an assertion instance. On every rising edge of *clk* signal, whenever *!rst_* is high, the monitor asserts that the last parameter should

[2] In PCI Local Bus Specification, a signal name ending with "#" indicates that signal is active low. In the examples with HDls, we will use "_" at the end of the signal name for the same purpose.

© 2005 by CRC Press LLC

evaluate to true. Here, the last parameter is the negation (!) of the bitwise-or (|) over the given bits. Note that this is a simple safety property, which is expected to hold always during simulation.

Example 3: Consider another example [15] from the PCI Local Bus Specification: *The assertion of **IRDY#** and deassertion of **FRAME#** should occur as soon as possible after **STOP#** is asserted, preferably within one to three cycles.*

For simplicity, consider the *FRAME#* and *STOP#* signals only, that is, check whether *frame_* will be de-asserted within 1 to 3 clock cycles after *stop_* is asserted, as shown below:

assert_frame # (1,1,3) check_frame_da (clk, **true**, !stop_, frame_)

Again, *check_frame_da* is an instance of the *assert_frame* module defined in the library. Three optional parameters #(1,1,3) are used, corresponding to the "severity level," "minimum number of clocks," and "maximum number of clocks," respectively. The monitor will check whether *frame_* goes high within 1 to 3 clock cycles after *!stop_*. Here, the severity level is set to 1 to continue the simulation even if the assertion is violated, and the reset parameter is set to **true**, as an example of where it is not needed.

OVL has many advantages. First, it can be used with any Verilog, VHDL or a mixed simulator, with no need for additional verification tools. Second, it is open, that is, the library can be modified easily, for example, for assessing functional coverage [15]. Another useful feature of OVL is that it does not slow down simulation, primarily because it is hard to specify very complex assertions. Unfortunately, OVL is used mainly for checking safety properties during simulation, and is not very useful for checking liveness or for formal verification. In some sense, OVL provides a transition from a traditional simulation-based methodology, to an assertion-based methodology.

Temporal *e*

Verisity's *e* language is an advanced verification language that is intended to cover many verification aspects. Like many high-level languages, it has constructs for Object-Oriented programming, such as class definitions, inheritance, and polymorphism [5]. It also provides elements of Aspect-Oriented Programming (AOP). AOP allows modifying the functionality of the environment without duplicating or modifying the original code, in a manner more advanced than simple inheritance. (See [5, 24] for more details.)

As a testbench language, *e* provides many constructs related to stimuli generation, such as specification of input constraints and facilities for data packing, as well as for assessing simulation coverage. It also provides support for property specification, and has been used widely both in simulation-based and formal verification. There is an ongoing effort to use *e* as the basis for IEEE's new verification language [4].

Example 4: As an example for stimuli generation, suppose we have a struct-type[3] *frame* for modeling an Ethernet frame, with one of the data fields defined as *%payload*. The type of payload can be defined in *e* as follows [24]:

```
struct payload {
    %id      : byte;
    %data    : list of byte;
    keep soft data.size() in [45..1499];
}
```

In this example, the "%" character in front of the field name means that the corresponding field is physical and represents data to be sent to the DUV. The **keep soft** keywords are used for bounding the values of the variable — the size of the *data* field in this case. It also allows specification of weighted ranges or constraints. In the example, the size will be varied automatically within the given range. (Using "!" character along with "%" would have indicated that the field would not be generated automatically.)

[3] A struct type basically corresponds to a class type in C++, that is, it allows method definitions along with data definitions. Since it is conceptually similar to other Object-Oriented languages, we omit the actual syntax.

© 2005 by CRC Press LLC

Typically, a user-defined function is used for driving stimuli to the DUV. For example, suppose *my_frame* is an instance of the struct *frame*. The following *e* code can be used to input the frame data serially into the DUV:

Example 5:

```
var bitList: list of bit;
bitList = pack (packing.low, my_frame);
for each (b) in bitList{
    'testbench.duv.transmit_stream0'= b;
    wait cycle;
};
```

In this example, the keyword **pack** provides the mechanism to pack all data fields into a single list of bits, which is then fed serially to the Verilog signal *testbench.duv.transmit_stream0*. After each bit transfer, the function waits for one clock, denoted by the **wait cycle** keywords.

Support for specification of temporal properties is provided in *e* through the use of Temporal Expressions (TEs). A TE is defined as a combination of events and temporal operators. The language also supports the keyword **sync**, which is used as a point of synchronization for TEs.

Example 6: Returning back to PCI specifications, consider the following requirement, and its corresponding specification in *e*: *Once a master has asserted **IRDY#**, it cannot change **IRDY#** or **FRAME#** until the current data phase completes regardless of the state of **TRDY#**.*

```
expect @new_irdy => { [..] * ((not @irdy_rise) and (not change (frame_)));
   @ data_phase_complete } @sys.pci_clk ;
   else dut_error("Error, IRDY# or FRAME# changed before current data phase completed.") ;
```

Here, suppose that the events (shown as *@event*) have been defined already. The shown expression specifies that whenever IRDY# is asserted (*@new_irdy*), deassertion of IRDY# (*@irdy_rise*) or a change in FRAME# should not occur, until the data phase is complete (*@data_phase_complete*). The use of *@sys.pci_clk* denotes that the event *pci_clk* is used for sampling signals in evaluating the given TE. This feature is also useful for verifying multiple clocked designs.

OpenVera and OVA

OpenVera from Synopsis is another testbench language similar to *e* in terms of functionality and similar to C++ in terms of syntax. Since conceptually OpenVera is very similar to *e*, here we do not include testbench examples for OpenVera. It has similar constructs for coverage, random stimuli generation, data packing, etc.

OpenVera Assertions (OVA) is a stand-alone language, which is also part of the OpenVera suite [25]. OpenVera comes with a checker library (OVA IP) similar to OVL. OVA and OpenVera also have event definitions, repetition operators (*[..]), and sequencing, where different sequences can be combined to create more complex sequences using logical and repetition operators.

Example 7: The following example shows the OVA description of the PCI specification from Example 3:

```
clock posedge clk {
   event chk:
   if (negedge stop_) then
   #[1..3] posedge frame_;
}
assert frame_chk : check (chk)
```

Note the specification of the sampling clock, the event, and the corresponding action. The implication operation (**if–then**) is similar to conditionals in programming languages, and # is the cycle delay operator.

© 2005 by CRC Press LLC

ForSpec

ForSpec is a specification and modeling language developed at Intel [26]. The underlying temporal logic in ForSpec is FTL, which is composed of regular language operators, and LTL-style temporal operators. ForSpec is aimed at an assume–guarantee verification paradigm, which is suitable for modular verification of large designs. The language also provides explicit support for multiple clocks, reset signals, and past-time temporal operators. Although none of these additional features increases the expressiveness of the basic language, they clearly ease specification of properties in practice. Example templates for asynchronous set/reset using FTL are shown below:

`accept(`*boolean_expr* & `clock) in` *formula_expr*
`reject(`*boolean_expr* & `clock) in` *formula_expr*

Recently, some constructs of ForSpec have also been added to OVA Version 2.3.[4] In particular, the concept of "temporal formulas" is added, which can be composed of applying temporal operators on sequences. The supported temporal operators are: **followed_by**, **triggers, until**, **wuntil**, **next**, **wnext** [25, 27]. Asynchronous set/reset have also been added.

Property Specification Language (PSL)

PSL is the language standard established by Accellera for formal property specification [3]. It originated from the language Sugar, developed at IBM. The first version of Sugar was based on CTL, and was aimed at easing expression of CTL properties by users for the RuleBase model checker [28]. PSL is based on Sugar Version 2.0, where the default temporal logic is based on LTL, called PSL/Sugar Foundation Language. The main advantage of LTL in assertion-based verification is that its semantics, that is, evaluation on a single execution path, is more natural for simulation-based methods where a single path is traced at a time. Although CTL is lower in model checking complexity, it is harder to support in simulation-based methods. For formal verification, CTL continues to be supported in PSL through an Optional Branching Extension (OBE). According to the Accellera standard, PSL assertions are declarative. Since many users prefer procedural assertions, nonstandard pragma-based assertions[5] are also supported.

PSL properties consist of four layers: Boolean layer, temporal layer, verification layer, and modeling layer. The bottom-most is the Boolean layer, which specifies the Boolean expressions that are combined using operators and constructs from the upper layers. The syntax of this layer depends on the hardware modeling language used to represent the design. Currently, PSL supports both Verilog and VHDL. (Sugar also supports the internal language EDL of RuleBase.)

The temporal layer specifies the temporal properties, through the use of temporal operators and regular expression operators. The temporal operators (**eventually**, **until**, **before**, **next**) and some regular expression operators have two different types. One is called the strong suffix, indicated with an "**!**" at the end (e.g., **eventually!**), which specifies that the operator must hold before the end of the simulation. The other one, called the weak suffix (without the "**!**"), denotes that it does not hold only when the chance of it being true disappears completely. PSL/Sugar also has some predefined temporal constructs regarded as syntactic sugar, targeted at easing usage without adding expressiveness.

The verification layer specifies the role of the property for the purpose of verification. This layer supports keywords — **assert**, **assume**, **assume–guarantee**, **restrict**, **restrict–guarantee**, **cover,** and **fairness**. The keyword **assert** indicates that the property should be checked as an assertion. The keywords **assume** and **assume–guarantee** denote that the property should be used as an assumption, rather than checked as an assertion. The keywords **restrict** and **restrict–guarantee** can be used to force the design into a specified state. The keyword **cover** is used for coverage analysis, and **fairness** to specify fairness constraints for the DUV. This layer also provides support for organizing properties into modular units.

[4] Not yet supported by Synopsys at the time of this writing.

[5] These assertions escape from simulators by defining them inside comments.

© 2005 by CRC Press LLC

Finally, the modeling layer provides support for modeling the environment of the DUV, in terms of the behavior of the design inputs, and the auxiliary variables and signals required for verification.

Example 8: Going back to the same PCI specification, as shown in Examples 3 and 7, the property is written in PSL as follows:

assert always (!stop_-> **eventually!** frame_);

Note that the above specification is qualitative in terms of when the *frame_* signal should be deasserted, that is, the **eventually!** operator does not specify that it should do so within 1 to 3 cycles after *stop_* is asserted.

Example 9: Consider a property that states that a request–acknowledge sequence should be followed by exactly eight data transmissions, not necessarily consecutive. This can be expressed using a Sugar Extended Regular Expression (SERE) as follows:

always {req;ack} |=> {start_trans;data[=8];end_trans}

In addition to the number of data transmissions, the property also specifies that *start_trans* is asserted exactly one cycle after *ack* is asserted (|=>). The notation [=8] signifies a (not necessarily consecutive) repetition operator, with parameter 8. Another SERE that is equivalent to *data*[=8] is shown as follows:

{!data[*];data;!data[*]}[*8]

PSL/Sugar also allows specification of a sampling clock for each property, or to use the default clock (as shown in the previous examples). The **abort** operator can be used to specify reset-related properties, inspired by ForSpec. To support modularity and reusability, SEREs can be named and used in other SEREs or properties. (This feature is similar to events in *e* and OVA.)

Example 10: Another PCI specification states that the least significant address bit AD[0] should never be 1 during a data transfer. This can be expressed in PSL as follows [15]:

```
sequence SERE_MEM_ADDR_PHASE = {frame_; !frame_ && mem_cmd};
property PCI_VALID_MEM_BURST_ENCODING =
  always {SERE_MEM_ADDR_PHASE} |-> {!ad[0]} abort !rst_ @(posedge clk);
assert PCI_VALID_MEM_BURST_ENCODING;
```

In this example, "|->" is a weak suffix implication operator, which denotes that whenever the first sequence holds, we should expect to see the second sequence. Note the definition of the named SERE using keyword **sequence**, and its use within a property specification. The property is used as assertion, to be checked by the verification tool.

86.4 Languages for Software Verification

In this section, we focus on verification efforts for software relevant to embedded system applications. (For more general software systems and software analysis techniques, see [29, 30].) The correctness requirements are typically in the form of Floyd–Hoare style assertions [31] (invariants, pre/post conditions of actions represented in predicate logic) for functional verification, or temporal logic formulas for behavioral verification.

Programming Languages

Given the popularity of C/C++ and Java, verifying programs directly written in these languages is very attractive in principle. However, there are many challenging issues — handling of integers/floating point data variables, function/procedure calls, and object-oriented features such as classes, dynamic objects, and polymorphism.

Verification of C/C++ Programs

The VeriSoft project [32] at Lucent Technologies focused on guided search for deadlocks and violations of assertions expressed directly in C/C++, and has been used for verifying many communication protocols.

© 2005 by CRC Press LLC

The SLAM project [33] has been successfully used at Microsoft for proving the correctness of device drivers written in C. Designers use a special language called SLIC [34] to provide correctness requirements. These requirements are translated automatically into special procedures, which essentially implement automata for checking safety properties. These procedures are added to the given program, such that a bug exists if a statement labeled "error" can be reached in the modified program. Verification is performed by obtaining a finite state abstract model, performing model checking, and refining the abstract model if needed. Other similar efforts [35, 36] have so far focused largely on the abstraction and refinement techniques. There has been relatively little effort in development of a separate verification language.

Verification of Java Programs

There have been many efforts for verification of Java programs also. The Extended Static Checker for Java (ESC/Java) [37] performs static checks that go beyond type checking. It automatically generates verifications conditions for catching common programming errors (such as null dereferences, array bounds errors, etc.), and synchronization errors (race conditions, deadlocks). These conditions are transparently checked by a backend theorem-prover. It also uses a simple annotation language for the user to provide object invariants and requirements, which aid the theorem-prover. The annotation language, called Java Modeling Language (JML), is part of a broader effort [38]. JML is used to specify the behavior and syntactic interfaces in Java programs, through pre/post conditions and invariants for classes and methods. Its syntax is quite close to that of Java, thereby making it easy to learn by programmers. JML is used by a host of verification tools, which span the spectrum from dynamic run-time assertion checkers and unit testers, to static theorem-provers and invariant generators. It has been applied successfully in smartcard applications implemented using a dialect of Java called Java Card [39].

Example 11: Consider the following code [37], which shows Java code for a class definition of integer multisets.

```
1     class Bag {
2     //@invariant 0<=size && size <=elements.length
3        int size;
4        int[] elements;
5        // @requires input != null
6        Bag(int[] input) {
7        …
8        }
9         int extractMin( ) {
10        …
11        }
12    }
```

As shown, the *bag* class provides two operations (details are not shown) — one for constructing a bag from an array of integers, and another for extracting the smallest element. The example also shows user annotations on Lines 2 and 5, to be used with ESC/Java. The annotation on Line 2 specifies an object invariant, which should hold for every initialized instance of the class. The annotation on Line 5 specifies a pre-condition, which is assumed to hold by the operation that follows.

Model checking techniques have also been used successfully for Java programs. Bandera [40] and Java PathFinder (JPF) [41] use various program analysis methods and abstractions to obtain a finite state model of the given program. This model is verified against temporal specifications provided by the user. In many cases, model checking is performed by translation of the (abstract) Java program into Promela, the input language of the model checker SPIN [9]. Promela focuses on system descriptions of asynchronous concurrent processes, and the correctness properties are specified in LTL. SPIN has been used successfully to verify the correctness of numerous protocols, distributed algorithms, controllers for reactive systems, etc.

© 2005 by CRC Press LLC

The Bandera project has also focused on development of the Bandera Specification Language (BSL) [42]. BSL provides support for defining general assertions, pre/post conditions on methods, and atomic predicates for specifying temporal properties. There has also been related work [43] on developing a pattern-based approach for specifying complicated temporal properties, and translating them into input for model checking tools.

Software Modeling Languages

The Unified Modeling Language (UML) [44] is emerging as a popular standard for designing object-oriented software systems. There has been recent interest in its use for specification and modeling of real-time and embedded systems also [45, 46]. It provides different kinds of diagrams to specify the system structural and behavioral aspects, including Statecharts [47] and Message Sequence Charts [48, 49]. A language called Object Constraint Language (OCL) [50] has been developed as part of UML, for specifying requirements such as invariants, and pre/post conditions on operations in class diagrams. Tools for simulation of UML models, and for automatic code generation from UML into C/C++ programs, have become popular for embedded software development in automotive and avionics applications. However, formal verification efforts have been hindered by a lack of a precise formal semantics for UML and OCL, which are still under development.

The Specification and Description Language (SDL) [51] is another popular standard, especially targeted for communication systems. It provides both graphical and textual syntax, for specifying systems at different levels of hierarchy. Tool support for SDL is widely available, especially for automatic code generation to C, C++, and Java. Verification is supported by methods based on Message Sequence Charts, as well as model checking [52].

Another set of efforts is based on the use of declarative specification languages such as Z [53], and more recently Alloy [54]. Their main drawback is that there is little support for automatic extraction of such models from existing programs, or for automatic generation of programs from these models. Furthermore, Z is not very amenable to automatic analysis. However, Alloy does provide automated verification support, and has been used for some embedded applications. It uses a set-based syntax for expressing formulas in first-order relational logic. The analysis tool attempts to find a finite scope model that satisfies all given constraints, by translation to a Boolean SAT problem.

86.5 Languages for SoCs and Embedded Systems Verification

In this section, we describe verification languages for SoCs and embedded systems. We start by describing system-level modeling languages that have been heavily influenced by existing HDLs. Next, we describe verification support for domain-specific languages, such as Esterel, and efforts in the area of hybrid systems.

System-Level Modeling Languages

As systems become increasingly complex, it becomes useful to specify designs at higher levels of abstraction. This allows early design exploration for optimizing system requirements such as performance, power consumption, chip area, etc. Many system-level modeling languages focus on hardware–software partitioning issues, and development of system-level verification platforms.

SystemC and SystemC Verification Library

SystemC is a C++-based modeling platform, which supports hardware module abstractions at RTL, behavioral, and system levels, as well as software modules. Both the DUV and the testbench are written in the SystemC language. The platform provides a class library and a simulation kernel.

The SystemC Verification Library adds features for transaction-based testbench development. A typical example [55] is shown in Figure 86.1, where a transactor bridging the gap between the testbench and the DUV is shown in the setting of the SystemC class library. A technique called *data introspection*, which uses

© 2005 by CRC Press LLC

C++ template specialization to attach a standard interface to arbitrary data types, is exploited to allow arbitrary data types to be used in constraints, assertions, transaction recording, and other high-level activities. Randomization of data generation for arbitrary data types is supported by defining a distribution through Boolean constraints and probability weights. The verification library also provides a callback mechanism to observe activities at transaction level during simulation, and a minimal set of HDL connection APIs, to permit interfacing with VHDL or Verilog. So far, there has not been much effort to add support for formal specification of properties within SystemC, although the standards can be potentially supported.

SpecC

SpecC is an executable modeling language based on C, targeted for hardware–software codesign [56]. The SpecC methodology advocates a clear separation between communication and computation in system-level designs. It provides support for creating an executable behavioral specification, design exploration including hardware–software partitioning, communication synthesis, and automatic generation of the software as well as hardware components. A significant effort has been made in providing a clean formal semantics, and in development of an associated simulation kernel. However, so far, there has not been much effort focused on its use in property specification or formal verification.

SystemVerilog and SystemVerilog Assertions

SystemVerilog is an extension of the Verilog hardware description language, with the latest version SystemVerilog 3.1 standardized by Accellera [57]. It adds many system-level modeling and verification capabilities to the older Verilog (IEEE Standard 1364). It also provides a Direct Programming Interface, which allows C functions to be called from Verilog code and vice versa.

For transaction-level testbench development, SystemVerilog has incorporated many features from C/C++ such as structures, pointers, classes, and inheritance. It also provides support for multiple threads, events, and semaphores for interprocess synchronization, mailboxes for interprocess communication, and random number classes to help generate random test vectors for simulation.

SystemVerilog also provides support for an assertion-based verification methodology, using the SystemVerilog Assertions (SVA) language, described below. The SystemVerilog standard has enhanced the scheduling scheme of Verilog, by defining new scheduling phases in which to sample stable signals, to evaluate the assertions, and to execute testbench code. This scheduling scheme avoids races between the DUV and testbench, guarantees that assertions and testbenches see stable values, and ensures common semantics across the simulation, verification, synthesis, and emulation tools.

SVA: SVA combines many ideas from the languages described in Section 86.3. Indeed, most examples described there have equivalent expressions in SVA. Properties in SVA are specified in terms of signal sequences, each of which is associated with a clock for sampling signals. Sequences are first-class objects

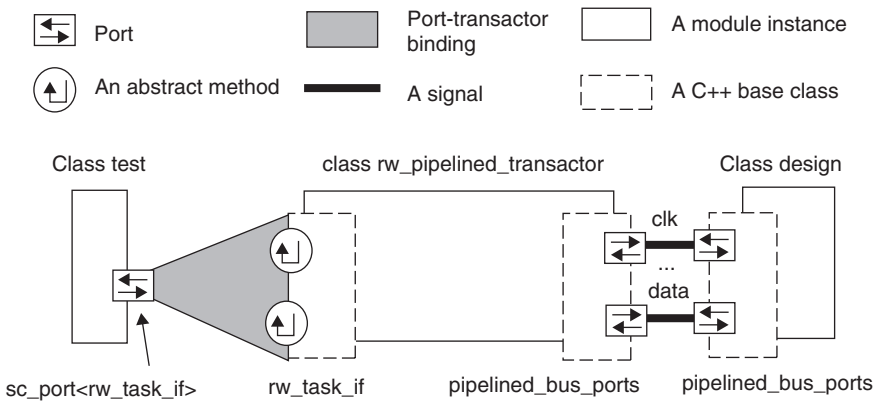

FIGURE 86.1 Transaction-level testbench in SystemC [55].

© 2005 by CRC Press LLC

and can be declared, parameterized, or combined to build other sequences. It also provides limited support for combining sequences with multiple clocks.

Example 12: The following example defines a request–acknowledge sequence called *req_ack* [15]. It is defined in terms of parameter signals, and can be reused in multiple properties. The notation ##[1:3] indicates 1 to 3 cycles of the associated clock.

```
sequence req_ack (req, del, ack) ;
  // ack occurs within 1 to 3 cycles after req
  (req ##[1:3] ack);
endsequence
```

SVA also allows dynamic local variables to be declared within a sequence, which remain valid during the current invocation of the sequence. These can be used to check regular properties.

Example 13: Consider the following sequence which captures the I/O behavior of a pipeline register with depth 16 [15].

```
sequence pipe_operation;
  int x;
  (write_en, (x = data_in) ) |-> ##16 (data_out == x);
endsequence
```

Note that the input value is saved in the local variable *x* at the beginning of the sequence, which is compared with the value of *data_out* after 16 cycles. (Here, |-> denotes an implication operator that matches the end of the previous subsequence with the beginning of the next.)

Different directives act on properties to indicate their role — *assert* (check for violations), *cover* (observe and track when property is exercised), and *bind* (attaches an externally specified assertion to the code). Assertions are classified as immediate or concurrent. The immediate assertions are like assert statements in an imperative programming language such as C/C++. They are executed immediately when encountered in the SystemVerilog code, while following its event-based simulation semantics. On the other hand, concurrent assertions usually describe behavior that spans time. These are executed in the special scheduling phase using sampled values. In both cases, the action taken after evaluating an assertion may include system tasks to control severity like '$error,' '$fatal,' '$warning,' and '$info' [15]. Immediate assertions can be either declarative or procedural. Declarative assertions require enabling conditions to be explicitly provided by the user, which are monitored continuously on clock edges. In the case of procedural assertions, the enabling conditions are automatically inferred from the code context. This makes the procedural assertions easier to maintain when the code changes.

Example 14: Consider a simple paramaterized property declaration, and its use as a concurrent assertion [15]:

```
property mutex (clk, reset_n, a, b);
  @(posedge clk) disable iff (reset_n) (! (a & b ))
endproperty
assert_mutex: assert property(mutex (clk_a, master_reset_n, write_en, read_en));
```

The **disable iff** clause in the mutex property indicates that the property is disabled, that is, treated as if it holds, when the *reset_n* signal is active. The assertion checks that *write_en* and *read_en* cannot occur at the same time, provided *master_reset_n* is not active.

Domain-Specific System Languages

In this section, we describe some domain-specific languages for embedded system applications, and highlight the support they provide for verification. Unlike the system-level languages influenced by HDLs, there has been relatively little standardization effort aimed at their verification features.

© 2005 by CRC Press LLC

Esterel

Esterel is a programming language used for the design of synchronous reactive systems [58]. The language provides features for describing the control aspects of parallel compositions of multiple processes, including elaborate clocking and exception-handling mechanisms. Typically, the control part of a reactive application is written in Esterel, which is combined with a functional part written in C. Esterel has a well-defined semantics, which is used by the associated compilers to automatically generate sequential C code for software modules, or Boolean gate-level netlists implementing finite state machines for hardware modules. Standard simulation or model checking can be performed on the synthesized finite state machines.

A central assumption in Esterel and other synchronous languages is the *synchrony hypothesis,* which assumes that a process can react infinitely fast to its environment. In practice, it is important to validate this assumption for the target machine. The tool TAXYS [59] checks this assumption by modeling the Esterel application and its environment as a real-time system. Two kinds of real-time constraints are specified as annotations in Esterel code — throughput constraints (which express the requirements that a system react fast enough for the given environment model), and deadline constraints (which express maximum delay between a given input and output of a system). These constraints are checked by Kronos [60], a model checker for real-time systems.

Example 15: An example of annotated application code [59] in Esterel with deadline constraints is shown below:

```
1     loop
2        await A; %{# Y = clock(last A) %}
3        call F( ); %{# Fmin < CPU < Fmax %}
4        %{# 0 < clock(last A) < d1 %}
5     end loop
6     ||
7     loop
8        await B;
9        call G( ); %{# Gmin < CPU < Gmax %}
10       %{# 0 < Y < d2 %}
11    end loop
```

In this example, it is required that the function *F* must terminate within *d1* time units after arrival of event *A*, and also that the function *G* must terminate within *d2* time units after the arrival of event *A,* which was consumed by *F*. These constraints are specified as shown in lines 4 and 10 (with line 2), respectively. Also note that the estimated runtimes for functions *F* and *G* are provided in lines 3 and 9, respectively.

Languages for Hybrid Systems

Many embedded system applications require an interaction of digital and analog components, for example automotive controllers, avionics systems, robotic systems, manufacturing plant controllers, etc. Since many such applications are also safety-critical, there has been a great deal of interest in the verification of such systems, called hybrid systems. The verification efforts can be broadly classified into those using classical control-theoretic methods, and others using automata-based methods.

A popular paradigm for control-theoretic methods is the MATLAB-based toolset, with the Simulink/Stateflow modeling language [61]. It provides standard control engineering components to model the continuous domain, and a Statechart-like language to model the discrete controller. MATLAB-based tools are used for analysis, optimization, and simulation of the continuous behavior specified in terms of differential equations. These tools have been used very successfully for applications dominated by continuous dynamics. However, complex interaction between the continuous and discrete control components has not received much attention. Furthermore, the simulation semantics has not been related to a formal semantics in any standard way.

© 2005 by CRC Press LLC

The automata-based methods typically use discrete abstractions of the hybrid system in a way that preserves the properties of interest, typically expressed in temporal logic [62]. Many model checkers for handling these abstractions have been applied in industry settings, for example Hytech [63], Uppaal [64], Kronos [60], and Charon [65]. The details of the discrete abstractions, and the resulting automata models, are beyond the scope of this chapter. In most cases, the correctness requirement is to avoid a set of "bad" states, typically specified using the syntax of the modeling language itself. The model checkers perform an exact (or approximate) reachability analysis to (conservatively) check that all reachable states are safe. There has also been work on translating subsets of the popular Simulink/Stateflow-based models to the formal automata-based models, using abstraction and model checking techniques [66, 67].

Recently, there has been some standardization effort in this domain — the Hybrid Systems Interchange Format (HSIF) standard [68] is aimed at defining an interchange format for hybrid system models, which can be shared between modeling and analysis tools. So far, the focus has been on representation of the system dynamics, which include both continuous and discrete behaviors. Support for verification-related features will potentially follow its wider adoption.

86.6 Conclusions

We have presented a tutorial on verification languages in industry practice for verification of embedded systems and SoCs. We have described features that aid development of testbenches and specification of correctness properties to be used by simulation-based as well as formal verification methods. With verification becoming a critical activity in the design cycle of such systems today, these languages are receiving considerable attention, and there are several standardization efforts under way.

87.1 Introduction

In modern complex Systems-on-Chip (SoC), software (SW) as an integral part of the SoC is gaining more and more importance. With increasing SoC complexity, SoC designers are facing an increasing complexity in the system's architecture other than the hardwre (HW) issues alone. The intricacy of the software needed to run on such devices is increasing tremendously as well.

Obviously, the challenges regarding design flow, design automation, and verification cannot be solved looking to the HW aspects of the design alone.

There is a large need for SoC designers to understand both their classical – the HW – world, and the world of Embedded Software as well. Particular attention needs to be paid on questions like

- How to deal with IP reuse that is composed of HW and SW.

© 2005 by CRC Press LLC

- How does SW affect the SoC design flow.
- How to enable portability across HW platforms, different application domains, and so forth.

This chapter introduces Embedded Software for SoC and EDA designers, and tries to raise their awareness on SW issues they might be directly impacted by. However, both classical HW designers and Embedded Software designers have a lot to teach each other; therefore, mutual understanding is crucial for solving the SoC design challenges.

In the last part of this chapter, the concept of Hardware-dependent Software (HdS) is introduced, and how HdS can help to solve some of the issues mentioned before in this chapter.

This chapter is derived from a tutorial paper [1], which has been given by Steven Olsen from Mentor Graphics, and by the author during CICC 2003 in San Jose.

87.2 Embedded Software and its Challenge for ASIC/Custom/SoC Designers

Increasing SoC Complexity

As stated in [2], the semiconductor industry continues to follow Moore's Law, doubling the complexity of ICs every 18 months, to the point where they will soon be able to manufacture chips with 100 million gates. Entire systems can fit in always less area; hence, just as the hardware design industry has begun to accept the need for design reuse as a way to manage their exorbitantly increasing design costs, the problem is changing in them.

Now that whole systems can be put on a single piece of silicon, IC design is as much an SW design issue as it was an HW design problem before. The typical SoC design today has two or more processors, memory, dedicated subsystems specific to the application, and a complex, sometimes hierarchical communications system between them. As such, these chips contain multiprocessor real-time operating systems (RTOS), complete with I/O drivers, utilities, and diagnostic subsystems along with their specific SW applications. The exploding complexity of SW in these new SoC designs has already resulted in the SW design costs exceeding the HW design costs for some of the more complex designs.

Looking at this total complexity increase, the question now is how to manage the SoC design costs, not how to manage just the SoC HW design costs. Answering this question is virtually impossible without a deep understanding of what Embedded Software in the world of SoC actually means, what SoC SW design costs are, and how an Embedded Software design flow really works.

For the HW design and reuse challenge, in the past there have been several quite successful attempts to overcome Moore's law by standardization efforts. Thus, the Virtual Socket Interface Alliance (VSIA) [3] defined the concept of Virtual components (VCs) with rules on how to specify their interfaces and characteristics, in order to promote IP reuse on HW level. For Embedded Software, standardization efforts are just starting. There is an initiative in VSIA currently working on HdS standardization (see Section 87.4 of this chapter), and there have been some attempts to standardize driver interfaces on OS level by the Unified Driver Interface (UDI) project [4].

Changing the SoC Design Paradigm

What does the classical SoC design process look like?

To design complex chips, architects start with a high-level concept, which they translate into a high- level functional model. This model reflects the basic functions of their system but contains no distinction between the SW and HW. In the process of defining the appropriate HW architecture for the design, they must separate out which parts of the functions belong in HW and which parts belong in SW. This is typically done by reorganizing the functional model into its HW and SW components, along with a model of the communication between them. This has been done, and probably will continue to be done, by a few high-level architects.

© 2005 by CRC Press LLC

The process of translating a cycle-accurate architectural model down to the actual silicon design is well understood and practiced, with sufficient design reuse and existing HW design techniques.

Likewise, there are no issues with translating the partitioned functional SW components into code for the finished working SoC.

What remains an issue, however, is the efficient HW/SW interface design and implementation. This is now becoming one of the most significant and growing efforts in SoC design.

It is clear that efficient HW/SW interface design is not possible without sufficient understanding of the other world's architectural principles, methods, and tools.

What does efficient interface design mean in this context?

First, those interfaces need to allow HW and SW designers to design their parts as independently as possible from each other, just to be able to parallelize their design processes.

Second, those interfaces need to be standardized. With the everincreasing number of HW architectures on the market, SW adaptations to any one of them become much too expensive. Ideally, some standard APIs could help to retain portability across different HW platforms.

Third, the way these interfaces are designed, as well as how the SoC overall design process is followed, needs to take into account, besides the "classical" HW design flow, the way in which modern embedded SW development works.

All this leads to a change in the SoC design paradigm that becomes much more SW centric than so far.

Validation and Verification Challenge

As we look at the overall SoC development costs, the SW/HW design ratio exceeds 2-to-1. While the development of the HW and the SW parts could easily be done in parallel, a greater effort must be spent to verify and validate the complete SoC. Meanwhile, verification and validation costs constitute up to 60% of overall SoC design costs.

Understanding how SW works and how it interacts with the HW can greatly reduce the overall verification complexity, and hence the cost.

Currently, verification and validation of the SoC largely rely on HW test benches to test the HW with the help of some deeply Embedded Software inside the SoC present to test the more complex internals of the SoC.

There needs to be a methodology that will allow system designers to model the core components irrespective of their HW or SW domain.

Some considerations based on SystemC as modeling language attempt to close this gap.

Another way to reduce complex SoC verification and validation costs is to reuse as much as possible prequalified IP blocks, and to define rules for their integration into the entire system. Here again, the right understanding of the HW–SW interface is key for lowering the overall system validation effort.

87.3 Embedded Software, Concepts, Methods, Tools

What is an Embedded System, What is Embedded SW?

For definitions used here, see [7].

Before talking about Embedded Software, it is necessary to understand what **embedded systems** are. Unlike general-purpose systems, like personal computers, embedded systems are **dedicated systems**. They serve a well-defined purpose, and usually all resources in the system are dimensioned according to their purpose.

Embedded systems typically interact with physical processes, be it via sensors, actuators, etc. Unlike general-purpose systems, critical properties of embedded systems tend to be nonfunctional: real-time, fault recovery, power, security, or robustness. They typically have to interact concurrently with multiple processes, and need to operate at the speed of their environment.

Simplistically speaking, **Embedded Software** is SW designed for and running on embedded systems. Since many of the properties mentioned before are actually implemented in HW, one of the most

© 2005 by CRC Press LLC

important properties of Embedded Software is its close link to HW. The close link is demonstrated not only by compiling for the direct HW dependence but also through intimate knowledge of the HW specifics (for instance, register and interrupt structures, bit orders, and so forth). Some of the properties mentioned above are increasingly implemented in SW, or directly influence the way Embedded Software is written. The classical example is real-time.

RTOS play an important role in Embedded Software. Besides serving as a layer on top of which parts of the Embedded Software can be implemented relatively independent of the actual HW platform, the RTOS also provides a framework to plug HW drivers.

Embedded Software itself can be structured into different SW layers:

- HdS (for details, see Section 87.4 of this chapter).
- HW-independent middleware or application software, which run on top of the HdS.
- The RTOS as a vertical "layer," which offers services that span both hardware-dependent and -independent parts that may be used by all the other Embedded Software layers. For details on real-time and RTOS, see [3.3.1.].

HW Related Trade-offs in Embedded SW

What are the specific challenges in designing Embedded Software — in particular HdS — in comparison with HW design on one hand, and classical application SW design on the other?

The HdS layer must expose HW internal features in a way that releases developers of higher layer SW from requiring too much processor-specific knowledge. Ideally, the SoC functionality should be exposed in a way, which completely hides the details of the underlying HW platform and its evolution. The best way to do so is via a functional API, the so-called HdS-API. For details, see Sectoin 87.4.

While application SW is reusable and portable per se via its large independence from actual HW platforms, Embedded Software (ESW) must be structured in such a way as to achieve portability or reuse. Highly optimized DSP algorithms, for instance, take full advantage of each HW feature. However, for this kind of SW, reuse methodologies are rather difficult to apply.

The specific properties of ESW impact its design methodology. Hence, the imminent HW dependency implies close coupling of ESW design with HW design. Early alignment on hardware features/interfaces is crucial for the design of the HdS parts of ESW. However, each HW change basically implies a modification in parts of the ESW (e.g., drivers or access functions). Conversely, stable HdS-APIs are crucial for starting application software design. ESW design principles have to deal with this problem.

Designing ESW means interfacing very different roles in the systems design process:

- *System designers*, for HW–SW partitioning.
- *HW engineers*: Concurrent development of drivers, load, and boot. Provision of HW test SW. Deep understanding of HW specifics.
- *SW engineers*: Provision of the HdS APIs. Sharing SW technology, methodology, tools. With respect to architecture, ESW needs to meet some specific requirements:
- *Portability*: HW-dependent parts are by definition not portable, but are intended to enable portability for higher layer SW.
- *Real-time*: Typical SW interprocess communication mechanisms like Common Object Request Broker Architecture (CORBA, an object-oriented communication mechanism that provides full location transparency) usually cannot be applied for real-time reasons. Often, ESW has to meet hard real-time requirements.

Parts of the ESW implement themselves RTOS-like services. Often, the implementation of ESW depends directly on the RTOS choice (message passing mechanism and memory management).

In summary, these are the most important differences between application SW and ESW, which are related to HW:

- Specific HW requirements: timing, (hard) real-time, performance of HW access functions, direct HW architecture dependence.

© 2005 by CRC Press LLC

- Mixed top-down and bottom-up development of ESW.
- Complex synchronization in overall product development process.

ESW often needs to run with instable HW, or no target HW at all available.

For high-level SW or middleware in many application domains, there are a large number of standards or quasistandards defined. Examples are CORBA for interprocess communication, high-level specification languages like Unified Modeling Language (UML), Specification and Description Language (SDL), or programming languages like ADA, or telecommunication protocols standardized by ITU.

In the embedded world, standardization is only starting. Examples are Portable Operating System Interface (POSIX) for operating system interfaces, or some work that is currently done in VSIA.

Basic Concepts in ESW

RTOS

What is real-time? The following answers on this question are heavily influenced by a tutorial given by Krithi Ramamrithan on DAC 2002 [5].

Embedded systems usually have to deal with events in the environment they are designed for. The system has to follow the real speed of the environment. Otherwise, damages, even loss of human life, might be the consequence. Meeting deadlines that are determined by the environment, means "**real-time**." Real-time does not necessarily mean "fast." However, real-time has to face the problem of the potentially changing "speed" of the environment.

Generally speaking, **real-time systems** are systems that react to events in the environment by performing predefined actions within specified time intervals.

Note that not all embedded systems are real-time.

The most important properties of real-time (RT) systems are:

- *Safety*: Nothing bad will happen
- *Liveness*: Something good will happen.
- *Timeliness*: Things will happen on time — by their deadlines, or periodically.

Different types of RT systems according to these questions:

- How *tight* are the deadlines?
- How *strict* are the deadlines?
- What are the *characteristics of the environment*; how static or dynamic must the system be?

According to these questions, the following types of RT systems can be distinguished:

- *Hard RT*: The results are useless or dangerous, if the deadline is not met.
- *Soft RT*: The results are of some lower value, if the deadline is exceeded.
- *Firm RT*: If the value drops to zero at the deadline.

Real-time behavior is mainly achieved by corresponding scheduling strategies. Examples are

- Strict table-driven approaches:
  - Perform static schedulability analysis by checking if a schedule is derivable.
  - The resulting scheduling table identifies the start times of each task.
  - This approach is applicable to periodic tasks.
- Static priority-driven preemptive approaches:
  - Tasks have, systematically assigned, static priorities.
  - Priorities take timing constraints into account.
  - Perform static schedulability analysis but no explicit schedule is constructed.
  - At runtime, tasks are executed highest-priority first, with preemptive-resume policy.

© 2005 by CRC Press LLC

- Dynamic planning-based approaches:
  - Feasibility is checked at runtime — a dynamically arriving task is accepted only if it is feasible to meet its deadline.
  - One of the results of the feasibility analysis is a schedule or plan that determines start times.
- Dynamic best-effort approaches:
  - The system tries to do its best to meet the deadlines.
  - But since no guarantees are provided, a task may be aborted during its execution.
  - Until the deadline arrives, or until the task finishes, whichever comes first, one does not know if a timing constraint will be met.

RTOS support process management and synchronization, memory management, interprocess communications, and I/O.

There are several categories of RTOS:

- Small, proprietary kernels (e.g. VRTX32, QNX Neutrino, pSOS, VxWorks).
- Real-time extensions to commercial/noncommercial timesharing operating systems, for example, RT-Linux
- Research kernels (e.g., MARS, ARTS).

Many general-purpose operating systems like Windows NT can be seen as, or easily be transformed to, soft real-time OS.

ESW Development and Tools

Many of the development tools known from the general-purpose SW world are applied for ESW as well.

However, the intimate relation of ESW and the underlying HW platform ask for some specific tools, especially in the domains of

- Host and target compilation
- Target debugging
- Hardware testing and bringup.

Many processor platforms provide their dedicated development tools. An example is ARM's ADS (ARM Developer Suite). RTOS providers often offer development suites around their flagship OS. Examples are WindRiver's Tornado, or GreenHills' Multi2000.

The ESW development process has to take its specific dependencies on the HW and SW development cycles into account. The specification of APIs must be a condition for starting the application SW design. On the other hand, the ESW design cannot be finished before the final HW prototype availability. Many techniques to decouple HW and ESW development are currently in investigation, or available in first products. Most of these techniques try to provide early HW models, which are on an interface level identical to the later prototype.

In general, the ESW process follows classical SW development paradigms. Usually, all of the phases, like specification, top-level design, detailed design, implementation, unit test, integration and integration test, and system qualification and acceptance test can be found as well. However, integration and integration test here mean mainly integration with the HW platform.

By its nature, ESW design deals with HW specific tools, like instruction set simulators, hardware simulators and emulators, and distributed debuggers.

UML-Based Design and Development of ESW

For an excellent introduction into UML for embedded systems designers, see [6].

Formal SW design methods have been in place for many years in application SW. The object-oriented paradigm in analysis, design, and programming led to a broad adoption of UML as a quasistandard in recent years.

With the increasing use of the Object-orientation paradigm for ESW as well, UML-based formal design methods have also been applied in this domain.

© 2005 by CRC Press LLC

What is **UML**? UML stands for "Unified Modeling Language." It intends to handle SW models. **Software models** in this sense are descriptions of the SW of a system that abstracts out irrelevant details, such as certain aspects of technology or implementation, so that we can more easily reason about the system itself.

Models allow for human communication, for formal analysis by mathematical methods, and for experimenting.

The usage of models in SW is steadily increasing. This way SW engineering gets closer to classical engineering disciplines. Based on executable models, automatic code generation becomes possible.

UML is based on the concept of the **object**. The idea is that all various features (procedures, data) of a logical unit are combined into one single package called an object. An SW system is defined as a structure of collaborating objects. More than one object can be constructed from the same definition — the **class**.

UML consists of:

- A basic set of (extensible) modeling concepts
- Formal rules of semantically meaningful composition (well-formedness)
- Graphical notation for modeling concepts.
- Different diagram types for different aspects (views) of the target system.

There are eight different diagram types (requirements, structure, behavior, and deployment).
There are several **UML model views**:

- Requirements (use case diagrams)
- Static structure (class diagrams) → kind of objects and their relationships
- Object behavior (state machines) → possible life histories of an object
- Interobject behavior (activity, sequence, and collaboration diagrams) → flow and control among objects to achieve system-level behavior.

Physical implementation structures (component and deployment diagrams) → SW modules and deployment on physical nodes.

In application SW development, UML is meanwhile widely used for

- Requirements management
- Stepwise design refinement
- Code generation.

UML as a standard is a basis for a family of languages, for example Real-time UML, or UML for eCommerce.

It allows defining **UML profiles**. Profiles are packages of related specializations of general UML concepts that capture domain-specific variations and usage patterns. In this sense, UML profiles are domain-specific interpretations of UML.

For using UML in real-time systems, some standard models have been defined, which cover

- Physical time
- Timing specifications
- Timing services and mechanisms
- Concurrency and scheduling
- SW and HW infrastructure and their mapping.

A **Real-Time Profile** needs to

- Be able to specify quantitative information directly in UML models.
- Be flexible: users need to model their RT systems using modeling approaches and styles of their own choice.
- Facilitate the use of analysis methods. As much as possible, the generation of analysis models and of the analysis process itself needs to be automated.

RT profiles are included in UML 2.0, which has been standardized in 2003.

© 2005 by CRC Press LLC

Using RT profiles in UML 2.0, SW performance engineering becomes possible. That is, "A systematic, quantitative approach to constructing software systems that meet performance objectives" (Connie Smith and Lloyd Williams).

87.4 Hardware dependent Software (HdS). Closing the Gap between HW and SW Design

As seen in the HW Related Trade-offs in Embedded SW section, an SoC can be regarded as an API to embedded SW developers. Hence, the SoC should have an abstraction layer, which exposes its functionality. We call it Hardware Abstraction Layer (HAL). The HAL might even enhance the SoC's capabilities. At the same time, it hides HW details that are irrelevant for upper-layer SW implementations. A typical example is an RTOS Board Support Package (BSP). It hides the processor internal timer and interrupt dispatching, but adds multitasking and timer functions.

Thus, it is useful to develop a standard abstraction for the SW that "sits directly on top" of the HW. This kind of SW is called **Hardware dependent Software (HdS).**

What is HdS?

Under HdS, we understand that all SW that is directly dependent on the underlying HW platform. Examples are:

- HW drivers
- Boot strategy, load
- Built-in tests (basic level, off-line tests)
- HW-dependent parts of communication Stacks
- Algorithms implemented in SW on DSP.

The main purpose of HdS is to shield the HW for upper-layer application SW. Ideally, this SW communicates with the HW platform via stable APIs only. Another core motivation to define HdS is retaining portability across various simulation and target environments.

The introduction of HdS allows decoupling of HW and SW design. With HdS, a portability layer is defined, which:

- Offers stable API toward SW, enables platform transparency (prototype, emulator, simulator).
- Translates SW application and RTOS requirements to HW resource accesses.

HdS Seen from Different Perspectives

HdS can be regarded from different perspectives. For details, see the HdS taxonomy axes that are defined in VSIA's HdS taxonomy document [5], which are in the process of being published.

1. **Life Cycle View**
   As already discussed in the HW Related Trade-offs in Embedded SW section, the HdS design flow is tightly coupled to an HW (ASIC, FPGA, component) design flow. Examples are: OS simulators, ISS models of processors, HW emulation, and fast prototypes (FPGA based HW models).
   HdS is developed and used in
   - HW development, bringup, and test
   - HW production (manufacturing)
   - SoC in final product (drivers, boot&load, On-line and off-line diagnostics).

   HdS is one basis for SW development — it provides SW APIs.

2. **Run-time and Real-time View.**
   HdS implements services like Boot, Configure, Execute, Reload, Target monitor,…

© 2005 by CRC Press LLC

With respect to real-time behavior, the HdS implementation takes scheduling models and timing characteristics into account.

Any HdS design has to incorporate communication mechanisms, for example address mapped, packet based, message based,… ones.

3. **HW architecture View**

   The HW platform defines a certain SW architecture. The HW architecture typically consists of a CPU subsystem (i.e., registers, address space, cache, interrupts), the memory subsystem, and the I/O subsystem.

   Multiprocessor architectures cause HdS to implement specific communication mechanisms. HdS cares for processor topology transparency toward application SW.

4. **SW Layering View**

   The HAL as part of HdS contains several hierarchical HW shielding levels:

   a. Access shielding
   b. Register shielding
   c. Functional shielding.

   HdS as an SW layer embeds into a general architectural model that is characterized by different abstraction levels, like Hardware layer, Primitive function layer, and Interface access layer, OS layer, and Application layer.

Standardization in SoC-based Embedded Systems

From an architectural point of view, ESW and HdS can be seen as SW layers on top of physical HW.

The following figure provides a view on HAL as part of HdS, and its relation to HW layer, OS layer, and application SW layer.

The layers introduced in the HdS seen from Different Perspectives section, can be mapped onto HW Space (the HW layer), Kernel space (the Primitive Function layer, the Interface Access Layer, and the OS Layer), and a User space (the application layer).

While the interface between Kernel space and User space is going to be standardized via the POSIX interface, VSIA has defined the OCB VCI interface for standardizing HW communication interfaces.

POSIX [8] is an RTOS interface standard toward middleware and application SW (IEEE standard P1003.1). It contains a minimal set of common OS commands, and was developed for UNIX. Currently, an extension toward real-time is under research. POSIX provides a portability interface toward SW.

VSIA's **On Chip Bus (OCB) VCI** was created to make HW IP more portable with a common bus interface. It includes a modeling language consisting of I/O operations at the transaction level (with read, write, open, close) to manage various types of multipacket transactions. OCB VCI provides a standardized IP block interface toward HW (Figure 87.1).

Inside the Kernel space, those parts that are directly dependent on HW register maps and HW interrupt structures can be separated from functional parts such as device driver logic, offline test segments, generic boot, and loads. This separation is done via a new HdS-API.

All parts below the HdS-API (the HAL, BSPs,) carry HW platform-specific information, and can partially be derived from the physical HW structure in terms of register maps.

The Kernel space parts above the HdS-API implement functional logic, and are independent of implementation details of the underlying HW platform.

Gaps in the SoC Design Flow. How A Standardized HdS-API could Help

Without any standard APIs between the OCB VCI and the POSIX, the entire kernel space SW (HdS + RTOS) depends on any HW modification. HW register structure changes need to be implemented in HdS, and in the RTOS' BSP, correspondingly.

After partitioning of high-level functional models into HW and SW IP blocks, they can be connected with a VCI-like interface on the HW side. Translation from the VCI transaction language to a specific VCI protocol is possible.

© 2005 by CRC Press LLC

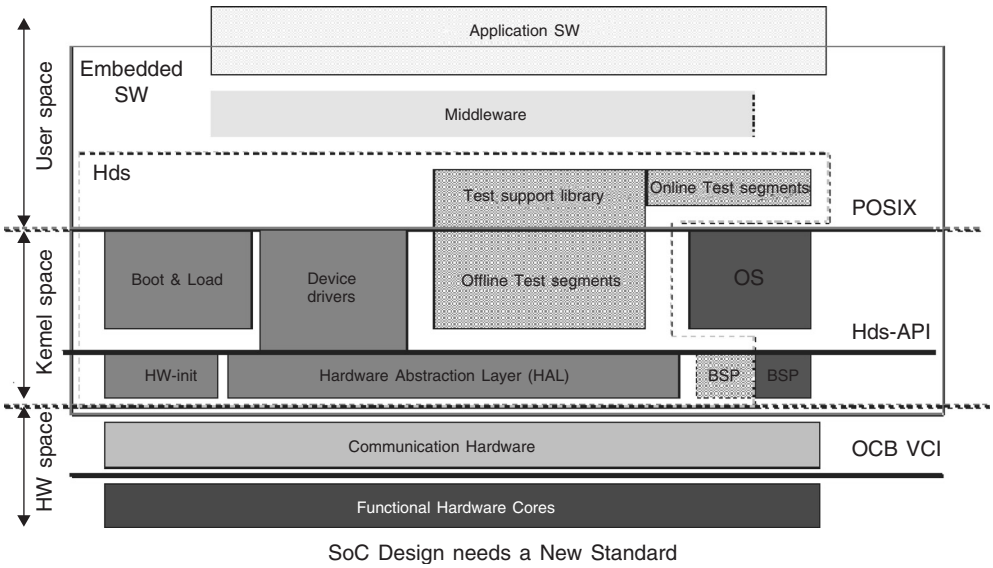

FIGURE 87.1 SoC Design needs a New Standard.

However, the entire kernel space depends on address-specific information. Hence, reuse and automation are difficult.

With a standard HdS-API, the SW above would be shielded from address-specific information.

It becomes possible to load initialization registers and device addresses from configuration databases. As a further step, this HdS-API allows for register-dependent interface code generation.

The HdS-API contains read, write, open, close, and control services — like standard OS or bus (i.e., VCI) interfaces. Drivers, diagnostics SW, and parts of the RTOS are built on top of this API. This way, this kernel space SW layer becomes portable over a large range of

- HW architectures, including processors, on the bottom
- SW applications, on the top.

With the potential for automating the generation, or at least reuse, of the kernel space SW below the HdS-API, SoC SW development effort can drastically be reduced.

Running Standardization Activities. The Role of VSIA's HdS-DWG

In 2002, VSIA investigated on SoC industry's needs to open for ESW. As a result, the HdS Design working group (DWG) was formed in 09/2001. In 2003, it was working with more than 25 members from 15 companies.

The DWG's mission consists of:

1. Improving company-internal and intercompany component reuse by defining or fixing an "HdS API."
2. Coming to industry specifications on HdS Virtual components.

An **HdS taxonomy document** [7] has been released by VSIA. This taxonomy

- Consolidates terms from the SoC and the SW world, which need to be agreed upon in the HdS context
- Defines HdS specific terms (HdS, HdS-API, kernel space, user space, driver, access shielding,…)
- Relates HdS concepts to different aspects, like life cycle, HW platform, SW platform, Real-time
- Determines HdS' architectural relation to HW, middleware, and application SW layers
- Provides a tutorial to train both HW and SW experts on HdS needs.

© 2005 by CRC Press LLC

In 2003, the DWG was working on the definition of the **HdS-API**. The target is to determine the characteristics of a common API, which defines the way to provide SoC IP's functionality to upper-layer SW. HdS-APIs are defined for different application domains (e.g., telecommunications, automotive, multimedia). Certainly, this API is defined in relation to other driver standardization initiatives, like the Project UDI [4].

The API will be described using UML, and defines

- An HdS Framework in terms of an HAL architecture
- An API mechanism, which determines how to specify an HdS API
- Elementary Services: These are the basic services either to be offered directly to the SW, or of which services are they composed.

This HdS-API will be the basis for HdS-VC Reuse guidelines to be worked on in 2004.

87.5 Conclusion

Deep understanding of ESW issues is imperative in modern SoC design. Many of the methods, tools, and architectures known from SW development also need to be considered in designing SoCs as systems. Examples have been discussed in this paper. However, designing embedded real-time systems needs the special attention of both SW and HW engineers.

Achieving reuse and portability for systems containing complex SoCs needs reconsidering of classical HW and SW architecture approaches. HdS, and especially the HdS-API, are ways to overcome the current productivity crisis with huge efforts spent on integrating applications on top of SoCs, or on porting systems from one HW platform to another one.

VSIA's current work on HdS promises to advance this process by defining an industrywide HdS-API standard.

88.1 Introduction

Informally speaking, a *real-time* computer system is a system where a computer senses events from the outside world and reacts to them; in such an environment, the *timely* availability of computation results is as important as their correctness.

Depending on the strictness of their timing requirements, real-time systems are often divided into three classes:

In *hard* real-time systems, the late availability of a computation makes its results completely useless and makes the application fail catastrophically; most safety-critical real-time applications, such as pacemakers, belong to this category;

In a *soft* real-time system, timing requirements are somewhat relaxed, so that the value of a computation decreases as its lateness increases, but the violation of a timing constraint, provided the probability of such an event is low, is acceptable. For example, if a video streaming application is unable to process all its input data on occasion, the video output will be degraded but will still be of acceptable quality;

© 2005 by CRC Press LLC

In between are *firm* real-time systems. In these systems, a computation has no value at all if it is late, like in hard real-time; however, like in soft real-time, the system will not undergo an unrecoverable failure when a timing constraint is violated. Many financial applications fall in this category.

Instead, the exact definition of *embedded* system is somewhat less clear. In general, an embedded system is a special-purpose computer system built into a larger device and is usually not programmable by the end user.

The major areas of difference between general-purpose and embedded computer systems are cost, performance, and power consumption: often, embedded systems are mass-produced, thus reducing their unit cost is an important design goal; in addition, mobile battery-powered embedded systems like cellular phones have severe power budget constraints to enhance their battery life.

Both these constraints have a profound impact on system performance, because they entail simplifying the overall hardware architecture, reducing clock speed, and keeping memory requirements to a minimum.

Moreover, embedded computer systems often lack traditional peripheral devices, such as a disk drive, and interface with application-specific hardware instead.

Another common requirement for embedded computer systems is some kind of real-time behavior; the strictness of this requirement varies with the application, but it is so common that, for example, many operating system vendors often use the two terms interchangeably, and refer to their products either as "embedded operating systems" or "real-time operating systems for embedded applications."

In general, the term "embedded" is preferred when referring to smaller, uniprocessor computer systems, and "real-time" is generally used when referring to larger appliances, but the today's rapid increase of available computing power and hardware features in embedded systems contributes to shade this distinction.

An early example of a recognizable, modern real-time embedded system was the Apollo Guidance Computer (AGC) [28] and its custom operating system, whose design began in 1961 at the MIT Instrumentation Laboratory; its most important duty was to run the inertial guidance system of the Apollo Command Module and LEM.

More recent examples include many kinds of computer system, from large appliances like phone switches to mass-market consumer products such as printers and digital cameras.

Therefore, a real-time operating system must not only manage system resources and offer a well-defined set of services to application programs, like any other operating system does, but must also provide guarantees about the *timeliness* of such services and honor them, that is, its behavior must be *predictable.* Thus, for example, the maximum time the operating system will take to perform any service it offers must be known in advance.

This proves to be a tight constraint, and implies that real-time does *not* have the same meaning as "real fast," because it often conflicts with other operating system's goals, such as good resource utilization and coexistence of real-time and non-real-time jobs, and adds further complexity to the operating system duty.

Also, it is highly desirable that a real-time operating system optimize some operating system parameters, mainly context switch time and interrupt latency, which have a profound influence on the overall response time of the system to external events; moreover, in embedded systems, the operating system footprint, that is, its memory requirements, must be kept to a minimum to reduce costs.

Last, but not the least, due to the increasing importance of open system architectures in software design, the operating system services should be made available to the real-time application through a standard application programming interface. This approach promotes code reuse, interoperability, and portability, and reduces the software maintenance cost.

The chapter is organized as follows: Section 88.2 gives a brief refresher on the main design and architectural issues of operating systems and on how these concepts have been put in practice. Section 88.3 discusses the main set of international standards concerning real-time operating systems and their application programming interface; this section also includes some notes on mechanisms seldom mentioned in operating system theory but of considerable practical relevance, namely real-time signals and timers. Section 88.4 concludes the paper and contains a short survey on some commercial and open source real-time operating systems in use today.

© 2005 by CRC Press LLC

88.2 Operating System Design and Architecture

The main goal of this section is to give a brief overview on the design and architectural issues of operating systems of interest to real-time application developers. See [27] for more general information, and [14] for an in-depth discussion about the design of the influential UNIX operating system.

Overall System Architecture

An operating system is a very complex piece of software; accordingly, its internal architecture can be built around several different designs. Four designs that have been tried in practice and are in common use are:

Monolithic Systems

This is the oldest design, but it is still popular for both real-time and general-purpose systems due to its simplicity and very low processor and memory overhead. For the same reason, it is also the design approach of choice for very small real-time executives for deeply embedded applications, such as [11], and for the real-time portion of more complex systems, like [6] and [19].

When using this approach, the operating system is written as a collection of procedures that are then bound together into a single executable file by the link editor. Each of them has a well-defined interface in terms of parameters, behavior, and results, and can freely call any other procedure when it needs to; hence, there is little or no information hiding.

In monolithic systems, the operating system as a whole runs in privileged mode, and the only internal structure is usually induced by the way operating system services are invoked: applications, running in user mode, request operating system services by placing service parameters in well-defined locations, for example, a set of registers or a stack frame, and then executing a special trap instruction, usually known as the *system call* instruction. This instruction brings the processor in privileged mode and transfers control to the system call dispatcher of the operating system. The system call dispatcher saves the user-mode registers into the appropriate *process control block,* determines which service must be carried out, and transfers control to the appropriate service procedure. Service procedures share a set of utility procedures, which implement generally useful functions on their behalf.

When the system call is finished, the operating system gives control back to the application, after restoring its user-mode registers; execution continues with the instruction following the system call. Figure 88.1 depicts the resulting structure.

The total *overhead* for the invocation of a nonblocking system service, that is, a service that the operating system is able to perform without any synchronization either among operating system modules or with an input/output (I/O) device, is therefore limited to the overhead of the system call instruction and return, plus the time needed to save and restore the user-mode registers of the invoking process. Besides, the interaction between operating system components is very fast, because they invoke each other by means of cheap function calls.

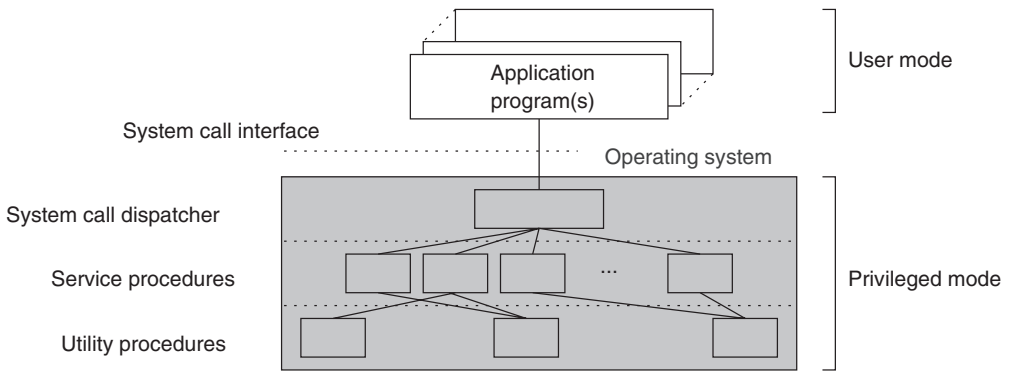

FIGURE 88.1 A monolithic operating system.

© 2005 by CRC Press LLC

Interrupt handling is done directly in the kernel for the most part and interrupt handlers do not have a full processor control block allocated to them. As a consequence, the interrupt handling overhead is very small because there is no full task switching at interrupt arrival, but the interrupt handling code cannot invoke most system services, notably blocking synchronization primitives, and the processor performs all interrupt handling in interrupt service mode. During this time, the operating system scheduler is disabled, and only hardware prioritization of interrupt requests is in effect; hence, the interrupt handling code is implicitly executed at a priority higher than the priority of all application tasks in the system, without regard to the actual priority of the task that will eventually make use of the interrupt itself.

In addition, the only synchronization mechanism available between interrupt handlers and other operating system components is to temporarily disable interrupts. To keep interrupt response latencies bounded and small, it is therefore necessary to keep these critical code paths as short as possible, and to keep track of their actual length whenever they are updated. In turn, this constraint may introduce additional complexity in the operating system algorithms.

To further reduce processor overhead on small systems, it is also possible to run the application as a whole in supervisor mode. In this case, the application code is bound with the operating system at link time, and system calls become regular function calls. The interface between application code and operating system becomes much faster, because no user-mode state must be saved on system call invocation and no trap handling is needed. On the other hand, the overall control that the operating system can exercise on bad application behavior is greatly reduced and debugging may become harder.

In addition, it becomes impossible to upgrade individual software components, for example, an application module, without replacing the executable image as a whole and then rebooting the system. This constraint can be of concern in applications where software complexity implies frequent replacement of modules, and/or no system down time is allowed.

Layered Systems

A refinement and generalization of the monolithic system design consists of organizing the operating system as a hierarchy of layers at system design time. Each layer is built upon the services offered by the one below it and, in turn, offers a well-defined and usually richer set of services to the layer above it. Operating system interface and interrupt handling are implemented like in monolithic systems; hence, the corresponding overheads are very similar.

Better structure and modularity make maintenance easier, both because the operating system code is easier to read and understand, and because the inner structure of a layer can be changed at will without interfering with other layers, provided the interlayer interface does not change.

Moreover, the modular structure of the operating system enables the finegrained configuration of its capabilities, to tailor the operating system itself to its target platform and avoid wasting valuable memory space for operating system functions that are never used by the application. As a consequence, it is possible to enrich the operating system with many capabilities, for example, network support, without sacrificing its ability to run on very small platforms when these features are not needed. A number of operating systems in use today, like [1,2,9,21–23,32], evolved into this structure, often starting from a monolithic approach, and offer sophisticated build or link-time configuration tools.

Historically, this concept was taken to an extreme and further generalized by the MULTICS operating system [17]. MULTICS was organized as a set of concentric rings, of which the outer ones were less privileged than the inner ones. The cross-ring call mechanism was implemented in hardware much like a system call, and the associated protection and security policy was controlled and enforced at runtime by the hardware itself. Thus, in this case, the layering was not a mere design aid, but greatly contributed to the overall system security and reliability. Unfortunately, this concept has not been further pursued by contemporary operating systems, also because its efficient implementation requires special-purpose hardware assistance.

Microkernel Systems

This design, sketched in Figure 88.2, moves many operating system functions from the kernel up into operating system server processes running in user mode, leaving a minimal *microkernel* and reducing to

© 2005 by CRC Press LLC

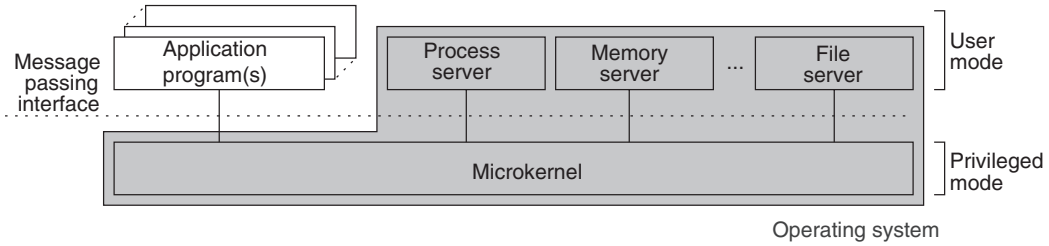

FIGURE 88.2 A microkernel-based operating system.

an absolute minimum the amount of privileged operating system code. Applications request operating system services by sending a message to the appropriate operating system server and waiting for a reply.

The main purpose of the microkernel is to handle the communication between applications and servers, to enforce an appropriate security policy on such communication, and to perform some critical operating system functions, such as accessing I/O device registers, that would be difficult, or inefficient, to do from user mode processes.

This approach has several advantages:

By splitting the operating system into smaller parts, each part becomes easier to manage and maintain. Also, the message-passing interface between user processes and operating system components encourages modularity and enforces a clear and well-understood structure on operating system components;

The reliability of the operating system is increased: since the operating system servers run in user mode, if one of them fails some operating system functions will no longer be available, but the system will not crash. Moreover, the failed component can be restarted and/or replaced without shutting down the whole system; the same mechanism can also be used to add and upgrade application modules without bringing the system down;

The model is easily extended to *distributed systems,* where operating system functions are split across a set of distinct machines connected by a communication network. Distributed systems are very promising in terms of performance, scalability, and fault tolerance, but many topics of interest for their design, such as distributed scheduling algorithms, resource sharing, and load balancing, are still an active research area. As a consequence, few operating system, for example [20,30], support them.

By contrast, making the message-passing communication mechanism efficient is usually a critical issue, as will be discussed further in the Interprocess Synchronization and Communication section. In addition, the system call invocation mechanism involves more overhead because, even for a nonblocking system call, the following steps must be performed:

- The application sends its request to the appropriate operating system server through the microkernel message-passing service, then blocks waiting for an answer.
- Assuming that the system server now has the highest priority, the scheduler wakes it up, and it starts executing the system service.
- When the system server finishes its job, it sends back a result message to the application, again through microkernel message-passing.
- At this point, the application can run again and the scheduler will eventually resume executing it.

Thus, the total overhead associated with the simplest kind of system call includes two microkernel service invocations, usually implemented by means of traps, two executions of the scheduler, and two full-fledged task switches.

Interrupts are handled in a similar way, that is, the interrupt handler proper runs in interrupt service mode and performs the minimum amount of work strictly required by the hardware, then wakes up an interrupt service task. In turn, the interrupt service task concludes interrupt handling running in user mode.

Being an ordinary task, the interrupt service task can, at least in principle, invoke the full range of operating system services, including blocking synchronization primitives, and must not concern itself with

© 2005 by CRC Press LLC

excessive usage of the interrupt service processor mode. On the other hand, system overheads related to interrupt handling increase, because the activation of the interrupt service task requires a task switch.

Operating systems adopting this design approach include [20,26,33].

Virtual Machines

The internal architecture of operating systems based on virtual machines, shown in Figure 88.3 and pioneered by IBM with CP/67, revolves around a basic observation: an operating system must perform two essential functions:

- multiprogramming and
- system services.

Accordingly, those operating systems fully separate these functions and implement them as two distinct operating system components:

- a *virtual machine monitor* runs in privileged mode; it does multiprogramming, and provides many virtual processors *identical* in all respects to the real processor it runs on. In addition, it implements basic synchronization and communication mechanisms between virtual processors, and partitions system resources between them;
- a *guest operating system,* which can even be monoprogrammed, runs on each virtual processor, and implements system services. Different virtual processors can run different operating systems, and they must not necessarily be aware of being run in a virtual machine.

In the oldest approach to virtual machine implementation, based on privileged instruction emulation, when an application program performs a system call instruction, the virtual machine monitor intercepts it and redirects it to the guest operating system running in its own virtual machine. The guest operating system itself is given the illusion of running in privileged mode, while the physical processor actually continues to operate in user mode; in this way, the virtual machine monitor is able to intercept all privileged instructions issued by the guest operating system, check them against the security policy of the system, and then perform them on behalf of the guest operating system, that is, *emulate* them.

Interrupt handling is implemented in a similar way: the virtual machine monitor catches all interrupt requests and then redirects them to the appropriate guest operating system handler, reverting to user mode in the process; thus, the virtual machine monitor can intercept all privileged instructions issued by the guest interrupt handler, and again emulate them as appropriate.

As a consequence, in this kind of virtual machine system the overhead experienced by system calls and interrupt handlers is strictly related to, and dominated by, the cost of emulation of privileged instructions issued by the guest operating system.

The full separation of roles described above has the advantage of making each system component smaller and easier to maintain. Moreover, the presence of a relatively small, centralized arbiter of all interactions between virtual machines makes the enforcement of security policies easier. The isolation of virtual machines

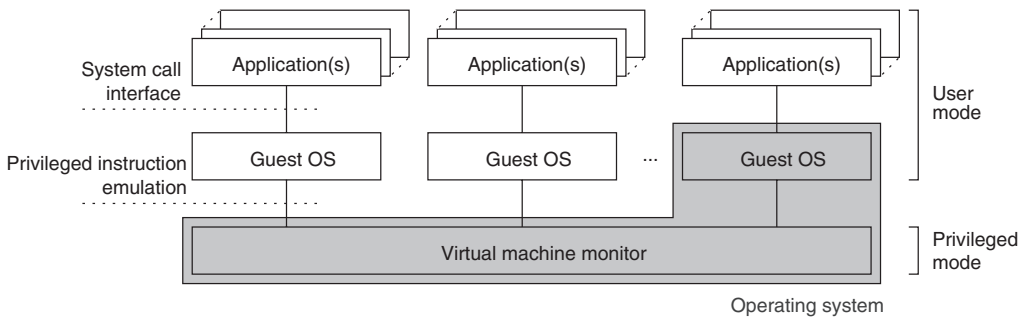

FIGURE 88.3 A virtual machine operating system.

© 2005 by CRC Press LLC

from each other also enhances reliability because, even if one virtual machine fails, it does not bring down the system as a whole. In addition, it is possible to run a distinct operating system in each virtual machine thus supporting, for example, the coexistence between a real-time and a general-purpose operating system.

By contrast, the perfect implementation of virtual machines requires hardware assistance, both to make it feasible and to be able to emulate privileged instructions with a reasonable degree of efficiency. For example, for this approach to work, it is necessary that privileged instruction traps are nondestructive with respect to processor state, and that such a trap is actually taken on any attempt to access the privileged processor state from user mode, *including* read-only access.

Communication between virtual machines is usually implemented by means of shared virtual devices, like disks, or virtual network interfaces. In all cases, when virtual machines run software with different timing requirements, for example, one virtual machine is devoted to real-time code and another to the user interface, the communication channel must not introduce any undue synchronization between the two worlds. Lock-free, shared data structures are often used for this purpose.

A variant of this design adopts an interpretive approach, and allows the virtual machines to be *different* from the physical machine. For example, Java programs are compiled into byte-code instructions suitable for execution by an abstract Java virtual machine. On the target platform, an interpreter executes the byte-code on the physical processor, thus implementing the virtual machine.

More sophisticated approaches to virtual machine implementation are also possible, the most common one being on-the-fly code generation, also known as just-in-time compilation.

With this approach, virtual machine instructions are dynamically translated into sequences of native instructions that are then executed directly by the physical processor. After translation, instructions are executed much quicker, but the translation itself is a lengthy process and the translated code is often larger than the original one.

Therefore, an important design issue of just-in-time compilers is to appropriately determine when code must be translated and for how much time the translated code must be retained in view of its repeated execution, thus attempting to avoid both the translation of code that will be executed rarely and the waste of valuable storage area to hold translated code that will never be executed again.

Besides the now ubiquitous Java virtual machines, a real-world example of operating system based on virtual machines, and in which the virtual machine concept plays a central role, is [30].

Process and Thread Model

A convenient and easy to understand way to design real-time and non-real-time software applications is to organize them as a set of cooperating sequential *processes.* A process is an activity, namely the activity of executing a program, and encompasses the program being executed, the data it operates on, and the current processor state, including the program counter and registers. In particular, each process has its own address space.

Multiprogrammed operating systems give the user the illusion of executing multiple processes in parallel, usually by multiplexing the physical processors and switching them from one process to another as directed by an all-important part of the operating system, the *scheduler.*

During its life, a process transitions between several *states* along a process state diagram; the most basic process states are depicted in Figure 88.4:

Running: The process is currently running on a processor. From this state, a process can become *blocked* when it starts waiting for an external event to occur; also, the operating system can forcibly move it into the *runnable* state when the scheduling algorithm assigns the CPU to another process, an action known as *preemption.*

Runnable, or Ready: The process is ready to be run; the process will transition into the *running* state when the scheduler assigns an otherwise idle processor to it.

Blocked: The process is not ready to run, because it is waiting for some events, for example, an I/O operation, to occur. When the event eventually occurs, the process goes into the *runnable* state and starts competing for the CPU again.

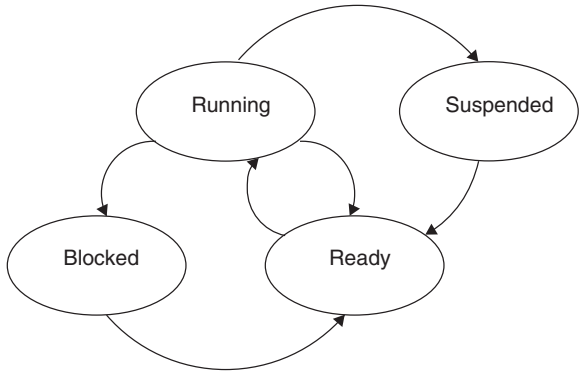

FIGURE 88.4 Basic process state diagram.

Suspended: The process is "passive," that is, it neither runs nor competes for processor usage nor is it waiting for an event to occur. Another process can activate it by means of a system service, and bring it into the *runnable* state. Also, a *running* process can voluntarily suspend itself, usually at the end of an execution cycle, thus entering the *suspended* state directly from the *running* state.

The process model just described is common to virtually all operating systems but; while general-purpose operating systems usually have one class of processes only and support the full state diagram outlined above for all of them, some real-time operating systems where process characteristics are well-known in advance, for example, those specified by [18], support a simplified state model for processes that cannot block, called *basic tasks* in [18], and remove the *blocked* state from their diagrams. The inherent advantage of basic tasks is that they require a lesser amount of run-time context to be stored in RAM, because it is never necessary to block them.

The efficient implementation of processes requires hardware assistance, namely the availability of a *Memory Management Unit* (MMU), to enforce separation between address spaces; also, the MMU must be reprogrammed to switch between address spaces while switching between processes. For this reason, in alternative or, in some cases, in addition to the process model described above, many real-time operating systems provide support for multiple *threads* of control within the same process. All threads in a process share the same address space; this gives both advantages and disadvantages:

Threads can be implemented for the most part in user mode, without the operating system's kernel intervention; moreover, when the processor is switched between threads, the address space remains the same and must not be switched. Both these facts make processor switching between threads very fast with respect to switching between processes;

Since all threads within a process share the same address space, there can be no protection among them; hence, for example, a thread is allowed to pollute by mistake another thread's data and the operating system has no way to detect errors of this kind.

Small operating systems for embedded applications, like [11,18,22], only support threads to keep overheads and hardware requirements to a minimum, while larger operating systems for more complex real-time applications offer the user a choice between a single or multiple process model to enhance the reliability of complex systems.

Another important operating system design issue is the choice between *static* and *dynamic* creation of processes and threads:

Some operating systems, usually oriented toward relatively simple embedded applications, for example [11,18], only support static tasks, that is, all tasks in the system are known in advance and it is not possible to create and destroy tasks while the system is running; thus, the total number of tasks in the system stays constant for all its life.

Other operating systems allow to create and destroy tasks at runtime, by means of a system call.

© 2005 by CRC Press LLC

Dynamic task creation has the obvious advantage of making the application more flexible, but it increases the complexity of the operating system, because many operating system data structures, first of all the process table, must be allocated dynamically and their exact size cannot be known in advance. In addition, the application code requires a more sophisticated error-handling strategy, with its associated overheads, because it must be prepared to cope with the inability of the operating system to create a new task, due to lack of resources.

Processor Scheduling

The *scheduler* is one of the most important components of a real-time operating system, as it is responsible for deciding to which runnable threads the available processors must be assigned, and for how long. Schedulers can be divided into two broad categories:

Static

A static scheduler performs all scheduling computations *before* the application runs. Thus, there are no upper limits on the complexity of the scheduling algorithm to be used, because the time spent in those computations does not adversely affect the application at runtime.

Moreover, it is possible to develop exact schedulability tests for a given task set; these tests assure that the task set is schedulable under the worst possible conditions, a property most enjoyable in hard real-time systems.

However, the set of application tasks and their execution characteristics, such as period, deadline, and computation time, must all be known in advance, before scheduling decisions are made.

The output of a static scheduler is a set of tables, which are then linked with the operating system image and obeyed at runtime by a *dispatcher,* a software component much simpler, and more efficient, than the scheduler.

Dynamic

A dynamic scheduler performs scheduling computations at runtime, that is, *while* the application is running. Since in this case the computation time of the scheduler is seen as a system overhead by the application, scheduling algorithms must be simpler and often based on heuristics.

Also, in some cases it may be impossible to develop exact schedulability tests, and the application must be prepared to encounter and cope with an *overload* condition, where the scheduler is temporarily unable to satisfy all the processor requirements of the runnable tasks.

For these reasons, dynamic schedulers are best suited for firm and soft realtime systems, especially when the exact number and nature of application tasks is not fully known in advance and/or it is desirable to run together tasks with and without real-time requirements. A typical example of this situation are portable, wireless multimedia appliances that are gaining popularity nowadays.

Among dynamic schedulers, several algorithms are in use and offer different trade-offs between real-time predictability, implementation complexity, and overhead. Since the optimum compromise often depends on the application's characteristics, most real-time operating systems support multiple scheduling policies simultaneously and the responsibility of a correct choice falls on the application programmer. The most common scheduling algorithms supported by real-time operating systems and specified by international standards are:

First in, first out with priority classes: Under this algorithm, also known as fixed priority scheduling, there is a list of runnable threads for each priority level. When a processor is idle, the scheduler takes the runnable thread at the head of the highest-priority, nonempty thread list and runs it.

When the scheduler preempts a running thread, because a higher-priority task has become runnable, the preempted thread becomes the head of the thread list for its priority; when a blocked thread becomes runnable again, it becomes the tail of the thread list for its priority.

Thus, threads are placed into thread lists according to the time they have spent in the list without being executed: the thread that has been on the list the longest time will generally be at the head of the list, while the thread that has been on the list the shortest time will be at the tail.

© 2005 by CRC Press LLC

The first in, first out scheduler never changes thread priorities at runtime; hence, the priority assignment is fully static; a well-known approach to static priority assignment for periodic tasks is the *rate monotonic* policy, in which task priorities are inversely proportional to their periods.

Since this is the simplest scheduling algorithm, virtually all real-time operating systems support it.

Round robin with priority classes: This algorithm extends the first in, first out algorithm just described with the additional condition that when a running thread has been executing for more than a maximum amount of time, the *quantum,* that thread is forcibly returned to the tail of its thread list and a new thread is selected for execution.

Similarly, when the scheduler resumes a thread after preemption, the thread is allowed to consume the unexpired portion of its *quantum.*

The effect of this extension is to ensure that when multiple, runnable threads share the same priority level, none of them can monopolize the processor; instead, the available processor time will be fairly divided among them.

Earliest deadline first: Unlike the scheduling policies discussed above, the earliest deadline first scheduler assigns thread priorities *dynamically.* In particular, this scheduler always executes the thread with the nearest deadline. It can be shown that this algorithm is optimal for uniprocessor systems, and supports full processor utilization in all situations.

However, its performance under overload is poor and dynamically updating thread priorities on the base of their deadlines may be computationally expensive, especially when this scheduler is layered on a fixed-priority lower-level scheduler.

Sporadic server: This scheduling algorithm was first introduced in [24], where a thorough description of the algorithm can be found.

The sporadic server algorithm is suitable for aperiodic event handling where, for timeliness, events must be handled at a certain, usually high, priority level, but lower priority threads with real-time requirements could suffer from excessive preemption if that priority level were maintained indefinitely. It acts on the base of two main scheduling parameters associated with each thread:

- the execution capacity and
- the replenishment period.

Informally, the execution capacity of a thread represents the maximum amount of processor time that the thread is allowed to consume at high priority in a replenishment period.

The execution capacity of a thread is preserved until an aperiodic request for that task occurs, thus making it runnable; then, thread execution depletes its execution capacity.

The sporadic server algorithm replenishes the thread's execution capacity after some or all of its capacity is consumed by thread execution; the schedule for replenishing the execution capacity is based on the thread's replenishment period.

Should the thread reach its processor usage upper limit, its execution capacity becomes zero and it is demoted to a lower priority level, thus avoiding excessive preemption against other threads. When replenishments have restored the execution capacity of the thread above a certain threshold level, the scheduler promotes the thread to its original priority again.

Most real-time operating systems implement at least the first in, first out and round-robin scheduling algorithms. More sophisticated policies are less common; for example, at the time of writing, the sporadic server algorithm was available in [16,20,33].

Interprocess Synchronization and Communication

An essential function of a multiprogrammed operating system is to allow processes to synchronize and exchange information; as a whole, these functions are known as IPC (InterProcess Communication). Many interprocess synchronization and communication mechanisms have been proposed and were objects of extensive theoretical study in the scientific literature. Among them, we recall:

© 2005 by CRC Press LLC

Semaphores

A semaphore, first introduced by Dijkstra in 1965, is a synchronization device with an integer value and on which the following two primitive, *atomic* operations are defined:

The P operation, often called DOWN or WAIT, checks if the current value of the semaphore is greater than zero. If so, it decrements the value and returns to the caller; otherwise, the invoking process goes into the blocked state until another process performs a V on the same semaphore;

The V operation, also called UP, POST, or SIGNAL, checks whether there is any process currently blocked on the semaphore. In this case, it wakes exactly one of them up, allowing it to complete its P; otherwise, it increments the value of the semaphore. The V operation never blocks.

One common use of a semaphore with an initial value of 1 is to ensure the *mutual exclusion* between processes in the access to a critical region:

- in each process, the critical region code is bracketed by a P/V pair;
- when a process successfully enters its critical region, the semaphore value decrements to 0, denoting that the critical region is now "busy";
- any other process that subsequently attempts to enter its critical region will block in the P, ensuring mutual exclusion;
- when a process exits from its critical region and executes the V, another process, formerly blocked in the P, is allowed to enter the critical region; in this case, the semaphore value stays at 0, because the critical region is still "busy." If there are no processes waiting for their turn to enter the critical region, the semaphore value returns to 1, denoting that the critical region is now "free" again.

When used in this way, a semaphore can have only two meaningful values, 1 and 0, denoting that the critical region protected by the semaphore currently is "free" and "busy," respectively. Moreover, in any given thread, invocations of P and V always appear in pairs, and P always comes before V. Taking these peculiarities into account, most operating systems provide a specialized and optimized variety of semaphore, devoted to mutual exclusion only, and call it a *mutual exclusion device,* or *mutex* for short.

Semaphores are a very low-level IPC mechanism; therefore, they have the obvious advantage of being simple to implement, at least on uniprocessor systems, and of having a very low overhead. By contrast, they are difficult to use, especially in complex applications.

Also related to mutual exclusion with semaphores is the problem of *priority inversion.* Priority inversion occurs when a high-priority process is forced to wait for a lower-priority process to exit a critical region, a situation in contrast to the concept of relative task priorities. Most real-time operating systems take this kind of blocking into account and implement several protocols to bound it:

In the *priority inheritance* protocol, a lower-priority process is temporarily promoted to the priority of the higher-priority process it is blocking, and returns to its original priority when it leaves the critical region.

In the *priority ceiling* protocol, explicitly called for by [18], when a process acquires a critical region, its priority is temporarily raised to that of the highest priority process that will ever use the critical region. Again, the process returns to its original priority when it leaves the critical region.

An alternative approach, taken, for example, by [6,9] is to leave the burden of avoiding priority inversion to the application, thus saving the significant overhead required by the kernel to resolve it. Proponents of this approach show that it is often better and more efficient to attack the priority inversion issue at the application design level, instead of relying on universal, time-consuming run-time mechanisms. However, this topic is still the subject of considerable debate; see, for example, [12,34].

Monitors

To overcome the difficulties of semaphores, in 1974/1975, Hoare and Brinch Hansen introduced a higher level synchronization mechanism, the monitor.

A monitor is a set of data structures and procedures that operate on them; data structures are shared among all processes that can use the monitor, and it effectively hides the data structures it contains; hence, the only way to access the data associated with the monitor is through the procedures in the monitor itself.

© 2005 by CRC Press LLC

In addition, all procedures in the same monitor are implicitly executed in mutual exclusion. Unlike semaphores, the responsibility of ensuring mutual exclusion falls on the compiler, not on the programmer, because monitors are a programming language construct, and the language compiler knows about them.

Inside a monitor, *condition variables* can be used to wait for events. Two *atomic* operations are defined on a condition variable:

The WAIT operation releases the monitor and blocks the invoking process until another process performs a SIGNAL on the same condition variable;

The SIGNAL operation unblocks exactly one process waiting on the condition variable. Then, to ensure that mutual exclusion is preserved, the invoking process is either forced to leave the monitor immediately (Brinch Hansen's approach), or is blocked until the monitor becomes free again (Hoare's approach).

Note that, unlike semaphores, condition variables have no memory; hence, a SIGNAL has no effect when performed on a condition variable on which no processes are currently blocked.

An alternative and simpler implementation of monitors, which does not require additional programming language constructs and can therefore be used with off-the-shelf compilers, consists of providing monitor enter and exit functions, and synchronization functions on condition variables, that must then be *explicitly* invoked by application code. However, in this case there is no information hiding and the mutual exclusion between monitor methods is not guaranteed, unless the application programmer bracketed them appropriately with the monitor enter and exit functions mentioned above.

It should also be noted that both semaphores and monitors merely convey synchronization signals among processes, and rely on the availability of a shared memory for data exchange.

Message Passing

Unlike all other IPC mechanisms described so far, message passing supports explicit *data* transfer between processes; hence, it does not require a shared memory and lends itself well to be extended to distributed systems. This IPC method provides for two primitives:

- the SEND primitive sends a message to a given destination;
- symmetrically, RECEIVE receives a message from a given source.

Many variants are possible on the exact semantics of these primitives; they mainly differ in the way messages are *addressed* and *buffered.*

A commonplace addressing scheme is to give to each process/thread in the system a unique address, and to send messages directly to processes. Otherwise, a message can be addressed to a *mailbox,* a message container whose maximum capacity is usually specified upon creation; in this case, message source and destination addresses are mailbox addresses.

When mailboxes are used, they also provide some amount of message buffering, that is, they hold messages that have been sent but have not been received yet. Moreover, a single task can own multiple mailboxes and can use them to classify messages depending on their source or priority.

A somewhat contrary approach to message buffering, simpler to implement but less flexible, is the *rendezvous* strategy: the system performs *no* buffering; hence, the sender and the receiver are forced to run in lockstep:

- the SEND does not complete until another process executes a matching RECEIVE;
- the RECEIVE waits until a matching SEND is executed.

Despite its simplicity and elegance, the message-passing mechanism suffers from several design issues, of which the most important is *performance,* because copying data between processes is always slower than using a shared memory and exchanging synchronization signals: considerable work has gone into making the mechanism efficient, and this still is an open research theme, especially for distributed systems.

For example, a common way to pose an upper bound on message passing time requirements, thus making the mechanism predictable, is to force a fixed message structure and/or limit the maximum message size.

© 2005 by CRC Press LLC

Moreover, when a memory management unit is available, it is possible to leverage its capabilities to switch one or more physical pages from an address space to another one without copying their contents, and with a negligible and deterministic overhead.

Lock-free Data Structures

This kind of data structure allows two or more processes to exchange data without introducing any undue synchronization between them. This feature is most important when the communicating processes have different priority levels and timing requirements. An example are the real-time FIFOs used by [6,19] to exchange data between real-time and non-real-time processes.

Operating systems usually provide (at least) one IPC mechanism natively, and implement the other ones on top of it, for example, by means of utility libraries. Often, the choice of the basic, primary IPC mechanism of an operating system depends on its overall architecture: for example, a microkernel-based operating system like [20,26,33] will have extensive message-passing capabilties, whereas the natural choice for a monolithic or layered operating system like [9,16,22,23] is to adopt shared memory and semaphores as its primary IPC mechanism. Therefore, an in-depth understanding of the operating system architecture can help application designers to enhance the performance of their solutions.

Network Support

There are two basic approaches to implement network support in a real-time operating system and to offer it to applications:

The POSIX set of standards [7] specifies the *socket* paradigm for uniform access to any kind of network support and most real-time operating systems, like [2,3,13,16,19,20,26,33], provide them. Sockets, fully described in [14], were first introduced in the "Berkeley Unix" operating system and are now available on virtually all general-purpose operating systems; as a consequence, most programmers are likely to be proficient with them.

The main advantage of sockets is that they support in a *uniform* way any kind of communication network, protocol, naming conventions, hardware, and so on. Semantics of communication and naming are captured by *communication domains* and socket *types,* both specified upon socket creation. For example, communication domains are used to distinguish between IPv4 and X25 network environments, whereas the socket type determines whether communication will be stream-based or datagram-based and also implicitly selects which network protocol a socket will use.

Additional socket characteristics can be set up after creation through abstract *socket options;* for example, socket options provide a uniform, implementation-independent way to set the amount of receive buffer space associated with a socket.

Thus, sockets enhance software portability and hardware independence, at the expense of an abstract view of network characteristics that, in some cases, makes network-specific capabilities difficult to use efficiently.

Some operating systems, mostly focused on a specific class of embedded applications, offer network support through a less general, but more rich and efficient, application programming interface. For example, [18] is an operating system specification oriented to automotive applications; it specifies a communication environment (OSEK/VDX COM) less general than sockets and oriented to real-time message-passing networks, such as the Controller Area Network (CAN).

In this case, for example, the application programming interface allows applications to easily set message filters and perform out-of-order receives, thus enhancing their timing behavior; both these functions are supported with difficulty by sockets, because they do not fit well with the general socket paradigm.

In both cases, network device drivers are usually supplied by third-party hardware vendors and conform to a well-defined interface defined by the operating system vendor.

The network software itself, although it is often bundled with the operating system and provided by the same vendor, can be obtained from third-party software houses, too. For example, [4,10] are TCP/IP protocol stacks that run on a wide variety of hardware platforms and operating systems.

© 2005 by CRC Press LLC

Often, these products come with source code; hence, it is also possible to port them to custom operating systems developed in-house, and can be extended and enhanced by the end user.

Hardware Requirements

Hardware platforms for embedded applications are much more varied than general-purpose platforms, such as personal computers. Accordingly, all real-time operating systems can run on more than one processor family and often accomplish this goal by interposing between the operating system kernel and the hardware a suitable, hardware-dependent abstraction layer (HAL). The main function of the HAL is to decouple abstract hardware functions that the kernel requires, for example, the "interrupt disable" operation, from the actual sequence of instructions required by the processor.

All popular 32-bit and many 16-bit processor families are currently supported by real-time operating systems, including, for example, *ARM, ColdFire, CPU32, MIPS, PowerPC, Sparc, SuperH, x86,* and many others. Some operating systems, like [20], are also starting to support some Digital Signal Processor families that in the past were confined to run either with no operating system at all, or with simple cyclic scheduling loops. Smaller, 8-bit processor families, such as the *8051,* are supported only by the simplest real-time executives, like [11].

To complement the HAL, operating system developers usually provide a set of platform-dependent device drivers, which enable operating system access to the peripheral devices the platform provides; in other cases, device drivers are provided by hardware developers directly.

The single most important hardware feature of interest to real-time operating systems for embedded applications is the availability of a Memory Management Unit.

This hardware component is crucial to the efficient implementation of multiple processes, each having its own, independent address space. By means of an MMU, the operating system can check every memory reference made by processes, and enforce memory protection, thus enhancing reliability because a process cannot pollute the address space of another process by effect of a software bug.

Also, the MMU makes memory management easier, because address spaces no longer have to be physically contiguous in memory, and the most sophisticated operating systems can use it to implement demand paging for non-time-critical tasks.

However, an MMU is a rather complex piece of hardware; hence, it is often not included in small microcontrollers, both for cost and power consumption reasons. When an MMU is not available, the operating system can still provide multiprogramming, but there will be a single process and address space in which multiple threads will run concurrently.

Another reason to avoid using the MMU, even when it is available, is that it must be reprogrammed on every context switch, thus adding a source of overhead; many modern MMUs attempt to reduce this overhead, for example, by tagging virtual addresses with per-process *Space Identifiers* (SI), but cannot fully eliminate it when the number of processes in the system grows beyond the available SI range.

Last, but not the least, MMUs often introduce a source of unpredictability in memory access timing; in fact, to accelerate address translation, they resort to a hardware component known as the *Translation Lookaside Buffer* (TLB). The TLB acts like a cache of the most recently performed address translations; however, since it has limited capacity and its entries are therefore subject to a replacement policy, its performance can be predicted only in statistical terms. The timing difference between a fast address translation performed through the TLB (TLB *hit)* and the much slower translation performed through a regular page table walk (TLB *miss)* can be of one or two orders of magnitude, especially when part of or all the page table walk must be performed in software, as is commonly done on modern RISC processors.

For this reason, in hard real-time applications it is important to be able to lock the most important TLB entries and thus avoid TLB misses for the most critical portions of code and data; this requires both hardware support and appropriate operating system interfaces.

An intermediate solution, adopted in some microprocessors and microcontrollers, is to implement a very simple memory management unit, often called *Protection Unit,* which does not perform address translation but still provides a selective protection mechanism for a physically contiguous area of memory and is fully deterministic with regard to timing.

© 2005 by CRC Press LLC

Additional Functions

Even if real-time operating systems sometimes do not implement several major functions that are now commonplace in general-purpose operating systems, such as demand paging, swapping, and filesystem access, they must be concerned with other, less well-known functions that ensure or enhance system predictability, for example:

- asynchronous, real-time signals, and cancellation requests, to deal with unexpected events, such as software and hardware failures, and to gracefully degrade the system's performance should a processor overload occur;
- high-resolution clocks and timers, to give real-time processes an accurate notion of elapsed time; and
- asynchronous I/O operations, to decouple real-time processes from the inherent unpredictability of many I/O devices.

88.3 The POSIX Standard

The original version of the Portable Operating System Interface for Computing Environments, better known as the POSIX set of standards, was first published between 1988 and 1990, and defines a standard way for applications to interface with the operating system. The set now includes over 30 individual standards, and covers a wide range of topics, from the definition of basic operating system services such as process management, to specifications for testing the conformance of an operating system to the standard itself.

Among these, of particular interest is the System Interfaces (XSH) Volume of IEEE Std 1003.1-2001 [7], which defines a standard operating system interface and environment, including real-time extensions. The standard contains definitions for system service functions and subroutines, language-specific system services for the C programming language, and notes on portability, error handling, and error recovery.

This standard has been constantly evolving since it was first published in 1988; the latest developments have been crafted by a joint working group of members of the IEEE Portable Applications Standards Committee, members of The Open Group, and members of ISO/IEC Joint Technical Committee 1. The joint working group is known as the Austin Group, after the location of the inaugural meeting held at the IBM facility in Austin, Texas in September 1998.

The Austin group formally began its work in July 1999, after the subscription of a formal agreement between The Open Group and the IEEE, with the main goal of revising, updating, and combining into a single document the following standards: ISO/IEC 9945-1, ISO/IEC 9945-2, IEEE Std 1003.1, IEEE Std 1003.2, and the Base Specifications of The Open Group Single UNIX Specification Version 2.

For real-time systems, the latest version of IEEE Std 1003.1 [7] incorporates the real-time extension standards listed in Table 88.1. Since embedded systems can have strong resource limitations, the IEEE Std 1003.13-1998 [8] profile standard groups functions from the standards mentioned above into units of functionality. Implementation can then choose the profile most suited to their needs and to the computing resources of their target platforms.

Functions defined in the oldest standard, 1003.1b, are supported across a wider number of operating systems; for this reason, we concentrate only on them and on 1003.1c, which specifies support for multiple threads in the same process.

Table 88.2 summarizes the functional groups of IEEE Std 1003.1-2001 that will be discussed next.

TABLE 88.1 Real-time Extensions Incorporated into IEEE Std 1003.1-2001

Standard	Description
1003.lb	Basic real-time extensions; first published in 1993
1003.lc	Threads extensions; published in 1995
1003.ld	Additional real-time extensions; published in 1999
1003.lj	Advanced real-time extensions; published in 2000

Process Scheduling

Functions in this group allow the application to select a specific policy that the operating system must follow to schedule a particular process, and to get and set the scheduling parameters associated with that process.

In order to support the orderly coexistence of multiple scheduling policies, the conceptual scheduling model defined by the standard assigns a global priority to all threads in the system and contains one ordered thread list for each priority; any runnable thread will be on the thread list for that thread's priority. When appropriate, the scheduler shall select the thread at the head of the highest priority nonempty thread list to become a running thread, regardless of its associated policy; this thread is then removed from its thread list. When a running thread yields the CPU, either voluntarily or by preemption, it is returned to the thread list it belongs to.

The purpose of a scheduling policy is then to determine how the operating system scheduler manages the thread lists, that is, how threads are moved between and within lists when they gain or lose access to

© 2005 by CRC Press LLC

the CPU. Associated with each scheduling policy is a priority range, which must span at least 32 distinct priority levels; all threads scheduled according to that policy must lie within that priority range, and priority ranges belonging to different policies can overlap in whole or in part.

The standard defines the following three scheduling policies, whose algorithms have been described in the Processor Scheduling section:

- first in, first out (`SCHED_FIFO`);
- round robin (`SCHED_RR`);
- optionally, a variant of the sporadic server scheduler (`SCHED_SPORADIC`).

A fourth scheduling policy, `SCHED_OTHER`, can be selected to denote that a thread no longer needs a specific real-time scheduling policy: general-purpose operating systems with real-time extensions usually revert to the default, non-real-time scheduler when this scheduling policy is selected.

Moreover, each implementation is free to redefine the exact meaning of the `SCHED_OTHER` policy and can provide additional scheduling policies besides those required by the standard, but any application using them will no longer be fully portable.

Real-time Signals

Signals are a mechanism to convey information to a process when it is not necessarily waiting for input; therefore, they allow an application to be notified asynchronously about the occurrence of an event.

In POSIX, there is a defined set of signals, and each member of the set has a unique signal number. Basically, the process can specify one of three possible actions to be taken when a signal arrives:

- ignore it completely,
- terminate, or
- execute a signal-handling procedure.

The real-time extensions of IEEE Std 1003.1-2001 add real-time features to the default signal-handling capabilities defined by the standard; in particular:

- they define a priority hierarchy between signals so that, when multiple signals are pending, the highest priority signal is serviced first; the default, non-real-time behavior is to process pending signals in an unspecified order; and
- they add support for signal queues, to keep track of multiple pending signals with the same signal number and to convey a limited amount of information with each signal request; under the default behavior, all signals but the first are lost and signal requests do not carry any additional information with them.

Interprocess Synchronization and Communication

The main interprocess synchronization and communication mechanisms offered by the standard are the semaphore and the message queue, both described in the Interprocess Synchronization and Communication section. The blocking synchronization primitives have a nonblocking and a timed counterpart, to enhance their real-time predictability. Moreover, asynchronous notification through a real-time signal is supported for message arrival. Areas of memory can be shared among multiple processes.

The multithreading extension, described in the Multiple Threads section, adds support for mutual exclusion devices, that is, binary semaphores, condition variables, and other synchronization mechanisms. The scope of these mechanisms can be limited to threads belonging to the same process to enhance their performance.

Memory Management

The standard allows processes to lock parts or all of their address space in main memory. The lock operation both forces the memory residence of the virtual memory pages involved, and prevents them from being paged out in the future. This is vital in operating systems that support demand paging, because the paging activity could introduce undue and highly unpredictable delays when a real-time process attempts to access a page that is currently not in the main memory and must therefore be retrieved from secondary storage.

© 2005 by CRC Press LLC

Other memory management functions establish a mapping between the address space of the calling process and a memory object, possibly shared between multiple processes. The mapping facility is general enough; hence, it can also be used to map other kinds of object, such as files and devices, into the address space of a process, provided both the hardware and the operating system have this capability, which is not mandated by the standard. For example, once a file is mapped, a process can access it simply by reading and writing the data at the address range to which the file was mapped.

Finally, it is possible for a process to change the access protections of portions of its address space; in this case, it is assumed that protections will be enforced by the hardware. For example, to prevent inadvertent data corruption due to a software bug, one could protect critical data intended for read-only usage against write access.

Asynchronous and List-Directed Input and Output

Many operating systems carry out I/O operations synchronously with respect to the process requesting them. Thus, for example, if a process invokes a file read operation, it stays blocked until the operating system has finished it, either successfully or unsuccessfully. As a side effect, any process can have at most one pending I/O operation at any given time.

While this programming model is simple, intuitive, and perfectly adequate for general-purpose systems, it shows its limits in a real-time environment, namely:

- I/O device access timings can vary widely, especially when an error occurs; hence, it is not always wise to suspend the execution of a process until the operation completes, because this would introduce a source of unpredictability in the system;
- it is often desirable, for example, to enhance system performance by exploiting I/O hardware parallelism, to start more than one I/O operation simultaneously, under the control of a single process.

To satisfy these requirements, the standard defines a set of functions to start one or more I/O requests, to be carried out in parallel with process execution, and whose completion status can be retrieved asynchronously by the requesting process.

Clocks and Timers

Real-time applications very often rely on timing information to operate correctly; the standard specifies support for one or more timing bases, called *clocks,* of known resolution and whose value can be retrieved at will. In addition, applications can set one or more per-process *timers,* using a specified clock as a timing base. Each timer has a current value and, optionally, a reload value associated with it. The operating system decrements the current value of timers according to their clock and, when a timer expires, it notifies the owning process with an asynchronous timer expiration signal; the signal can either be handled directly, or trigger the awakening of a thread in the process. On timer expiration, the operating system also reloads the timer with its reload value, if it has been set, thus possibly realizing a repetitive timer.

Since, due to scheduling or processor load constraints, a process could lose one or more expiration signals, the standard also specifies a way for applications to retrieve the number of "missed" signals, that is, the number of extra timer expirations that occurred between the time at which a given timer expired, and when the signal associated with the expiration was eventually delivered to, or accepted by, the process.

Multiple Threads

The optional multithreading extension to the standard adds functions to populate a process with new threads and to cancel them in a carefully controlled way. Controlled cancellation is crucial, for example, to prevent the cancellation of a thread while it is inside a critical region; otherwise, the critical region would stay locked forever, likely inducing a deadlock in the system.

The multithreading extension also offers additional synchronization mechanisms, whose scope can be limited to threads belonging to the same process in order to achieve greater performance:

© 2005 by CRC Press LLC

Mutex Devices: A *mutex* is a binary semaphore that can be used to ensure the mutual exclusion between multiple threads; it is simpler and more efficient than a full-fledged semaphore. Optionally, it is possible to associate to each mutex a protocol to deal with priority inversion.

Condition Variables: In concert with a *mutex,* condition variables can be used to implement a synchronization mechanism similar to the monitor.

Read/Write Locks: A read/write lock implements a specialized and widely used synchronization mechanism in which the access to the critical region is granted to multiple "readers," but to only one "writer" at a time. In addition, when a writer is in the critical region, no other process can enter it, not even readers.

Finally, there is support for multiple, thread-specific data areas. Each thread-specific data area is accessed by means of a data key; while the data key is shared between threads, each thread has got a corresponding, private data area. To make storage management easier, it is also possible to associate to each data key a destructor function, which the system will automatically invoke when a thread-specific data area must be freed, for example, because the owning thread is being canceled.

88.4 Real-time Operating Systems

Although in the general-purpose operating system camp a handful of products dominates the market, there are more than 30 real-time operating systems available for use today, both commercial and experimental, and new ones are still being developed. This is due both to the fact that there is much research in the latter area, and that real-time embedded applications are inherently less homogeneous than general-purpose applications, such as those found in office automation; hence, *ad hoc* operating system features are often needed. In addition, the computing power and the overall hardware architecture of embedded systems are much more varied than, for example, those of personal computers.

Therefore, due to lack of space, this section neither can nor pretends to be a thorough survey; instead, it will focus on some well-known operating systems, mainly to show the broad variety of design and implementation approaches tried in practice.

Commercial Operating Systems

Unless otherwise noted, operating systems in this category claim full conformance with the core services specified by IEEE Std 1003.1, real-time extensions 1003.1b, thread extensions 1003.1c, and possibly other additional extensions specified by the POSIX set of standards. However, although their application programming interface is uniform, they differ considerably in their internal architecture, namely:

AMX [9] from KADAK Products Ltd. is a layered multitasking kernel with a small memory footprint and low overhead, suitable for embedded applications. Of interest is the ability to reduce the kernel footprint down to about 30 kilobytes on most supported platforms. Additional kernel components, such as synchronization objects and memory managers, can be added at kernel configuration time, and consume more space. However, it does not handle the priority inversion problem directly, does not support multiple, independent address spaces, and does not claim conformance to the POSIX set of standards. A filesystem implementation and network support are available separately.

Inferno [30] from Vita Nuova Holdings Ltd. was originally developed by the Computing Science Research Center of Bell Labs with the main purpose of creating and supporting distributed services and has then evolved into a commercial product. It does not claim conformance with the POSIX set of standards.

The research work also included the specification of a new application programming language, Limbo. Limbo syntactically resembles C, but it has a number of additional features that make it easier to use, safer, and more suited to a networked environment.

The operating system design is based on the virtual machine concept, and all Limbo programs are compiled into instructions for a virtual machine called *Dis.*

Of particular interest is the notion of a unified *name space* for distributed systems. In Inferno, all components of a distributed system present their resources as "files" in a hierarchical name space. The objects appearing as files often represent actual files, but may very well be devices, interfaces to services, control

© 2005 by CRC Press LLC

points, and so on. This approach provides a uniform naming, structuring, and access control mechanism for all system resources. A network protocol, *Styx,* encodes file operations between client programs and the filesystem, and translates them into messages for transmission on a computer network.

LynxOS [13] from LynuxWorks Inc. is a layered system with a multithreaded, fully reentrant kernel. Of interest is an additional real-time scheduling policy, named *priority-based quantum;* it is similar to the round-robin policy, but it is possible to assign a different quantum length for each priority. In addition, it features full binary compatibility with Linux; hence, Linux program executables will run on it. Also supported are multiple address spaces and multiple processor privilege levels.

Nucleus [1] from Accelerated Technology is a highly modular and scalable operating system. Available modules range in complexity from an embedded electronic mail client, Nucleus EMAIL, to SSL support and can be configured at will. The kernel itself is seen as a replaceable module; several kernel "flavors" are available and are suitable for different application domains. For example, one of them, Nucleus OSEK, conforms with the OSEK/VDX specification [18], while another one, Nucleus MMU, incorporates support for memory protection when a hardware Memory Management Unit is available for use. Additional modules provide network support, the Controller Area Network in particular, filesystems, and graphics.

OS-9 [21] now from RadiSys Corporation, and formerly marketed by Microware, is based on a modular, layered kernel and supports a wide range of features, including networking, filesystems, and drivers for a variety of peripheral devices. Its footprint ranges from about 256 kilobytes for a base system, up to 8 megabytes for a full-fledged kernel including graphics and Java virtual machine support.

OSEK/VDX [18] is an open operating system specification developed as a joint project in the German automotive industry, later endorsed by many other partners. The main project goal is to support portability and reusability of automotive application software by means of a standard interface with the operating system and the communication network.

Thus, OSEK/VDX proposes itself as a less general, but more effective alternative to the POSIX set of standards in a well-defined application domain characterized by rather severe constraints on the available computing power, memory capacity, and network implementation.

The specification covers the operating system proper, communication, and network management; it has been implemented in many commercial products, for example [1,5,15,25,29,31]. Since the specification does not mandate any particular system architecture, implementors are free to choose the approach they prefer, provided the operating system interface conforms to the standard; even if most implementations adhere to the layered architecture, there is at least one microkernel-based implementation [25].

The OSEK/VDX specification does not support multiple address spaces, and the task set is defined statically at system generation time, thus removing the burden of dynamic task creation.

pSOSystem [32] is a modular, layered system with an extensive application programming interface, and conforms to POSIX multithreading and real-time signal standards. It includes filesystem and network support, and provides multiple, independent processes and memory protection on some platforms. Many kernel features are implemented as kernel components and libraries that can be freely included in the kernel configuration, or removed when they are not needed.

QNX [20] from QNX Software Systems Ltd. is based on a microkernel. It is a full-fledged, highly reliable operating system: thanks to its architecture, it is possible to cleanly terminate and restart any operating system module, including device drivers, upon software failure. In addition, the microkernel can be instrumented as a debugging aid in detecting timing problems and faults.

To aid the development of complex applications, it can also support symmetric multiprocessing (SMP) and distributed systems with little or no impact on application code, because the message passing paradigm implicit in microkernel-based operating systems can be extended transparently to handle those architectures. The native application programming interface fully conforms to the POSIX set of standard with many optional extensions implemented.

RTMX O/S [23] from RTMX Inc. is an extension to the freely available OpenBSD Unix-like operating system, which in turn was derived from the 4.4BSD system developed by the University of California at Berkeley and also informally known as "Berkeley Unix." Therefore, its design is heavily based on the traditional, monolithic design of the 4.4BSD operating system kernel.

© 2005 by CRC Press LLC

RTMX further enhances the already rich set of OpenBSD application programming interfaces with real-time functions, but the basic OpenBSD kernel cannot be scaled down very much, and is not well suited for small, resource-limited embedded platforms.

VxWorks [33] from Wind River Systems, Inc. is based on a message-passing microkernel. With over 1800 application program interfaces, it is a full-fledged operating system and also supports networking and filesystems. In spite of this, it is highly scalable, thanks to its microkernel-based architecture that allows most operating system modules to be removed when not in use; hence, it can run on very small embedded systems as well. Moreover, VxWorks supports on-the-fly replacement of system modules without restarting the whole system, to enhance reliability and service-ability.

Open Source Operating Systems

Many open source real-time operating systems are available, whose source code can be used both to develop real-world applications, and for study and experimentation. They usually do not claim conformance with the POSIX set of standards; instead, they often implement the most advanced, state-of-the-art architectures and algorithms because researchers can play with them at will and their work can immediately be reflected in real applications. Among the open source operating systems that have found their way into commercial products, we recall:

ChorusOS [26] was developed in origin by Sun Microsystems Inc. for embedded telecommunication applications and then was open sourced. It is a highly scalable system based on a microkernel architecture and configurable components; real-time scheduling policies and synchronization objects are component themselves, and can be either included or not in the operating system configuration.

Conformance with the POSIX set of standard is available, and provided by a group of operating system components. ChorusOS also supports filesystems, networking (both TCP/IP and ISO/OSI), virtual address spaces, and demand paging.

CREEM [11] is among the smallest real-time executives for microcontrollers, as it has the ability to run on small 8-bit processors with as little as 128 bytes of RAM. It is based on an unconventional dataflow application design and message passing, and implements only three operating system services. The system scheduling policy and task synchronization are entirely based on messages waiting for delivery, and the bulk of the scheduling algorithm is performed statically off-line. By contrast, it can be difficult to use, because its programming paradigm is not well known among programmers.

eCos [22] development is coordinated by Red Hat Inc. and is based on a modular, layered real-time kernel. The most important innovation in eCos is its extensive configuration system that operates at kernel build time with a large number of configuration points placed at source code level, and allows a very fine-grained adaptation of the kernel itself to both application needs and hardware characteristics. The output of the configuration process is an operating system library that can then be linked with the application code.

Its application programming interface is compatible with the POSIX set of standards, but it does not support multiple processes with independent address spaces, even when a Memory Management Unit is available.

μClinux [2] is a stripped-down version of the well-known Linux operating system; its most interesting features are the ability to run on microcontrollers that lack a Memory Management Unit and its small size, compared with a standard Linux kernel. As it is, μClinux does *not* have any real-time capability, because it inherits its standard processor scheduler from Linux; however, both RT-Linux [6] and RTAI [19] real-time extensions are available for it.

RT-Linux [6] and *RTAI* [19] are hard real-time-capable extensions to the Linux operating system; they are similar, and their architecture was first outlined in 1997 [3]. The main design feature of both RT-Linux and RTAI is the clear separation between the real-time and non-real-time domains: in RT-Linux and RTAI, a small monolithic real-time kernel runs real-time tasks, and coexists with the Linux kernel.

As a consequence, non-real-time tasks running on the Linux kernel have the sophisticated services of a standard time-sharing operating system at their disposal, whereas real-time tasks operate in a protected, predictable, and low-latency environment.

© 2005 by CRC Press LLC

The real-time kernel performs first-level real-time scheduling and interrupt handling, and runs the Linux kernel as its lowest priority task. In order to keep changes in the Linux kernel to an absolute minimum, the real-time kernel provides for an emulation of the interrupt control hardware. In particular, any interrupt disable/enable request issued by the Linux kernel is not passed to the hardware, but is emulated in the real-time kernel instead; thus, for example, when Linux disables interrupts, the hardware interrupts actually stay enabled and the real-time kernel queues and delays the delivery of any interrupt of interest to the Linux kernel. Real-time interrupts are not affected at all, and are handled as usual, without any performance penalty.

To handle communication between real-time and non-real-time tasks, RT-Linux and RTAI implement lock-free queues and shared memory. In this way, real-time applications can rely on Linux system services for non-time-critical operations, such as filesystem access and graphics user interface.

RTEMS [16] development is coordinated by On-Line Applications Research Corporation, which also offers paid technical support. Its application development environment is based on open-source GNU tools, and has a monolithic/layered architecture, commonly found in high-performance real-time executives.

RTEMS complies with the POSIX 1003.1b application programming interface and supports multiple threads of execution, but does not implement a multiprocess environment with independent application address spaces. It also supports networking and a filesystem.

University of Texas at Austin

89.1 Introduction

Embedded systems are pervasive in modern life. State-of-the-art embedded technology drives the ongoing revolution in consumer and communication electronics, and is the basis of substantial innovation in many other domains, including medical instrumentation, process control, etc. [MRW02]. The impact of embedded systems in well-established "traditional" industrial sectors, for example, automotive industry, is also increasing at a fast pace [MRW02, BGJ+97].

Unfortunately, as CMOS technology rapidly scales, enabling the fabrication of ever faster and denser integrated circuits (ICs), the challenges that must be overcome to deliver each new generation of electronic products multiply. In the last few years, power dissipation has emerged as a major concern. In fact, projections on power density increases due to CMOS scaling clearly indicate that this is one of the fundamental problems that will ultimately preclude further scaling [Bor99, ITR]. Although the power challenge is indeed considerable, much can be done to mitigate the deleterious effects of power dissipation, thus enabling performance and device density to be taken to truly unprecedented levels by the semiconductor industry throughout the next 10–15 years.

Power density has a direct impact on packaging and cooling costs, and can also affect system reliability, due to electro-migration and hot-electron degradation effects. Thus, the ability to decrease power density, while offering similar performance and functionality, critically enhances the competitiveness of a product. Moreover, for battery-operated portable systems, maximizing battery lifetime translates into

© 2005 by CRC Press LLC

maximizing the duration of service, an objective of paramount importance for this class of products. Power is thus a *primary figure of merit* in contemporaneous embedded system design.

Digital CMOS circuits have two main types of power dissipation: *dynamic* and *static.* Dynamic power is dissipated when the circuit performs the function(s) it was designed for, for example, logic and arithmetic operations (computation), data retrieval, storage, transport, etc. Ultimately, all these activities translate into switching of the logic states held on circuit nodes. Dynamic power dissipation is thus proportional to C, $V_{DD}^2 fr$, where C denotes the total circuit capacitance, V_{DD} and f denote the circuit supply voltage and clock frequency, respectively, and r denotes the fraction of transistors expected to switch at each clock cycle [PR02, GGH97]. In other words, dynamic power dissipation is impacted to first order by circuit size/complexity, speed/rate, and switching activity. In contrast, static power dissipation is associated with preserving the logic state of circuit nodes between such switching activity, and is caused by subthreshold leakage mechanisms. Unfortunately, as device sizes shrink, the severity of leakage power is increasing at an alarming pace [Bor99].

Clearly, the power problem must be addressed at all levels of the design hierarchy, from system to circuit, as well as through innovations on CMOS device technology [CSB92, PR02, JYWV03]. In this survey, we provide a snapshot on the state of the art on *system* and *architecture level* design techniques and methodologies aimed at reducing both static and dynamic power dissipation. Since such techniques focus on the highest level of the design hierarchy, their potential benefits are immense. In particular, at this high level of abstraction, the specifics of each particular class of embedded applications can be considered as a *whole* and, as it will be shown in our survey, such an ability is critical to designing power/energy efficient systems, that is, systems that spend energy strictly when and where it is needed. Broadly speaking, this requires a proper *design* and *allocation* of *system resources,* geared toward addressing critical performance bottlenecks in a power–efficient way. Substantial power/energy savings can also be achieved through the implementation of adequate *dynamic power management policies,* for example., tracking instantaneous workloads (or levels of resource utilization) and "shutting down" idling/unused resources, so as to reduce leakage power, or "slowing down" under utilized resources, so as to decrease dynamic power dissipation. These are clearly system level decisions/policies, in that their implementation typically impacts several architectural subsystems. Moreover, different decisions/policies may interfere or conflict with each other and, thus, assessing their overall effectiveness requires a system-level (i.e., *global)* view of the problem.

A typical embedded system architecture consists of a *processing subsystem* (including one or more processor cores, hardware accelerators, etc.), a *memory subsystem, peripherals,* and global and local *interconnect structures* (buses, bridges, crossbars, etc.). Figure 89.1 shows an abstract view of two such architecture instances. Broadly speaking, system-level design consists of defining the specific embedded system architecture to be used for a particular product, as well as defining how the target embedded application (implementing the required functionality/services) is to be mapped into that architecture.

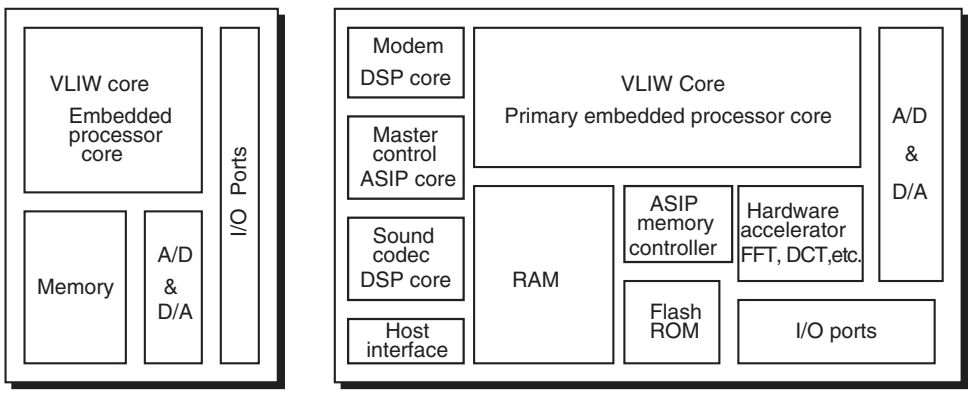

FIGURE 89.1 Illustrative examples of a simple and a more complex embedded system architecture.

© 2005 by CRC Press LLC

Embedded systems come in many varieties and with many distinct design optimization goals and requirements. Even when two products provide the same basic functionality, say, video encoding/decoding, they may have fundamentally different characteristics, namely, different performance and quality-of-service requirements: one may be battery operated and the other not, etc. The implications of such product differentiation are of paramount importance when power/energy are considered. Clearly, the higher the system's required performance/speed (defined by metrics such as throughput, latency, bandwidth, response time, etc.), the higher its power dissipation. The key objective is thus to *minimize* the power dissipated to deliver the required level of performance [CB95a, PR02]. The trade-offs, techniques, and optimizations required to develop such *power-aware* or *power-efficient* designs vary widely across the vast spectrum of embedded systems available in today's market, encompassing many complex decisions driven by system requirements as well as intrinsic characteristics of the target applications [MSS+03].

Consider, for example, the design task of deciding on the number and type of processing elements to be instantiated on an embedded architecture, that is, defining its *processing subsystem.* Power, performance, cost, and time-to-market considerations dictate if one should rely entirely on readily available processors (i.e., off-the-shelf micro-controllers, DSPs, and/or general-purpose RISC cores), or one should also consider custom execution engines, namely, application-specific instruction set processors (ASIPs), possibly reconfigurable, and/or hardware accelerators (see Figure 89.1). *Hardware/software partitioning* is a critical step in this process [MRW02]. It consists of deciding which of an application's segments/functions should be implemented in *software* (i.e., run on a processor core) and which (if any) should be implemented in *hardware* (i.e., execute on high-performance, highly power-efficient custom hardware accelerators). Naturally, hardware/software partitioning decisions should reflect the power/performance criticality of each such segment/function. Clearly, this is a complex multiobjective optimization problem defined on a huge design space that encompasses, both *hardware*- and *software*-related decisions. To compound the problem, the performance and energy efficiency of an architecture's processing subsystem cannot be evaluated in isolation, since its effectiveness can be substantially impacted by the memory subsystem (i.e., the adopted memory hierarchy/organization) and the interconnect structures supporting communication/data-transfers between processing components and to/from the environment in which the system is embedded. Thus, decisions with respect to these other subsystems and components must be concurrently made and jointly assessed.

Targeting up front a specific *embedded system platform,* that is, an architectural "subspace" relevant to a particular class of products/applications, can considerably reduce the design effort [VM01, RV02]. Still, the design space remains (typically) so complex that a substantial *design space exploration* may be needed in order to identify power/energy efficient solutions for the specified performance levels. Since *time to market* is critical, methodologies to efficiently drive such an exploration, as well as fast simulators and low complexity (yet good fidelity) performance, power and energy estimation models, are critical to aggressively exploiting effective power/energy-driven optimizations, within a reasonable time frame.

Our survey starts by providing an overview on state-of-the-art models and tools used to evaluate the goodness of individual system design points. We then discuss power management techniques and optimizations aimed at aggressively improving the power/energy efficiency of the various subsystems of an embedded system.

89.2 Energy and Power Modeling

This section discusses *high-level* modeling and power estimation techniques aimed at assisting system and architecture-level design. It would be unrealistic to expect a high degree of accuracy on power estimates produced during such an early design phase, since accurate power modeling requires detailed physical-level information that may not yet be available. Moreover, highly accurate estimation tools (working with detailed circuit/layout-level information) would be too time consuming to allow for any reasonable degree of design space exploration [MRW02, PR02, BHLM94].

Thus, practically speaking, power estimation during early design space exploration should aim at ensuring a high degree of *fidelity* rather than necessarily *accuracy.* Specifically, the primary objective

© 2005 by CRC Press LLC

during this critical exploration phase is to assess the *relative* power efficiency of different candidate system architectures (populated with different hardware and/or software components), the *relative* effectiveness of alternative software implementations (of the same functionality), the *relative* effectiveness of different power management techniques, etc. Estimates that correctly expose such relative power trends across the design space region being explored provide the designer with the necessary information to guide the exploration process.

Instruction and Function Level Models

Instruction-level power models are used to assess the relative power/energy efficiency of different processors executing a given target embedded application, possibly with alternative memory subsystem configurations. Such models are thus instrumental during the definition of the main subsystems of an embedded architecture, as well as during hardware/software partitioning. Moreover, instruction-level power models can also be used to evaluate the relative effectiveness of different software implementations of the same embedded application, in the context of a specific embedded architecture/platform.

In their most basic form, instruction-level power models simply assign a power cost to each assembly instruction (or class of assembly instructions) of a programmable processor. The overall energy consumed by a program running on the target processor is estimated by summing up the instruction costs for a dynamic execution trace, which is representative of the application [TMW94, CP92, RJ98, BFSS00].

Instruction-level power models were first developed by experimentally measuring the current drawn by a processor while executing different instruction sequences [TMW94]. During this first modeling effort, it was observed that the power cost of an instruction may actually depend on previous instructions. Accordingly, the instruction-level power models developed in [TMW94] include several interinstruction effects. Later studies observed that, for certain processors, the power dissipation incurred by the hardware responsible for fetching, decoding, analyzing and issuing instructions, and then routing and reordering results, was so high that a simpler model that only differentiates between instructions that access *on-chip* resources and those that go *off-chip* would suffice for such processors [RJ98].

Unfortunately, power estimation based on instruction-level models can still be prohibitively time consuming during early design space exploration, since it requires collecting and analyzing large instruction traces and, for many processors, considering a quadratically large number of interinstruction effects. In order to "accelerate" estimation, processor-specific coarser *function-level* power models were later developed [QKUP00]. Such approaches are faster because they rely on the use of macromodels characterizing the *average energy consumption* of a library of functions/subroutines executing on a target processor [QKUP00]. The key challenge in this case is to devise macro-models that can properly quantify the power consumed by each subroutine of interest, as a function of "easily observable parameters." Thus, for example, a quadratic power model of the form $an^2 + bn + c$ could be first tentatively selected for a *insertion sort* routine, where n denotes the number of elements to be sorted. Actual power dissipation then needs to be measured for a large number of experiments, run with different values of n. Finally, the values of the macromodel's coefficients a, b, and c are derived, using regression analysis, and the overall accuracy of the resulting macro-model is assessed [QKUP00].

The "high-level" instruction and function-level power models discussed so far allow designers to "quickly" assess a large number of candidate system architectures and alternative software implementations, so as to narrow the design space to a few promising alternatives. Once this initial broad exploration is concluded, power models for each of the architecture's main subsystems and components are needed, in order to support the detailed architectural design phase that follows.

Micro-architectural Models

Micro-architectural power models are critical to evaluating the impact of different processing subsystem choices on power consumption, as well as the effectiveness of different (micro-architecture level) power management techniques implemented on the various subsystems.

© 2005 by CRC Press LLC

In the late 1980s and early 1990s, cycle accurate (or more precisely, cycle-by-cycle) simulators, such as Simplescalar [BA97], were developed to study the effect of architectural choices on the performance of general-purpose processors. Such simulators are in general very flexible, allowing designers/architects to explore the complex design space of contemporaneous processors. Namely, they include built-in parameters that can be used to specify the number and mix of functional units to be instantiated in the processor's datapath, the issue width of the machine, the size and associativity of the L1 and L2 caches, etc. By varying such parameters, designers can study the performance of different machine configurations for representative applications/benchmarks. As power consumption became more important, simulators to estimate *dynamic* power dissipation (e.g., "Wattch [BTM00]," "Cai-Lim model [CL99]," and "Simplepower [YVKI00]") were later incorporated into these existing frameworks. Such an integration was performed seamlessly, by directly augmenting the "cycle-oriented" performance models for the various micro-architectural components with corresponding power models.

Naturally, the overall accuracy of these simulation-based power estimation techniques is determined by the level of detail of the power models used for the micro-architecture's constituent components. For out-of-order RISC cores, for example, the power consumed in finding independent instructions to issue is a function of the number of instructions currently in the instruction queue and of the actual dependencies between such instructions. Unfortunately, the use of detailed power models accurately capturing the impact of input and state data on the power dissipated by each component would prohibitively increase the already "long" micro-architectural simulation runtimes. Thus, most state-of-the-art simulators use very simple/straightforward empirical power models for datapath and control logic, and slightly more sophisticated models for regular structures such as caches [BTM00]. In their simplest form, such models capture "typical" or "average" power dissipation for each individual micro-architectural component. Specifically, each time a given component is accessed/used during a simulation run, it is assumed that it dissipates its corresponding "average" power. Slightly more sophisticated power macromodels for datapath components have been proposed in [JKSN99, BBM00, TGTS98, KE98, CRC00, MG01], and have shown to improve accuracy with a relatively small impact on simulation time.

So far, we have discussed power modeling of micro-architectural components; yet, a substantial percentage of the overall power budget of a processor is actually spent on the *global clock* (up to 40–45% [PR02]). Thus, global clock power models must also be incorporated in these frameworks. The power dissipated on global clock distribution is impacted to first order by the number of pipeline registers (and thus by a processor's pipeline depth) and by global and local wiring capacitances (and thus by a processor's core area) [PR02]. Accordingly, different processor cores and/or different configurations of the same core may dissipate substantially different clock distribution power. Power estimates incorporating such numbers are thus critical during processor core selection and configuration.

The component-level and clock distribution models discussed so far are used to estimate the dynamic power dissipation of a target micro-architecture. Yet, as mentioned above, static/leakage power dissipation is becoming a major concern, and thus, micro-architectural techniques aimed at reducing leakage power are increasingly relevant. Models to support early estimation of static power dissipation emerged along the same lines as those used for dynamic power dissipation. The "Butts–Sohi" model, which is one of the most influential static power models developed so far, quantifies static energy in CMOS circuits/components using a lumped parameter model that maps *technology* and *design* effects into corresponding characterizing parameters [BS00]. Specifically, static power dissipation is modeled as $V_{DD}Nk_{design}I_{leak}$, where V_{DD} is the supply voltage and N denotes the number of transistors in the circuit. k_{design} is the *design-dependent* parameter — it captures "circuit style"-related characteristics of a component, including average transistor aspect ratio, average number of transistors switched off during "normal/typical" component operation, etc. Finally, I_{leak} is the *technology-dependent* parameter. It accounts for the impact of threshold voltage, temperature, and other key parameters, on leakage current, for a specific fabrication process.

From a system designer's perspective, static power can be reduced by lowering supply voltage (V_{DD}), and/or by *power supply gating* or V_{DD}-gating (as opposed to clock-gating) unused/idling devices (N). Integrating models for estimating static power dissipation on cycle-by-cycle simulators thus enables embedded system designers to analyze critical static power versus performance tradeoffs enabled by "power-aware"

© 2005 by CRC Press LLC

features available in contemporaneous processors, such as dynamic voltage scaling and selective datapath (re)configuration. An improved version of the "Butts–Sohi" model, providing the ability to dynamically recalculate leakage currents (as temperature and voltage change due to operating conditions and/or dynamic voltage scaling), has been integrated into the Simplescalar simulation framework, called "HotLeakage," enabling such high-level trade-offs to be explored by embedded system designers [ZPS+03].

Memory and Bus Models

Storage elements, such as caches, register files, queues, buffers, and tables constitute a substantial part of the power budget of contemporaneous embedded systems [PAC+97]. Fortunately, the high regularity of some such memory structures (e.g., caches) permits the use of simple, yet reasonably accurate power estimation techniques, relying on automatically synthesized "structural designs" for such components.

The Cache Access and Cycle TIme (CACTI) framework implements this synthesis-driven power estimation paradigm. Specifically, given a specific cache hierarchy configuration (defined by parameters such as cache size, associativity, and line size), as well as information on the minimum feature size of the target technology [WJ96], it internally generates a coarse structural design for such cache configuration. It then derives delay and power estimates for that particular design, using parameterized built-in C models for the various constituent elements, namely, SRAM cells, row and column decoders, word and bit lines, precharge circuitry, etc. [KG97, RJ01].

CACTI's synthesis algorithms used to generate the structural design of the memory hierarchy (which include defining the aspect ratio of memory blocks, the number of instantiated subbanks, etc.) have been shown to consistently deliver reasonably "good" designs across a large range of cache hierarchy parameters [RJ01]. CACTI can thus be used to "quickly" generate power estimates (starting from high-level architectural parameters) exhibiting a reasonably good fidelity over a large region of the design space. During design space exploration, the designer may thus consider a number of alternative L1 and L2 cache configurations and use CACTI to obtain "access-based" power dissipation estimates for each such configuration with good fidelity. Naturally, the memory access traces used by CACTI should be generated by a micro-architecture simulator (e.g., Simplescalar) working with a memory simulator (e.g., Dinero [EH98]), so that they reflect the bandwidth requirements of the embedded application of interest.

Buses are also a significant contributor to dynamic power dissipation [PR02, CWD+98]. The dynamic power dissipation on a bus is proportional to $CV_{DD}^2 fa$, where C denotes the total capacitance of the bus (including metal wires and buffers), V_{DD} denotes the supply voltage, and fa denotes the average switching frequency of the bus [CWD+98]. In this high-level model, the average switching frequency of the bus (fa) is defined by the product of two terms, namely, the average number of bus transitions per word, and the bus frequency (given in bus words per second). The average number of bus transitions per word can be estimated by simulating sample programs and collecting the corresponding transition traces. Although this model is coarse, it may suffice during the early design phases under consideration.

Battery Models

The capacity of a battery is a nonlinear function of the current drawn from it, that is, if one increases the average current drawn from a battery by a factor of two, the "remaining" *deliverable battery capacity,* and thus its lifetime, decreases by more than half. Peukert's formula models such nonlinear behavior by defining the capacity of a battery as k/I^{α}, where k is a constant depending on the battery design, I is the discharge current, and α quantifies the "nonideal" behavior of the battery [MS96].[1] More effective system-level trade-offs between quality/performance and duration of service can be implemented by taking such nonlinearity (also called *rate-capacity* effect) into consideration. However, in order to properly evaluate the effectiveness of such techniques/trade-offs during system-level design, adequate battery models and metrics are needed.

[1]For an "ideal" battery, that is, a battery whose capacity in independent of the way current is drawn, $\alpha = 0$, while for a real battery α may be as high as 0.7 [MS96].

© 2005 by CRC Press LLC

Energy-delay product is a well-known metric used to assess the energy efficiency of a system. It basically quantifies a system's performance loss per unit gain in energy consumption. To emphasize the importance of accurately exploring key tradeoffs between *battery lifetime* and *system performance,* a new metric, viz., *battery-discharge delay product,* has recently been proposed [PW02]. Task scheduling strategies and dynamic voltage scaling policies adopted for battery-operated embedded systems should thus aim at minimizing battery-discharge delay product, rather than energy-delay product, since it captures the important rate-capacity effect alluded to above, whereas energy-delay product is insensitive to it. Yet, a metric such as battery-discharge delay product requires the use of precise/detailed battery models. One such detailed battery model has been recently proposed, which can predict the remaining capacity of a rechargeable lithium-ion battery in terms of several critical factors, viz., discharge-rate (current), battery output voltage, battery temperature, and cycle age (i.e., the number of times a battery has been charged and discharged) [RP03].

89.3 System/Application-Level Optimizations

When designing an embedded system, in particular, a battery-powered one, it may be useful to explore different *task implementations* exhibiting different power/energy vs. quality-of-service characteristics, so as to provide the system with the desired functionality while meeting cost, battery lifetime, and other critical requirements. Namely, one may be interested in trading off accuracy for energy savings on a handheld GPS system, or image quality for energy savings on an image decoder, etc. [SCB96, QP99, SBGM00]. Such application-level "tuning/optimizations" may be performed statically (i.e., one may use a single implementation for each task) or may be performed at runtime, under the control of a system-level power manager. For example, if the battery level drops below a certain threshold, the power manager may drop some services and/or swap some tasks to less power-hungry ("lower quality") software versions, so that the system can remain operational for a specified window of additional time. An interesting example of such dynamic power management was implemented for the Mars Pathfinder, an unmanned space robot that draws power from both a nonrechargeable battery and solar cells [LCBK01]. In this case, the power manager tracks the power available from the solar cells, ensuring that most of the robot's active work is done during daylight, since the solar energy cannot be stored for later use.

In addition to dropping and/or swapping tasks, a system's dynamic power manager may also shut down or slow down subsystems/modules that are idling or underutilized. The Advanced Configuration and Power Interface (ACPI) is a widely adopted standard that specifies an interface between an architecture's power managed subsystems/modules (e.g., display drivers, modems, hard-disk drivers, processors, etc.) and the system's dynamic power manager. It is assumed that the power-managed subsystems have at least two power states (ACTIVE and STANDBY) and that one can dynamically switch between them. Using ACPI, one can implement virtually any power management policy, including fixed time-out, predictive shutdown, predictive wake-up, etc. [ACP]. Since the transition from one state to another may take a substantial amount of time and consume a nonnegligible amount of energy, the selection of a proper power management policy for the various subsystems is critical to achieve good energy savings with a negligible impact on performance. The so-called time-out policy, widely used in modern computers, simply switches a subsystem to STANDBY mode when the elapsed time after the last utilization reaches a given fixed threshold. Predictive shutdown uses the previous history of the subsystem to predict the next expected idle time and, based on this, decides if it should or should not be shut down. More sophisticated policies, using stochastic methods [SCB96, QP99, SBGM00, SBA+01], can also be implemented; yet, they are more complex, and thus the power associated with running the associated dynamic power management algorithms may render them inadequate or inefficient for certain classes of systems.

The system-level techniques discussed above act on each subsystem as a whole. Although the effectiveness of such techniques has been demonstrated across a wide variety of systems, finer-grained self-monitoring techniques, implemented at the subsystem level, can substantially add to these savings. Such techniques are discussed in the following sections.

© 2005 by CRC Press LLC

89.4 Energy-Efficient Processing Subsystems

As mentioned earlier, hardware/software codesign methodologies partition the functionality of an embedded system into hardware and software components. Software components, executing on programmable micro-controllers or processors (either general-purpose or application-specific) are the preferred solution, since their use can substantially reduce design and manufacturing costs, as well as shorten time-to-market. Custom hardware components are typically used only when strictly necessary, namely, when an embedded system's power budget and/or performance constraints preclude the use of software. Accordingly, a large number of power-aware processor families are available in today's market, providing a vast gamut of alternatives suiting the requirements/needs of most embedded system [GH96, BB96]. In the sequel, we discuss power-aware features available in contemporaneous processors, as well as several power-related issues relevant to processor core selection.

Voltage and Frequency Scaling

Dynamic power consumption in a processor (be it general-purpose or application-specific) can be decreased by reducing two of its key contributors, viz., supply voltage and clock frequency. In fact, since the power dissipated in a CMOS circuit is proportional to the square of the supply voltage, the most effective way to reduce power is to scale down the supply voltage. Note, however, that the propagation delay across a CMOS transistor is proportional to $V_{DD}/(V_{DD} - V_T)^2$, where V_{DD} is the supply voltage and V_T is the threshold voltage. So, unfortunately, as the supply voltage decreases, the propagation delay increases as well, and so clock frequency (i.e., speed) may need to be decreased [IY98].

Accordingly, many contemporaneous processor families, such as Intel's XScale [INT], IBM's PowerPC 405LP [IBM], and Transmeta's Crusoe [TRA], offer *dynamic voltage and frequency scaling* features. For example, the Intel 80200 processor, which belongs to the XScale family of processors mentioned above, supports a software-programmable clock frequency. Specifically, the voltage can be varied from 1.0 to 1.5 V, in small increments, with the frequency varying correspondingly from 200 to 733 MHz, in steps of 33/66 MHz.

The simplest way to take advantage of the scaling features discussed above is by carefully identifying the "smallest" supply voltage (and corresponding operating frequency) that guarantee that the target embedded application meets its timing constraints, and run the processor for that fixed setting. If the workload is reasonably constant throughout execution, this simple scheme may suffice. However, if the workload varies substantially during execution, more sophisticated techniques that dynamically adapt the processor's voltage and frequency to the varying workload can deliver more substantial power savings. Naturally, when designing such techniques it is critical to consider the cost of transitioning from one setting to another, that is, the delay and power consumption overheads incurred by each transition. For example, for the Intel 80200 processor mentioned above, changing the processor frequency could take up to 20 μsec, while changing the voltage could take up to 1 msec [INT].

Most processors developed for the mobile/portable market already support some form of built-in mechanism for voltage/frequency scaling. Intel's SpeedStep technology, for example, detects if the system is currently plugged into a power outlet or running on a battery, and based on that, either runs the processor at the highest voltage/frequency or switches it to a less power-hungry mode. Transmeta's Crusoe processors offer a power manager called LongRun [TRA], which is implemented in the processor's firmware. LongRun relies on the historical utilization of the processor to guide clock rate selection: it increases the processor's clock frequency if the current utilization is high and decreases it if the utilization is low.

More sophisticated/aggressive dynamic scaling techniques should vary the core's voltage/frequency based on some predictive strategy, while carefully monitoring *performance,* so as to ensure that it does not drop beyond a certain threshold and/or that task deadlines are not consistently missed [WWDS94, GCW95, PBB98, PBB00] (see Figure 89.2). The use of such voltage/frequency scaling techniques must necessarily rely on adequate dynamic workload prediction and performance metrics, and thus requires the direct intervention of the operating system and/or of the applications themselves. Although more complex than the

© 2005 by CRC Press LLC

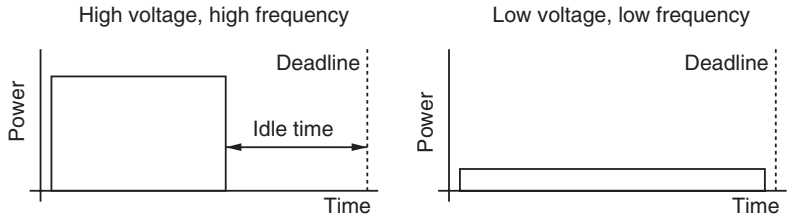

FIGURE 89.2 Power consumption without and with dynamic voltage and frequency scaling.

simple schemes discussed above, several such predictive techniques have been shown to deliver substantial gains for applications with well-defined task deadlines, for example, hard/soft real-time systems.

Simple *interval-based prediction schemes* consider the amount of idle time on a previous interval as a measure of the processor's utilization for the next time interval, and use that prediction to decide on the voltage/frequency settings to be used throughout its duration. Naturally, many critical issues must be factored when defining the duration of such an interval (or "prediction window"), including overhead costs associated with switching voltage/frequency settings. While a prediction scheme based on a single interval may deliver substantial power gains with marginal loss in performance [WWDS94], looking exclusively at a single interval may not suffice for many applications. Namely, the voltage/frequency settings may end up oscillating in an inefficient way between different settings [GCW95]. Simple smoothing techniques, for example, using an exponentially moving average of previous intervals, can be used to mitigate the problem [GCW95, FRM02].

Finally, note that, the benefits of dynamic voltage and frequency scaling are not limited to reducing dynamic power consumption. When the voltage/frequency of a battery-operated system is lowered, the instantaneous current drawn by the processor decreases accordingly, leading to a more effective utilization of the battery capacity, and thus to increased duration of service.

Dynamic Resource Scaling

Dynamic resource scaling refers to exploiting adaptive, fine-grained hardware resource reconfiguration techniques in order to improve power efficiency. Dynamic resource scaling requires enhancing the micro-architecture with the ability to selectively "disable" components, fully or partially, through either *clock gating* or V_{DD}*-gating.*[2] The effectiveness of dynamic resource scaling is predicated on the fact that many applications have variable workloads, that is, have execution phases with substantial instruction-level parallelism (ILP), and other phases with much less inherent parallelism. Thus, by dynamically "scaling down" micro-architecture components during such "low activity" periods, substantial power savings can potentially be achieved.

Techniques for reducing *static* power dissipation on processor cores can definitely exploit resource scaling features, once they become widely available on processors. Namely, underutilized or idling resources can be partially or fully V_{DD}-gated, thus reducing leakage power. Several utilization-driven techniques have already been proposed, which can selectively shut down functional units, segments of register files, and other datapath components, when such conditions arise [BM00, DKA+02, PKG01, BAB+02]. Naturally, the delay overhead incurred by power supply gating should be carefully factored into these techniques, so that the corresponding static energy savings are achieved with only a small degradation in performance.

Dynamic energy consumption can be also reduced by dynamically "scaling down" power-hungry micro-architecture components, for example, reducing the size of the issue window and/or reducing the effective width of the pipeline, during periods of low "activity" (say, when low ILP code is being executed). Moreover, if one is able to scale down these micro-architecture components that define the critical path delay of the machine's pipeline (typically located on the rename and window access stages), additional

[2]Note that, in contrast to clock gating, all state information is lost when a circuit is V_{DD}-gated

© 2005 by CRC Press LLC

opportunities for voltage scaling, and thus dynamic power savings, can be created. This is thus a very promising area still undergoing intensive research [HSA01].

Processor Core Selection

The power aware techniques discussed thus far can be broadly applied to general-purpose as well as application-specific processors. Naturally, the selection of processor core(s) to be instantiated in the architecture's processing subsystem is likely to also have a substantial impact on overall power consumption, particularly when computation-intensive embedded systems are considered. A plethora of programmable processing elements, including micro-controllers, general-purpose processors, digital signal processors (DSPs), and application-specific instruction set processors (ASIPs), addressing the specific needs of virtually every segment of the embedded systems' market, is currently offered by vendors.

As alluded to above, for computation-intensive embedded systems with moderately high to stringent timing constraints, the selection of processor cores is particularly critical, since high-performance usually signifies high levels of power dissipation. For these systems, ASIPs and DSPs have the potential to be substantially more energy efficient than their general-purpose counterparts; yet, their "specialized" nature poses significant compilation challenges[3] [JdV00]. In contrast, general-purpose processors are easier to compile to, being typically shipped with good optimizing compilers, as well as debuggers and other development tools. Unfortunately, their "generality" incurs a substantial power overhead. In particular, high-performance general-purpose processors require the use of power-hungry hardware assists, including reservation stations, reorder buffers and rename logic, and complex branch prediction logic to alleviate control stalls. Still, their flexibility and high-quality development tools are very attractive for systems with stringent time-to-market constraints, making them definitively relevant for embedded systems.

IBM/Motorola's PowerPC family and the ARM family are examples of "general-purpose" processors enhanced with power-aware features that are widely used in modern embedded systems. A plethora of specialized/customizable processors is also offered by several vendors, including *specialized media cores* from Philips, Trimedia, MIPS, etc., *DSP cores* offered by Texas Instruments, StarCore and Motorola, and *customizable cores* from Hewlett-Packard-STMicroelectronics and Tensilica.

The ISAs and features offered on these specialized processors can vary substantially, since they are designed and optimized for different classes of applications. However, several of them, including TI's TMS320C6x family, HP-STS's Lx, the Starcore and Trimedia families, and Philip's Nexperia use a "Very Large Instruction Word" (VLIW) [CND+88, BYA93] or "Explicitly Parallel Instruction Computing" (EPIC) [SR00] paradigm. One of the key differences between VLIW and superscalar architectures is that VLIW machines rely on the compiler to extract instruction-level parallelism, and then schedule and bind instructions to functional units *statically,* while their high-performance superscalar counterparts use dedicated (power hungry) hardware to perform run-time dependence checking, instruction reordering, etc. Thus, in broad terms, VLIW machines eliminate power-hungry micro-architecture components by moving the corresponding functionality to the compiler.[4] Moreover, wide VLIW machines are generally organized as a set of small clusters with local register files.[5] Thus, in contrast to traditional superscalar machines, which rely on power-hungry multi-ported monolithic register files, multicluster VLIW machines scale better with increasing issue widths, for example, dissipate less dynamic power and can work at faster clock rates. Yet, they are harder to compile to [HHG+95, Ell85, DT93, DKK+99, JdVL00, LJdV02, PJ03]. In summary, the VLIW paradigm works very well for many classes of embedded applications, as attested to by the large number of VLIW processors currently available in the market. However, it poses substantial compilation challenges, some of which are still undergoing active research [MG95, Lie97, JYWV03]. Fortunately, many processing-intensive embedded applications have

[3]Several DSP/ASIP vendors provide preoptimized assembly libraries to mitigate this problem.

[4]Since functional unit binding decisions are made by the compiler, VLIW code is larger than RISC/superscalar code. We will discuss techniques to address this problem later in our survey.

[5]A cluster is a set of functional units connected to a local register file. Clusters communicate with each other through a dedicated interconnection network.

© 2005 by CRC Press LLC

only a few time-critical loop kernels. Thus, only a very small percentage of the overall code needs to be actually subject to the complex, time-consuming compiler optimizations required by VLIW machines. In the case of media applications, for example, such loop kernels may represent as little as 3% of the overall program, and yet take up to 95% of the execution time [FWL99].

When the performance requirements of an embedded system are extremely high, using a dedicated coprocessor aimed at accelerating the execution of time-critical kernels (under the control of a host computer) may be the only feasible solution. Imagine, one such programmable coprocessor, was designed to accelerate the execution of kernels of streaming media applications [KDR+01]. It can deliver up to 20 GFLOPS at a relatively low power cost (2 GFLOPS/W); yet, such a power efficiency does not come without a cost [KDR+01]. As expected, Imagine has a complex programming paradigm, that requires extracting all time-critical kernels from the target application, and carefully reprogramming them using Imagine's "stream-oriented" coding style, so that both data and instructions can be efficiently routed from the host to the accelerator. Programming Imagine thus requires a substantial effort, yet its *power-efficiency* makes it very attractive for systems that demand such high levels of performance. Finally, at the highest end of the performance spectrum, one may need to consider using fully customized hardware accelerators. Comprehensive methodologies to design such accelerators are discussed in detail in [RMV+87].

89.5 Energy-Efficient Memory Subsystems

While processor speeds have been increasing at a very fast rate (about 60% a year), memory performance has increased at a comparatively modest rate (about 7% a year), leading to the well-known "processor-memory performance gap" [PAC+97]. In order to alleviate the memory access latency problem, modern processor designs use increasingly large on-chip caches, with up to 60% of the transistors dedicated to on-chip memory and support circuitry [PAC+97]. As a consequence, power dissipation in the memory subsystem contributes to a substantial fraction of the energy consumed by modern processors. A study targeting the StrongARM SA-110, a low-power processor widely used in embedded systems, revealed that more than 40% of the processor's power budget is taken up by on-chip data and instruction caches [MWA+96]. For high-performance general-purpose processors, this percentage is even higher, with up to 90% of the power budget consumed by memory elements and circuits aimed at alleviating the aforementioned memory bottleneck [PAC+97]. Power-aware memory designs have thus received considerable attention in recent years.

Cache Hierarchy Tuning

The energy cost of accessing data/instructions from off-chip memories can be as much as two orders of magnitude higher than that of an access to on-chip memory [HWO97]. By retaining instructions and data with high spatial and/or temporal locality on-chip, caches can substantially reduce the number of costly off-chip data transfers, thus leading to potentially quite substantial energy savings.

The "one-size-fits-all" nature of the general-purpose domain dictates that one should use large caches with a high degree of associativity, so as to try to ensure high hit rates (and thus low average memory access latencies) for as many applications as possible. Unfortunately, as one increases cache size and associativity, larger circuits and/or more circuits are activated on each access to the cache, leading to a corresponding increase in dynamic energy consumption.

Clearly, in the context of embedded systems, one can do much better. Specifically, by carefully tuning/scaling the configuration of the cache hierarchy, so that it more efficiently matches the bandwidth requirements and access patterns of the target embedded application, one can essentially achieve memory access latencies similar to those delivered by "larger" (general-purpose) memory subsystems, while substantially decreasing the average energy cost of such accesses.

Since several of the cache hierarchy parameters exhibit conflicting trends, an aggressive design space exploration over many candidate cache configurations is typically required in order to properly tune the cache hierarchy of an embedded system. Figure 89.3 summarizes the results of one such design space exploration performed for a media application. Namely, the graph in Figure 89.3 plots the energy-delay

© 2005 by CRC Press LLC

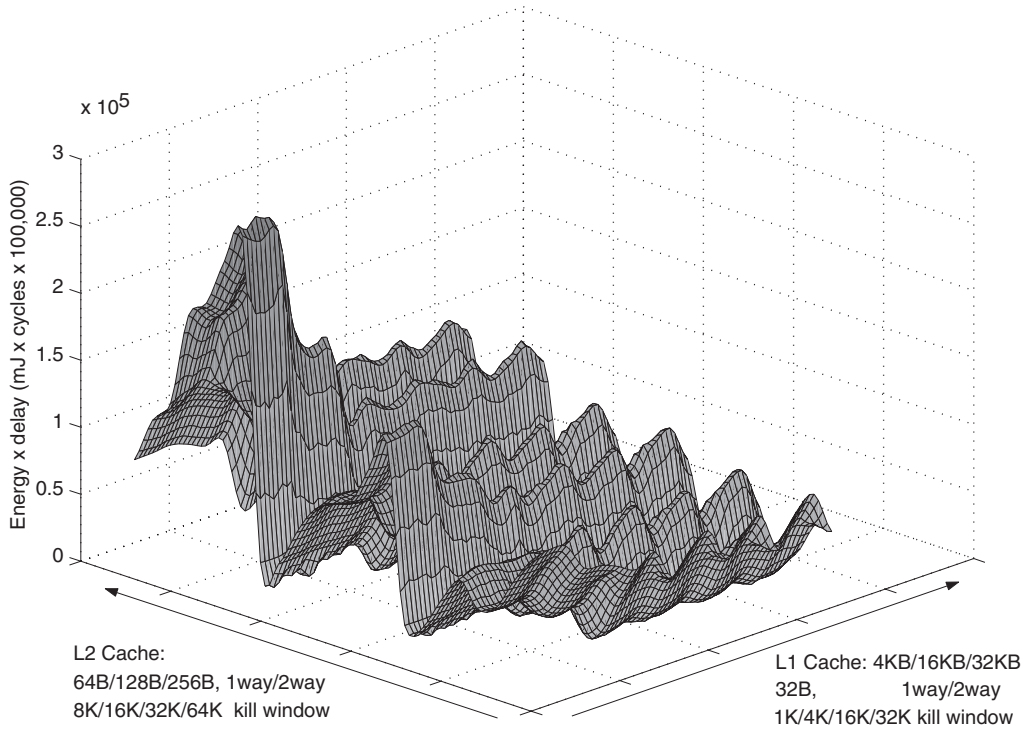

FIGURE 89.3 Design space exploration: energy-delay porduct for various L1 and 12 L2 D-cache configurations for a JPEG applicatoin running on an Xscale-like processor core.

product metric for a wide range of L1 and L2 on-chip D-cache configurations. The delay term is given by the number of cycles taken to process a representative data set from start to completion. The energy term accounts for the energy spent on data memory accesses for the particular execution trace.[6] As can be seen, the design space is very complex, reflecting the conflicting trends alluded to above. For this case study, the best set of cache hierarchy configurations exhibit an energy-delay product that is about one order of magnitude better (i.e., lower) than that of the worst configurations. Perhaps even more interesting, some of the worst memory subsystem configurations use quite large caches with a high degree of associativity, clearly indicating that no substantial performance gains would be achieved (for this particular media application) by using such an aggressively dimensioned memory subsystem.

For many embedded systems/applications, the power efficiency of the memory subsystems can be improved even more aggressively; yet, this requires the use of novel (nonstandard) memory system designs, as discussed in the sections that follow.

Novel Horizontal and Vertical Cache Partitioning Schemes

In recent years, several novel cache designs have been proposed to aggressively reduce the average *dynamic energy consumption* incurred by memory accesses. Energy efficiency is improved in these designs by taking direct advantage of specific characteristics of target classes of applications. The memory footprint of instructions and data in *media applications,* for example, tend to be very small, thus creating unique opportunities for energy savings [FWL99]. Since streaming media applications are pervasive in today's portable electronics market, they have been a preferred application domain for validating the effectiveness of such novel cache designs.

[6]Specifically, the energy term accounts for accesses to the on-chip L1 and L2 D-caches, and to main memory.

© 2005 by CRC Press LLC

Vertical partition schemes [GK99, SD95, KGMS00, FTS95], as the name suggests, introduce additional small buffers/caches *before* the first level of the "traditional" memory hierarchy. For applications with "small" working sets, this strategy can lead to considerable dynamic power savings.

A concrete example of a vertical partition scheme is the *filter cache* [KGMS97], which is a very small cache placed in front of the standard L1 data cache. If the filter cache is properly dimensioned, dynamic energy consumption in the memory hierarchy can be substantially reduced, not only by accessing most of the data from the filter cache but also by powering down (clock-gating) the L1 D-cache to a STANDBY mode during periods of inactivity [KGMS97]. Although switching the L1 D-cache to STANDBY mode results in delay/energy penalties when there is a miss in the filter cache, it was observed that for media applications, the energy-delay product did improve quite significantly when the two techniques were combined.

Predecoded instruction buffers [BHK+97] and *loop buffers* [LMA99] are variants of the vertical partitioning scheme discussed above, yet applied to instruction caches (I-caches). The key idea of the first partitioning scheme mentioned above is to store recently used instructions on an instruction buffer, in a decoded form, so as to reduce the average dynamic power spent on fetching and decoding instructions. The second partitioning scheme allows one to hold time-critical loop bodies (identified a priori by the compiler or by the programmer) on small and thus energy-efficient dedicated loop buffers.

Horizontal partition schemes refer to the placement of additional (small) buffers or caches at the *same level* as the L1 cache. For each memory reference, the appropriate (level one) cache to be accessed is determined by dedicated decoding circuitry residing between the processor core and the memory hierarchy. Naturally, the method used to partition data across the set of first-level caches should ensure that the cache selection logic is simple, and thus cache access times are not significantly affected.

Region-based caches implement one such "horizontal partitioning" scheme, by adding two small 2 KB L1 D-caches to the first level of the memory hierarchy; one for stack and one for global data. This arrangement has also been shown to achieve substantial gains in dynamic energy consumption for streaming media applications with a negligible impact on performance [LT00].

Dynamic Scaling of Memory Elements

With an increasing number of on-chip transistors being devoted to storage elements in modern processors, of which only a very small set is active at any point in time, *static power dissipation* is expected to soon become a key contributor to a processor's power budget. State-of-the-art techniques to reduce static power consumption in on-chip memories are based on the simple observation that, in general, data or instructions fetched into a given cache line have an immediate flurry of accesses during a "small" interval of time, followed by a relatively "long" period of time where they are not used, before eventually being evicted to make way for new data/instructions [WHK91, BGK95]. If one can "guess" when that period starts, it is possible to "switch off" (i.e., V_{DD}-gate) the corresponding cache lines without introducing extra cache misses, thereby saving static energy consumption with no impact on performance [KHM01, ZTRC01].

Cache Decay was one of the earliest attempts to exploit such a "generational" memory usage behavior to decrease leakage power [KHM01]. The original Cache Decay implementation used a simple policy that turned off cache lines after a *fixed* number of cycles (decay-interval) since the last access. Note that if the selected decay interval happens to be too small, cache lines are switched off prematurely, causing extra cache misses, and if it is too large, opportunities for saving leakage energy are missed. Thus, when such a simple scheme is used, it is critical to tune the "fixed" decay-interval very carefully, so that it adequately matches the access patterns of the embedded application of interest. Adaptive strategies, varying the decay interval at runtime so as to dynamically adjust it to changing access patterns, have been proposed more recently, so as to enable the use of the cache decay principle across a wider range of applications [KHM01, ZTRC01]. Similar leakage energy reduction techniques have also been proposed for issue queues [BAB+02, FG01, PKG01] and branch prediction tables [HJS+02].

Naturally, leakage energy reduction techniques for instruction/program caches are also very critical [YPF+01]. A technique has been recently proposed that monitors the performance of the instruction

© 2005 by CRC Press LLC

cache over time, and dynamically scales (via V_{DD}-gating) its size, so as to closely match the size of the working set of the application [YPF+01].

Software-Controlled Memories, Scratch-Pad Memories

Most of novel designs and/or techniques discussed so far require an *application-driven* tuning of several architecturally visible parameters. However, similar to more "traditional" cache hierarchies, the memory subsystem interface implemented on these novel designs still exposes a flat view of the memory hierarchy to the compiler/software. That is, the underlying details of the memory subsystem architecture are essentially transparent to both.

Dynamic power dissipation incurred by accesses to basic memory modules occurs due to switching activity in bit-lines, word-lines, and input and output lines. Traditional caches have additional switching overheads, due to the circuitry (comparators, multiplexers, tags, etc.) needed to provide the "flat" memory interface alluded to above. Since the hardware assists necessary to support such a transparent view of the memory hierarchy are quite power hungry, additional energy-saving opportunities can be created by relying more on the compiler (and less on dedicated hardware) to manage the memory subsystem. The use of software-controlled (rather than hardware-controlled) memory components is thus becoming increasing prevalent in power-aware embedded system design.

Scratch-Pads are an example of such novel, software-controlled memories [PDA97, CJDR99, BMP00, BS+01, KRI+01, UWK+01]. Scratch-Pads are essentially on-chip partitions of main memory directly managed by the compiler. Namely, decisions concerning data/instruction placement in on-chip Scratch-Pads are made statically by the compiler, rather than dynamically, using dedicated hardware circuitry. Therefore, these memories are much less complex and thus less power hungry than traditional caches. As one would expect, the ability to aggressively improve energy-delay efficiency through the use of Scratch-Pads is predicated on the quality of the decisions made by the compiler on the subset of data/instructions that are to be assigned to that limited memory space [PDA97, PCD+01]. Several compiler-driven techniques have been proposed to identify the data/instructions that can be assigned to the Scratch-Pad more profitably, with the frequency of use being one of the key selection criteria [SFL98, IY00, SWLM02].

The *Cool Cache* architecture [UAK+03], also proposed for media applications, is a good example of a novel, power-aware memory subsystem that relies on the use of software-controlled memories. It uses a small Scratch-Pad and a "software controlled cache," each of which is implemented on a different on-chip SRAM. The program's scalars are mapped to the small (2 KB) Scratch-Pad [UWK+01].[7] Nonscalar data are mapped to the software-controlled cache, and the compiler is responsible for translating virtual addresses to SRAM lines, using a small register lookup area. Even though cache misses are handled in software, thereby incurring substantial latency/energy penalties, the overall architecture has been shown to yield substantial energy-delay product improvements for media applications, when compared to traditional cache hierarchies [UAK+03].

The effectiveness of techniques such as the above is so pronounced that several embedded processors currently offer a variety of software-controlled memory blocks, including configurable Scratch-Pads (TI's 320C6x [TI]), lockable caches (Intel's XScale [INT] and Trimedia [TRI]), and stream buffers (Intel's StrongARM [INT]).

Improving Access Patterns to Off-Chip Memory

During the last few decades, there has been a substantial effort in the compiler domain aimed at minimizing the number of off-chip memory accesses incurred by optimized code, as well as enabling the implementation of aggressive prefetching strategies. This includes devising compiler techniques to restructure, reorganize, and lay out data in off-chip memory, as well as techniques to properly reorder a program's memory access patters [WL91, CMT94, CM95, Wol95, KRCB01].

[7] This size was found to be sufficient for most media applications.

© 2005 by CRC Press LLC

Prefetching techniques have received considerable attention lately, particularly in the domain of embedded streaming media applications. Instruction and data prefetching techniques can be hardware or software driven [Jou90, CB95b, FPJ92, PY96, CKP91, KL91, MLG92, ZLF00]. *Hardware-based* data prefetching techniques try to dynamically predict when a given piece of data will be needed, so as to load it into cache (or into some dedicated on-chip buffer), before it is actually referenced by the application (i.e., explicitly required by a demand access) [CB95b, FPJ92, PY96]. In contrast, *software-based* data prefetching techniques work by inserting prefetch instructions for selected data references at carefully chosen points in the program – such explicit prefetch instructions are executed by the processor, to move data into cache [CKP91, KL91, MLG92, ZLF00].

It has been extensively demonstrated that, when properly used, prefetching techniques can substantially improve average memory access latencies [Jou90, CB95b, FPJ92, PY96, CKP91, KL91, MLG92, ZLF00]. Moreover, techniques that prefetch substantial chunks of data (rather than, say, a single cache line), possibly to a dedicated buffer, can also simultaneously decrease dynamic power dissipation [CK03]. Namely, when data are brought from off-chip memory in large bursts, energy-efficient burst/page access modes can be more effectively exploited. Moreover, by prefetching large quantities of instructions/data, the average length of DRAM idle times is expected to increase, thus creating more profitable opportunities for the DRAM to be switched to a lower power mode. [FEL01, DSK+02, RJ03]. Naturally, it is important to ensure that the overhead associated with the prefetching mechanism itself, as well as potential increases in static energy consumption due to additional storage requirements, do not outweigh the benefits achieved from enabling more energy-efficient off-chip accesses [RJ03].

Special-Purpose Memory Subsystems for Media Streaming

As alluded to before, streaming media applications have been a preferred application domain for validating the effectiveness of many novel, power-aware memory designs. Although the compiler is consistently given a more preeminent role in the management of these novel memory subsystems, they require no fundamental changes to the adopted programming paradigm. Additional opportunities for energy savings can be unlocked by adopting a programming paradigm that directly exposes those elements of an application that should be considered by an optimizing compiler, during performance versus power trade-off exploration. The two special-purpose memory subsystems discussed below do precisely that, in the context of streaming media applications.

Xtream-Fit is a special-purpose data memory subsystem targeted to generic uni-processor embedded system platforms executing media applications [RJ03]. Xtream-Fit's on-chip memory consists of a Scratch-Pad, to hold constants and scalars, and a novel software-controlled Streaming Memory, partitioned into regions, each of which holds one of the input or output streams used/produced by the target application. The use of software-controlled memories by Xtream-Fit ensures that dynamic energy consumption is low, while the region-based organization of the streaming memory enables the implementation of very simple and yet effective shutdown policies to turn off different memory regions, as the data they hold become "dead." Xtream-Fit's programming model is actually quite simple, requiring only a minor "reprogramming" effort. It simply requires organizing/partitioning the application code into a small set of processing and data transfer tasks. Data transfer tasks prefetch streaming media data (the amount required by the next set of processing tasks) into the streaming memory. The amount of prefetched data is explicitly exposed via a single customization parameter. By varying this single customization parameter, the compiler can thus aggressively minimize energy-delay product, by considering both dynamic and leakage power, dissipated in on-chip and off-chip memories [RJ03].

While Xtream-Fit provides sufficient memory bandwidth for generic uni-processor-embedded media architectures, it cannot support the very high bandwidth requirements of high-performance media accelerators. For example, imagine, the multicluster media accelerator alluded to previously, uses its own specialized memory hierarchy, consisting of a streaming memory, a 128 KB stream register file, and stream buffers and register files local to each of its eight clusters. Imagine's memory subsystem delivers a very high bandwidth (2.1 GB/sec) with very high energy efficiency; yet, it requires the use of a specialized programming

© 2005 by CRC Press LLC

paradigm. Namely, data transfers to/from the host are controlled by a stream controller, and between the stream register file and the functional units by a micro-controller, both of which have to be programmed separately, using Imagine's own "stream-oriented" programming style [Mat01].

Systems that demand still higher performance and/or energy efficiency may require memory architectures fully customized to the target application. Comprehensive methodologies for designing high-performance memory architectures for custom hardware accelerators are discussed in detail in [CWD+98, GDN03].

Code Compression

Code size affects both program storage requirements and off-chip memory bandwidth requirements, and can thus have a first-order impact on the overall power consumed by an embedded system. Instruction compression schemes decrease both such requirements by storing in main memory (i.e., off-chip) frequently fetched/executed instruction sequences in an encoded/compressed form [WC92, LBCM97, LW99]. Naturally, when one such scheme is adopted, it is important to factor in the overhead incurred by the on-chip decoding circuitry, so that it does not outweigh the gains achieved on storage and interconnect elements. Furthermore, different approaches have considered storing such select instruction sequences *on-chip* in either *compressed* or *decompressed* forms. On-chip storage of instructions in compressed form saves on-chip storage; yet, instructions must be decoded every time they are executed, adding additional latency/power overheads.

Instruction subsetting is an alternative instruction compression scheme, where instructions not used commonly are discarded from the instruction set, thus enabling the "reduced" instruction set to be encoded using less bits [DPT98]. The Thumb instruction set is a classic example of a compressed instruction set, featuring the most commonly used 32-bit ARM instructions, compressed to 16-bit wide format. The Thumb instruction set is decompressed transparently to full 32-bit ARM instructions in real time, with no performance loss.

Interconnect Optimizations

Power dissipation in on- and off-chip interconnect structures is also a significant contributor to an embedded system's power budget [SK00]. A shared bus is a commonly used interconnect structure, as it offers a good trade-off between generality/simplicity and performance. Power consumption on the bus can be reduced by decreasing its supply voltage, capacitance, and/or switching activity. *Bus splitting,* for example, reduces bus capacitance by splitting long bus lines into smaller sections, with one section relaying the data to the next [HP00]. Power consumption in this approach is reduced at the expense of a small penalty in latency, incurred at each relay point. Bus switching activity, and thus dynamic power dissipation, can also be substantially reduced by using an appropriate bus encoding scheme [SB95, MOI96, BMM+97, BMM+98, PD99, CKC00]. *Bus-invert coding* [SB95], for example, is a simple, and yet widely used coding scheme. The first step of bus-invert coding is to compute the Hamming distance between the current bus value and the previous bus value. If this value is greater than half the number of total bits, then the data value is transmitted in inverted form, with an additional invert bit to interpret the data at the other end. Several other encoding schemes have been proposed, achieving lower switching activity at the expense of higher encoding and decoding complexity [MOI96, BMM+97, BMM+98, PD99, CKC00].

With the increasing adoption of system-on-chip (SOC) design methodologies for embedded systems, devising energy-delay efficient interconnect architectures for such large-scale systems is becoming increasingly critical and is still undergoing intensive research. [PR02].

89.6 Summary

Design methodologies for today's embedded systems must necessarily treat power consumption as a primary figure of merit. At the system and architecture levels of design abstraction, power-aware

© 2005 by CRC Press LLC

embedded system design requires the availability of high-fidelity power estimation and simulation frameworks. Such frameworks are essential to enabling designers to explore and evaluate, in reasonable time, the complex energy-delay trade-offs realized by different candidate architectures, subsystem realizations, and power management techniques, and thus quickly identify promising solutions for the target application of interest. The detailed system- and architecture-level design phases that follow should adequately combine coarse, system-level dynamic power management strategies, with fine-grained, self-monitoring techniques, exploiting voltage and frequency scaling, as well as advanced dynamic resource scaling and power-driven reconfiguration techniques.

90.1 Introduction

Motivation

The application area of the Hypertext Transfer Protocol (HTTP) is becoming larger and larger. While it has been known as the protocol to transfer HTML files originally, it is being used more and more by other applications in order to pass data through a firewall. This is due to the fact that the port related to HTTP, is almost never blocked by a firewall. In other words, running an application on top of HTTP allows to by-pass network security elements like packet filters. Examples for such applications are web mail and Web-based Distributed Authoring and Versioning (WebDAV) [3,4]. Since these web services contain no security features in their standards, they depend on the security provided by HTTP and/or lower protocol layers. While most implementations of protocols below HTTP lack user authentication, this particular feature is provided by extensions to HTTP: Basic and Digest Access Authentication [6].

© 2005 by CRC Press LLC

There is a tendency in industrial communication to replace proprietary communication protocols by the standardized TCP/IP protocol stack [8]. This involves an increase of connectivity in plant networks opening new opportunities to improve the efficiency of maintaining and running systems of automation devices. In the course of this development, the number of embedded web servers has increased rapidly. These web servers allow web-based configuring, control, and monitoring of devices and industrial processes. Due to the convergence of the communication networks of the different layers (control network, local area network, wide area network), establishing an access to smallest processors from any place in the plant or even the world becomes technically feasible. However, besides many opportunities, this technology involves many security challenges [1].

Usually embedded web servers are run on processors with limited resources, both in terms of memory and processor power. These restrictions favor the deployment of lightweight security mechanisms. Different vendors offer tailored versions of the comprehensive security protocol suites Secure Sockets Layer (SSL) and IP Security Protocol (IPSec). However, these versions are still not suitable for all types of processors and applications due to their consumption of memory and computational power. In the case where the range of applications is restricted to HTTP, Digest Access Authentication (DAA) is an alternative solution. This protocol extension to HTTP is economical with respect to memory and processor power requirements. Although designed for user authentication in particular, much more functionality has been foreseen in its original definition. In this chapter, we focus on the mechanisms and functionalities as well as the potential of HTTP Digest Authentication.

Security Objectives

We distinguish the following security objectives for communication systems:

- *Confidentiality*: Guarantee that information is shared only among authorized persons *or* organizations. Encryption of the transmitted data using cryptography makes unauthorized disclosure ineffective.
- *Integrity*: A system protects the integrity of data if it makes unauthorized modifications detectable. This can be achieved by adding a cryptographic check sum.
- *Authenticity:* Guarantee that a receiver of a message can ascertain its origin and that an intruder cannot masquerade as an authorized person. Authenticity is a prerequisite for access control.
- *Access control:* Guarantee that only authorized people or devices have access to specific information.
- *Availability*: Guarantee that a peer is always able to communicate.

In a business-oriented sense of security, auditibility, nonreputability, and third-party protection also belong to the set of security objectives. Note that the relevance of the individual security objectives varies from case to case and depends considerably on the specific application. For example, a business web application where potentially a monetary transaction is involved has security requirements different from an industrial application. While for the former application, confidentiality of the data transfer is a major issue, this is less sensitive in the latter case. In turn, other security objectives such as user authentication and integrity protection are much more critical in industrial communication. In other words, the protection of secure user authentication and of the integrity of the data has a higher priority than the confidentiality. This consideration becomes an issue in particular, when the embedded web server is not integrated in a well-protected network, but stands at a remote place. Such situations may occur in distributed applications.

Outline

First, an overview about the functionality of the security extensions in the TCP/IP protocol suite is given with a focus on SSL and IPSec. Starting with a brief review of the HTTP message exchange, the mechanisms of HTTP Basic and Digest Authentication are detailed and all its additional valuable options (integrity protection and mutual authentication) are discussed. Furthermore, the current implementation status of different (embedded) web servers (Apache 2.0.42, Allegro Rom Pager 4.05, GoAhead 2.1.2) and browsers (Mozilla 1.01, Internet Explorer 6.0.26, Opera 6.05) is investigated. The results of functionality and interoperability tests are presented.

90.2 Security Extensions in the TCP/IP Stack

Security services are provided at different layers in the TCP/IP communication protocol suite by protocol extensions [10]. An overview of these extensions is depicted in Figure 90.1. Due to the nature of the communication protocol stack, the security services are transparent to upper-layer protocols. Note that the security extensions on the Internet layer and the transport layer, IPSec and SSL, respectively, provide a large range of security services and, therefore, are widely implemented.

Link-Layer Security

As extensions to the Point-to-Point Protocol (PPP), the cryptographically weak Password Authentication Protocol (PAP) and the stronger Challenge Handshake Authentication Protocol (CHAP) provide authentication. To establish tunnels starting with a PPP connection into a LAN or a WAN, Point-to-Point Tunnel Protocol (PPTP) or the Layer 2 Tunnel Protocol (L2TP) can be used.

IPSec

This network-layer security protocol is particularly interesting if several network applications need to be secured. As protection is applied at the IP layer, IPSec provides a single means of protection for all the data exchanged (UDP and TCP applications). It is transparent to all upper layers. The security services provided by IPSec are:

- Access control (IP filtering).
- Data integrity.
- Encryption (optional).
- Data origin authentication (optional).

All these services are based on cryptographic mechanisms giving them a high security level when they are used with strong algorithms. However, it is a drawback of IPSec that for each target network a nontrivial, specific configuration is required. While IPSec provides machine-to-machine security, it cannot perform authentication of the user. Therefore, IPSec is mainly deployed to establish Virtual Private Networks (VPN).

A tested IPSec implementation on a Coldfire MCF5307 at 65 MHz showed a memory requirement of 64 kByte where the Internet Key Exchange (IKE) Protocol was not part of the implementation. Experiments consisting of ping requests between two Coldfires were executed. The time between a ping request and the reception of its reply was observed to become twice or even three times longer when IPSec was activated using the Authentication Header (AH) or the Encapsulation Security Payload (ESP) configuration, respectively.

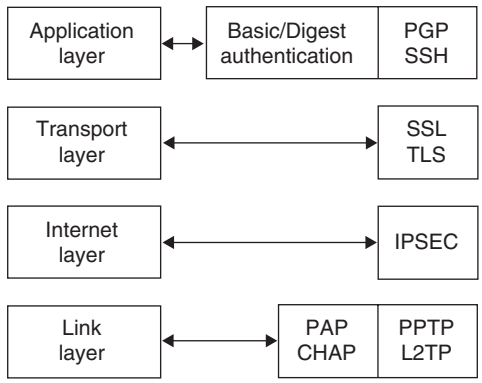

FIGURE 90.1 Network layers and respective security protocols.

© 2005 by CRC Press LLC

SSL/TLS

The SSL is a protocol created by Netscape Communications Corporation. The standardized version is also known as Transport Layer Security (TLS). SSL is invisible to the end user and transparent to upper layers. It protects all applications running on top of TCP, but does not protect UDP applications. The "https" prefix on the URI and the lock icon indicate that the SSL protocol is in use. If the server's certificate is not signed by a certificate authority known to the client, the user has the choice to accept or to refuse the certificate. The security services provided by SSL/TLS are:

- Session key management and negotiation of cryptographic algorithms.
- Confidentiality by means of encryption.
- Strong server authentication using certificates.
- Data integrity protection.

Note that SSL is supposed to provide optional client authentication. However, client authentication is rarely performed by SSL in practice. Under the protection of the encryption provided by SSL, user authentication is often implemented at the application level. All in all, SSL provides a high level of security, but requires considerable memory and computation power, particularly in the dimensions of embedded web servers.

Application-Layer Security

With respect to authentication, the procedures mentioned in the previous sections work on lower layers and focus on the identity of machines.

On the application layer, the individual applications provide own security enhancements. Typical security tools are PGP/GnuPG to secure mail transfer and SSH (secure shell). With respect to HTTP, there exist the protocol extensions HTTP basic and digest authentication, which authenticate users to control their access to protected files. Authentication of the user stands in contrast to machine authentication provided by the tools detailed in the sections above. Since the focus is set on the protocol extensions of HTTP in the rest of the article, a brief review of HTTP is given in the Appendix.

90.3 Basic Access Authentication Scheme

The HTTP Basic Authentication scheme [6] is the simplest authentication scheme and provides little protection. This is due to the fact that username and password can be discovered when the message exchange is sniffed. The HTTP message exchange for basic authentication is depicted in Figure 90.2. On receipt of a "401 unauthorized" message, the browser prompts the user for its username and its password (see Figure 90.3). These are transmitted in the clear over the wire in the "Authorization" request-header-field for each accessed document within the same protection space.

1. The browser issues an HTTP GET command to the server, with the requested URI.
2. The server answers with a 401 unauthorized HTTP error code and requests the browser to send a valid username and password (credentials[1]) using basic authentication. The realm[2] (string) is also included in the challenge sent to the client. All this information can be found in the "WWW-authenticate" request-header-field.
3. The browser prompts the user for username and password. The realm (here "Basic Test Zone") is usually shown to the user. The credentials encoded in Base64 are sent with a new GET request. Decoding is trivial because Base64 is a simply invertible encoding scheme not based on any cryptography. The credentials are sent in the "Authorization" response-header-field.

[1]Credentials: Information that can be used to establish the identity of an entity. Credentials include such things as private keys, tickets, or simply a username and password pair. This is also known as the shared secret.

[2]Realm: Name identifying a protection space (zone) on a server. Usually shown to the user at password prompt.

© 2005 by CRC Press LLC

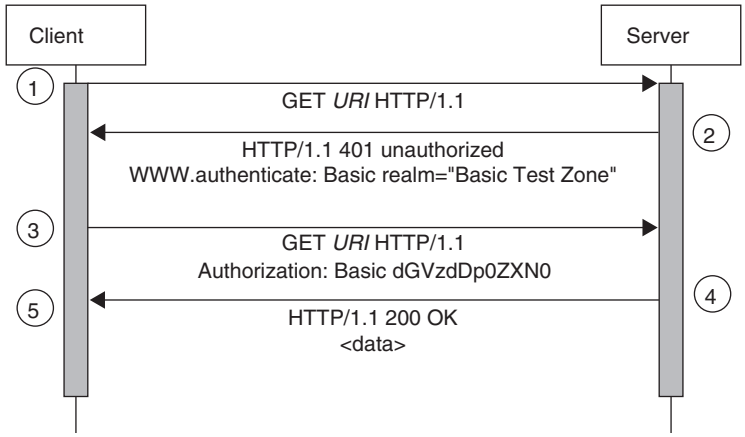

FIGURE 90.2 HTTP basic authentication negotiation.

4. After the server has verified and accepted the password, the page is sent back to the client with an HTTP 200 response.
5. The client displays the page, and automatically sends the same credentials for any subsequent request made under the same protection space. This means that the password is sent in clear with each request.

Note that unless confidentiality is provided by means of other security protocols on a lower layer (see Section 90.2), username and password are transmitted in an unprotected way.

90.4 Digest Access Authentication Scheme

Cryptographical Prerequisites

Unless public keys are used, authentication is based on a shared secret (credentials) between the authenticating and authenticated entity. Usually, these credentials consist of the relation between a username and its password. One possibility to authenticate a peer over the network is the submission of username and password as executed in the Basic Authentication scheme (see Section 90.3). However, since they are submitted in clear over the network, someone who has access to the network traffic can eavesdrop the credentials. The principle of challenge and response overcomes this drawback while avoiding sending the password in clear. Instead, the authenticating entity A sends x to the authenticated entity B. B calculates $z_B = f(x, y)$, where y is the shared secret between A and B. A calculates $z_A = f(x, y)$ as well and checks whether z_A coincides with z_B. If so, the identity of B is proven to A.

To make the procedure of challenge and response secure, there are two requirements. First, x needs to be unique so that z_B is of no value if someone intercepts it. Second, f has to be a one-way (hash) function. The properties of a hash function are:

- a finite-length output message (hash) is calculated from an arbitrary-length input message,
- it is easy to determine the output message,
- given an output message, it is hard to find a corresponding input message, and
- it is hard to find another input message with the same output message.

Functions with all the features mentioned above meet the requirements for a method to calculate cryptographic check sums. It is their quasiuniqueness (hard to find two input messages with the same output) that allows an owner B of a message z to show only the message's hash to another owner A and A can still trust that really z is owned by B. The same property is used to protect the integrity either in data storage or message transmission. A comparison of the hash of the received message or the stored

© 2005 by CRC Press LLC

data, respectively, with the original hash covers any change in the message or the data, provided the hash was stored or transmitted in a secure way. The most frequently used hash functions are MD5 and SHA-1 [9].

Digest Authentication

Although very similar to the basic authentication scheme, DAA [6] is much more secure (Figure 90.4). Instead of sending the username and the password in an unprotected way, a unique code is calculated from username, password, and a unique number received from the server. Figure 90.5 shows the HTTP DAA transactions between a web server and a browser. The "cnonce," "nonce," "responses," and "rspauth" parameter values have been shrunk for the sake of readibility of the chart.

1. The browser requests a document in the usual way, with an HTTP request message.
2. The server sends back a "401 unauthorized" challenge response message. The server generates a so-called nonce (number used once) and sends it to the client. Note that the nonce is different for every 401 message.
3. The browser prompts the user for its username and its password, and computes a 128-bit response using the MD5 algorithm [9] as a one-way (hash-) function:

   response = MD5[MD5(username:password):nonce:nc:cnonce:qop:MD5(method:uri)]

   This response is sent to the server along with the nonce received, the uri requested, its own generated cnonce (client nonce), and the username. Note that qop stands for Quality of Protection and indicates whether additional integrity protection is provided. Here, this is not the case; hence, qop="auth."
4. The server calculates an own response following the same scheme as given in Step 3, where the information sent to the client before and its own version of the username and password (or optionally a hashed form of them) are used. It compares the received version with the computed one and grants access to the resource (HTTP 200 OK response) if appropriate.
   If the authorization fails, a new 401 error message is sent. All the 401 error messages include an HTML error page to be displayed by the browser. Browsers usually reprompt the user for a new username and password three times before giving up and displaying the error page.

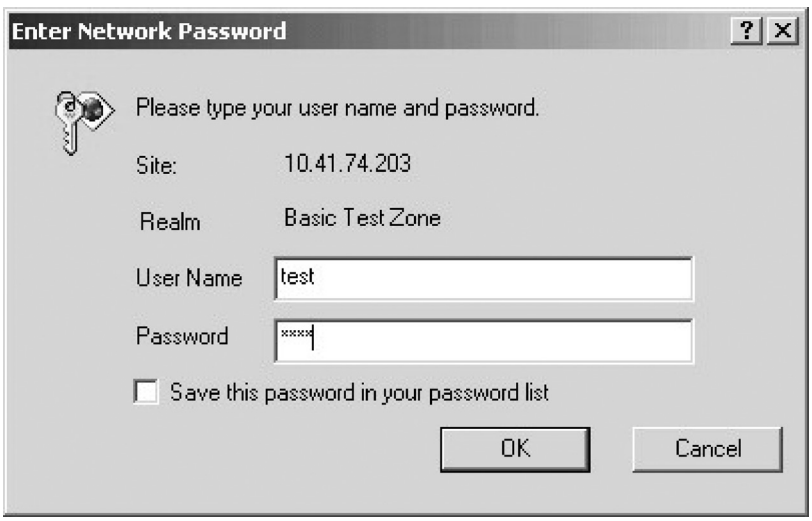

FIGURE 90.3 Internet Explorer's basic authentication prompt.

© 2005 by CRC Press LLC

FIGURE 90.4 Internet Explorer's digest authentication prompt.

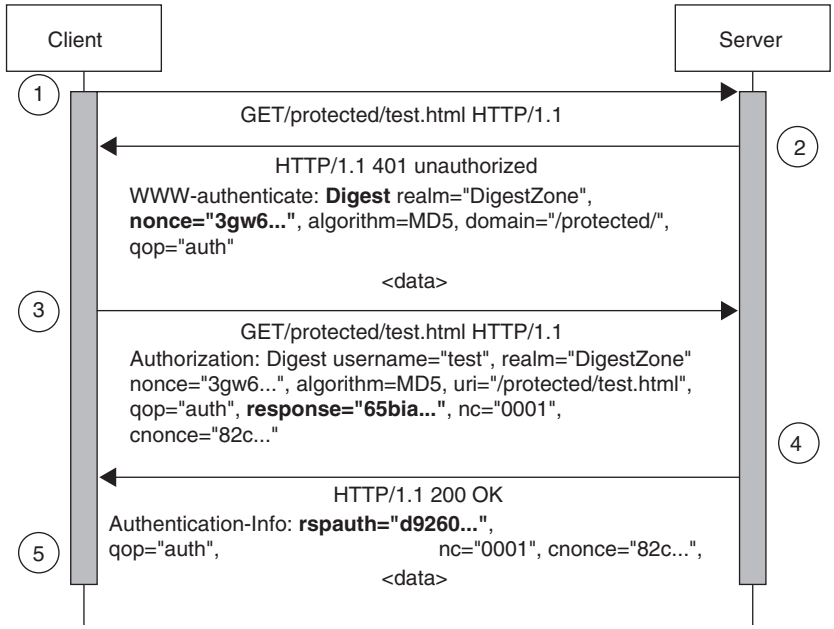

FIGURE 90.5 HTTP digest authentication: negotiation.

5. For any subsequent request, the client usually generates a different cnonce. A counter, nc, is incremented. This new cnonce and counter, along with the new uri is used to recompute a new valid response value. Usually, the browser stores the username and the password temporarily in the memory in order to enable a user to reaccess a given protection space without further typing.

Digest Authentication with Integrity Protection

The RFC for digest authentication [6] provides a way to include the hash of the entity (the payload, usually HTML code) in the computed MD5-hash response:

response = MD5[MD5(username:realm:password):nonce:nc:cnonce:qop:MD5(method:uri:MD5{entity})]

© 2005 by CRC Press LLC

In that way, any modification of the transmitted information will result in a different MD5-hash response, easily detectable. While in a response message, the integrity of the served document is insured, the integrity of POST data is protected in a request message. To indicate that the server supports integrity protection, the argument Quality Of Protection is set to "auth-int."

Note: for GET requests with arguments, the integrity of the payload (the arguments) is already protected without the option qop=auth-int, because the URI with its arguments is included in the MD5-hash. For integrity protection of the response from the server the rspauth field must be present. See the next section on mutual authentication.

Digest Authentication with Mutual Authentication

We have already seen that digest authentication identifies the client. However, DAA also foresees the ability that the client checks whether the server is trustworthy, providing mutual authentication. The server already knows that the client is trustworthy, because the browser has sent the proof that the user knows their shared secret. This happened by sending the response to the server (see Step 3 in Figure 90.5). It is exactly the same mechanism used to authenticate the server. After receiving a correct credential along with the GET request, the server sends back a proof that it also knows the shared secret. This is done via the "rspauth" field sent in the "Authentication-Info" header of the HTTP 200 OK message, along with the document previously requested. The challenge initiating the server response is the cnonce from the client.

rspauth = MD5[MD5(username:realm:password):nonce:nc:cnonce:qop:MD5(:uri)

The browser uses this information to authenticate the server. If integrity protection is activated, the hash for the entity is included in rspauth.

rspauth = MD5[MD5(username:realm:password):nonce:nc:cnonce:qop:MD5(:uri:MD5{entity})][3]

The nonce from the server is used to challenge the client with data that cannot be anticipated. In the same way, when server authentication is used, leading to mutual authentication with DAA, the cnonce from the client is used as a challenge that the server cannot anticipate. Therefore, it is not possible to precompute responses to those challenges.

This is known as a mutual challenge/response mechanism. Its concept is pictorially depicted in Figure 90.6.

Summary

DAA offers a secure, yet light authentication scheme, perfectly adapted to the embedded systems. In this environment, authentication and integrity protection is important, whereas confidentiality is often not an issue. Unfortunately, integrity protection and mutual authentication have not been supported by today's typical client/server implementations so far.

Table 90.1 compares DAA and SSL's mandatory and optional features as well as their memory requirements. Note that at the time of the tests, the *optional* features were supported by some implementations only.

90.5 Weaknesses and Attacks

Basic Authentication

If an attacker has access to the network link media, he can eavesdrop the HTTP transaction very easily and get the username and the password if there is no underlying encryption as provided by SSL or IPSec. In those cases, HTTP Basic Authentication should be replaced by the Digest scheme.

Replay Attacks

Security threats appear when data, for example, sensitive commands, are sent to the server. With POST and some other HTTP method, data are transmitted in the entity of the message. An attacker could replay

[3]The only difference from the client response is the missing field "method."

[c] According to information from Allegro.

valid credentials from a successfully intercepted POST request with modified form data (commands) thus taking control of the remotely controlled system. In contrast, the arguments sent in a GET request are part of the arguments to compute the digest. Thus, GET requests are safer and must be used in priority to send data to the server. The fact that the data are stored in the browser's cache using the GET method has no effect to the security, because of the uniqueness of the nonce.

Proper nonce generation together with a reliable check for uniqueness provides good protection against replay of previously used valid credentials. Although the definition of a nonce requires its uniqueness, implementors might be tempted to reuse a nonce. This must be avoided in any case. Within a session, a replay attack is prevented by the increase of the counter "nc," making the previously calculated hash value invalid. Note that the change of 1 bit in the argument of a hash function changes half of the bits of the hash value [9]. Furthermore, integrity protection would prevent from tampering information when POST is used.

On an embedded device, where usually only one legitimate user at a time is likely to access the system, locking the protection space (realm) to only one client at a time contributes to protection as well.

Man-in-the-Middle Attack

An attacker might be able to insert himself into the routing path between a client and a server. Capturing the packet containing the server's response with the challenge for digest authentication, he can replace the WWW-Authenticate field with that asking the client for Basic Authentication: Username and password can be gained because the client returns them in an unprotected form due to the faked WWW-Authenticate field.

© 2005 by CRC Press LLC

Disabling of Basic Authentication in the browser and requiring mutual authentication could prevent such an attack.

Dictionary Attack/Brute Force Attack

This attack assumes that the user chooses a simple password. In the client's request message (Step 3), all information to calculate the response field apart from the password is available. Having such a message in his hands, an attacker might compute thousands of responses generated with a list of possible passwords from a dictionary and see if it coincides with the response sent by the browser. However, the success of a dictionary attack can be avoided by proper selection of the password, for example, avoid common words and include small and capital letters as well as special characters.

For a brute force attack the list of possible passwords is replaced by any combination of characters. However, the fact that a hash must be calculated for each password guess makes a brute force attack very cumbersome. Passwords with more than eight characters, small and capital letters, as well as special characters should be used. Use of common words should be avoided.

Buffer Overflow

In general, a buffer overflow attack occurs when an attacker tries to store too much information in a very small memory space [7]. With respect to embedded web servers, web pages often serve as a portal for CGI programs. Input data for such a program are transmitted in the HTTP message. If the size of such data is too large, it can be written in the memory over the executable code of the browser/server and can be executed by the operating system, unless a careful error check is performed. Mostly, this will crash the server, resulting in a Denial of Service. However, it can also allow a skilled attacker to gain access to everything the server has access to, for example, all confidential information and the code controlling the devices in the automation system.

Note that buffer overflow can be avoided when in all applications and in particular in those called by CGI requests careful data range validation checks are performed. Additionally, for integrated third-party code, it is highly recommended to update the code to the latest available version and to apply the security patches or the service packs as soon as they are released.

URI Check

Some web servers do not verify whether the "uri" field located in the "Authorization" header corresponds to the requested URI in the GET request. An attacker may replay a stored valid request from a client for a given "uri," but may modify the GET line to get some other protected documents he wants or, even worse, the server may accept modified parameters in a GET request. This might allow an attacker to send arbitrary commands to an embedded device. Details on uri check implementations are given in the next section.

90.6 Implementations

The available embedded web server implementations and browsers have been tested for their support of DAA. Investigations have shown that the implementations do not match the definition in every aspect. This section briefly outlines the results. A comparison of some server implementations is given in Table 90.2.

Servers

(1) *Apache 2.0.42*: Among the DAA implementations tested, Apache has the best one. While mutual authentication is in place and working, integrity protection is not yet implemented. The nonce lifetime is adjustable and the uri is checked. Apache is also the most robust server in terms of exploits, because a large community uses it daily. Note that DAA is compatible with the Opera browser only if the AuthDigestDomain directive is configured in the file htaccess. The Internet Explorer (IE) removes the

© 2005 by CRC Press LLC

TABLE 90.2 Comparison between DAA Server and Implementation

Feature	Server		
	Apache	RomPager	GoAhead
Basic Access Authentication	✓	✓	✓
Digest Access Authentication	✓	✓	✓
mutual authentication	✓	x	x
integrity protection	x	x	x
nonce check	✓	✓	x
uri check	✓	✓	x

arguments when copying the GET query in the uri field. Therefore, DAA does not work for GET requests with parameters between IE and Apache. The nonce is composed of a timestamp (in the clear), followed by the "=" sign, and the SHA-1 hash [9] of the previous timestamp, realm, and a server secret (private key):

$$\text{nonce} = \text{timestamp}:\text{“=”}:\text{SHA1}(\text{timestamp}+\text{secret})$$

(2) *Allegro RomPager 4.05*: In the RomPager web server [11], DAA is implemented without mutual authentication and integrity protection. It is known for its option "StrictDigestAndlp," that is, the validity of the unique nonce is time-limited and never more than one IP address are granted access simultaneously. This feature makes sense in embedded systems because it prevents replay attacks.
RomPager makes a full uri check. In addition, it is implemented to be able to cope with the less secure uri behavior of the IE.
RomPager assumes that requests received via HTTP 1.0 come from a browser not supporting digest. As a consequence, DAA does not work with IE and Opera when being connected via a proxy. Therefore, Opera needs to be configured without proxies. On IE, the "Use HTTP 1.1 through proxy connections" option can be set. The nonce is generated using the time, the server IP address, the previous nonce (if there was one), and the server name.

$$\text{nonce} = \text{MD5}(\text{Time:Server-IP-Address: [previous nonce:] Server-Name})$$

(3) *GoAhead 2.1.2*: GoAhead is a free software and open source server, developed for embedded devices on a variety of platforms. As for RomPager, no mutual authentication and integrity protection is supported. A given nonce never expires and is never checked. Hence, there is no protection from replay attacks. The server removes the parameters of a GET query request in the digest "uri" field. This causes Mozilla not to work for those types of requests.

$$\text{nonce} = \text{MD5}(\text{RANDOMKEY: timestamp:myrealm})$$

Browsers

It is difficult to select a browser among the three tested here. They all have their strengths and weaknesses. Internet Explorer is the only one using a different prompt for Basic and Digest Authentication (see Figures 90.3 and 90.4). Being aware of this feature, an attentive user can recognize a Man-in-the-Attack . However, the IE removes GET arguments in the uri. Mozilla is an open-source browser, and thus, very easy to modify. On the other hand, it is not very user-friendly at the time (slow and continually asking for the username and password). Opera is the pickier one in terms of security and the only one supporting mutual authentication. With respect to DAA, a combination of the three products mentioned above would probably meet the features expected from a perfect DAA implementation. These are as follows:

- Option to disable Basic Authentication.
- The user shall be notified by a visual clue that DAA is used, when he is prompted for username/password as well as during browsing.
- Support of DAA with mutual authentication with a visual clue that the server has been authenticated. Possibility to refuse pages served with DAA if the server has not been authenticated.

© 2005 by CRC Press LLC

- Support of DAA with integrity protection, with a visual clue that it is used.
- Verification that the URI requested with DAA is in the protection space.

DAA Compatibility

Table 90.3 summarizes the compatibility of different clients vs. different servers. Note that the compatibility tests did not include server authentication and data integrity protection.

90.7 Conclusions

DAA is a lightweight, yet efficient way of providing user authentication. Applications running on top of HTTP can benefit from DAA's features. Typically, these are web services like WebDAV and HMI applications in automation systems migrating from proprietary communication protocols toward TCP/IP technology. Wherever Basic Authentication is still in use and not protected by a security protocol of a lower layer, it should be replaced by DAA. From the point of view of the embedded community, it is highly desirable that browser and web server vendors implement mutual authentication and integrity protection, because only together they achieve a high security level. In situations where encryption is not required, an implementation of DAA including all features proposed by the RFC [6], namely mutual authentication and integrity protection, would serve as a sufficient, yet lightweight, security mechanism for embedded systems.

Appendix: A Brief Review of the HTTP

HTTP is widely used to exchange text data across different platforms on a TCP/IP network. The definition of HTTP 1.1 is stated in [5]. HTTP is based on standard request/response messages transmitted between a client (browser) and a web server. An example of a typical HTTP handshake is depicted in Figure 90.7. The procedure is straightforward:

1. The browser sends a GET request to the server, indicating the requested resource.
2. The server responds with a 200 OK message along with the document requested.

Using Figure 90.7, the key aspects of HTTP are briefly explained. An HTTP message consists of a header and in most cases an entity. Note while all the data in the header are transferred as ASCII text, the entity might contain non-ASCII data, for example, .jpg-files.

Header
A Header is composed of a Start-Line and Header-Fields.

Start-Line
There are two types of start-lines:
A request start-line is of the form Method URI HTTP-Version, for example,
GET /simple.html HTTP/1.1.

TABLE 90.3 DAA: Client/Server Compatibility

	Clients		
Servers	Mozilla 1.01 Netscape 7.0	E 6.0.26	Opera 6.05
Apache 2.0.42 (win32)	✓	✓[a]	✓[b]
RomPager 4.05	✓	✓	✓
GoAhead 2.1.2	✓[b]	✓	x

[a] Not working for GET with parameters.
[b] Requires valid domain.

© 2005 by CRC Press LLC

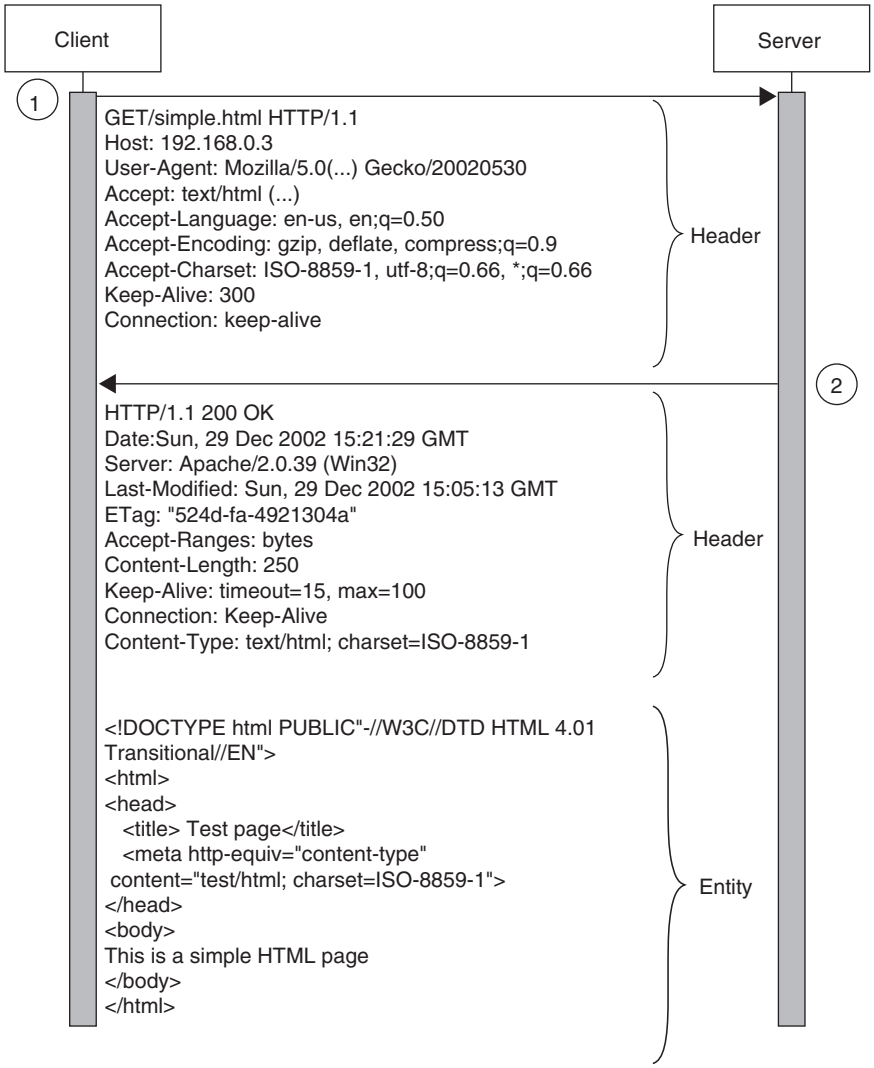

FIGURE 90.7 Example of an HTTP message exchange.

A status start-line has the form HTTP-Version Status-Code Phrase, for example, HTTP/1.1 200 OK.

Header-Fields
Header-Fields give various information, including date, language, and security information. In this document, the security-relevant header fields are discussed in the main part. Examples:
Host: 192.168.0.3
Date: Sun, 29 Dec 2002 15:21:29 GMT
WWW-authenticate: Digest realm="abc",…

Method
The most relevant methods are GET and POST.
GET: The most common method to request a document. The GET request can also include arguments in the URI. This is widely used to transmit commands from the client to the server.
POST: Method used to send information to the server, usually from a web page form.

© 2005 by CRC Press LLC

URI
Uniform Resource Identifiers [2]. URIs in HTTP can be represented in absolute form or relative to some known base URI. Example:
http://www.test.ch/simple.html or /simple.html.

Entity
The rest of the message, for example, an HTML document.

Acknowledgment

The authors would like to thank Emanuel Corthay from the Swiss Federal institute of Technology Lausanne for his valuable contribution in the examination of the individual implementations.

91.1 Introduction

In an increasing number of distributed embedded applications, the individual nodes must communicate with each other over insecure channels like, for example, the public Internet or via wireless communication links. In order to withstand malevolent attacks, the end-to-end communication channels must be secured using cryptographically strong encryption and authentication algorithms. Fortunately, powerful secure communication protocols exist today and most of them are readily available as OpenSource software implementations. The biggest obstacle to their widespread use in distributed embedded systems is the limited memory and the restricted processing power available from today's low-cost and mostly low-power microcontroller platforms. In this chapter, we are going to show some promising approaches regarding how security can be brought to embedded systems running time-critical applications.

This chapter on secure communications in embedded systems will be structured as follows:

- Section 91.2 of this chapter will give an overview of the secure communication solutions available for distributed embedded systems.
- Section 91.3 treats two of the key problems that have to be dealt with when implementing cryptagraphically strong security in embedded systems. One problem is the generation of random numbers used for keying material and the other problem is the efficient handling of the computationally expensive public key operations required in most of the modern security protocols.
- Section 91.4 gives a typical example of a secure communications solution for a low-end embedded platform. It is shown that an SSL/TLS-enabled Web server can be implemented with a small memory foot print.
- Section 91.5 concludes this chapter by summarizing the relevant facts.

© 2005 by CRC Press LLC

91.2 Security in the OSI Communications Stack

Security can be implemented at different levels of the communications stack. The well-known OSI communications model defines a physical layer at the very bottom and goes up via the data link, network, and transport layers up to the topmost application layer (see Figure 91.1). The OSI presentation and session layers have been omitted since they are not relevant in our context. In the following paragraphs we will briefly describe how security can be applied at each layer.

Physical Layer Security

At the low end of the communications stack, the physical layer does not offer much protection in a strict cryptographical sense. Often, the binary payload bits are scrambled with a fixed pseudorandom code, primarily in order to avoid the occurrence of long runs of ones or zeroes and some wireless channels like, for example, Bluetooth use fast frequency hopping in order to increase the physical robustness of the link. Although these measures offer some protection from casual eavesdropping, they do not withstand any serious attempts at intercepting the communication traffic.

Data Link Layer Security

Most wireless communication systems like, for example, IEEE 802.11 WLAN, Bluetooth, or GSM use authentication and encryption at the data link layer in order to protect the data transmission over the vulnerable air interface. Unfortunately, the Wireline Equivalent Privacy (WEP) encryption protocol of the IEEE 802.11 Wireless LAN standard is known to possess several serious deficiencies that make transmission highly insecure [1, 2]. The same is true for the A5 encryption cipher used by the GSM global cellular phone system that can be cracked by a simple PC in real time [3]. Thus, if distributed embedded systems are communicating either over WLAN or GSM wireless links, no real security can be expected from the default layer 2 encryption and authentication protocols.

The most popular layer 2 protocol over wired links is Ethernet, which does not possess any inherent security mechanisms. Over asynchronous modem links or synchronous ISDN connections, the payload frames of the Point-to-Point Protocol (PPP) could optionally be encrypted using the PPP Encryption Control Protocol (ECP) [4], but two large vulnerabilities remain: first, PPP frames are not authenticated, making them prone to malicious changes and second, the PPP connection setup based on the auxiliary Link Control Protocol (LCP) is not secured at all, exposing it to man-in-the-middle attacks and session-hijackings.

Generally, it can be summarized that with the current layer 2 protocols in use, the data-link layer is not a suitable location for implementing strong communications security.

Communication layers	Security protocols
Application layer	ssh, S/MIME, PGP, http digest
Transport layer	SSL, TLS, WTLS
Network layer	IPsec
Data link layer	WEP (WLAN), A5 (GSM), PPP
Physical layer	Scrambling, frequency hopping

FIGURE 91.1 Security implemented at different layers of the OSI stack.

© 2005 by CRC Press LLC

Network-Layer Security

The most flexible approach to security can be realized at the network layer since this is the lowest communications layer that allows the implementation of end-to-end security in routed, multihop networks. If we restrict ourselves to the ubiquitous IP network-layer protocol, then the corresponding IP security protocol (IPsec) [5, 6] is the preferred choice. The IPsec protocol comes in two flavors: the Authentication Header (AH) protocol [7] secures IP packets from unwanted modifications by adding a cryptographic check sum, thus guaranteeing data integrity of the payload and most of the IP headers including the source and destination addresses. The Encapsulating Security Payload (ESP) protocol [8] offers strong encryption of IP packets and is usually preferred over AH since optional authentication of the payload data is also available with ESP. Only in the special cases where encryption is not permitted by national law or where it would to put too much of a computational burden on the embedded platforms is AH used. Both ESP and AH are special IP protocols with protocol numbers 50 and 51, respectively. Because these protocols do not have port numbers, they cannot be masqueraded in the same way as UDP or TCP datagrams.

IPsec further differentiates between Transport Mode, which is mainly used for point-to-point connections between two single hosts and Tunnel Mode, which tunnels the traffic between two subnetworks that are protected by a security gateway. Since in embedded systems usually direct host-to-host connections predominate, we will restrict our discussion to the AH and ESP transport mode payloads only, which are shown in Figure 91.2.

The required overhead for ESP protection is shown in more detail in Figure 91.3. The ESP header consists of a 32-bit Security Parameters Index (SPI), which is used by the receiver to look up the session keys plus negotiated cryptographic parameters for the given IPsec connection. Each direction in a bidirectional IPsec connection has an SPI value of its own. The following 32-bit monotonically increasing Sequence Number prevents replay attacks. The ESP trailer is used to pad the payload data to an integer multiple of the block size required by the symmetric block cipher. The standard Triple DES (3DES) encryption algorithm works on 64-bit blocks of data, so that in the worst case, 7 bytes must be padded, whereas the Advanced Encryption Standard (AES), the official successor to 3DES, uses 128-bit data blocks, so that the overhead becomes 15 bytes at the worst. Add to this 2 bytes for the pad length and next header fields. The block encryption algorithms also need an initialization vector (IV) comprising the size of one data block. This means an additional 8 bytes of overhead for 3DES and 16 bytes for AES, respectively. Finally, the cryptographic checksum used for ESP authentication takes up another 12 bytes, resulting to a total overhead of 37 bytes for 3DES encryption and 53 bytes for AES. This is not much if large volumes of data are transferred as for, for example, during an ftp download, but it can have a large impact if many small IP packets are transmitted, for example, when running a telnet session.

The kernel part of an IPsec stack that implements the real-time ESP encapsulation of IP packets can be made quite compact. For distributed systems running an embedded Linux operating system like, for

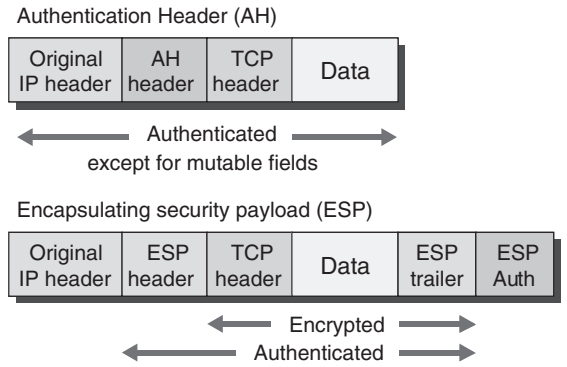

FIGURE 91.2 IPsec Transport Mode.

© 2005 by CRC Press LLC

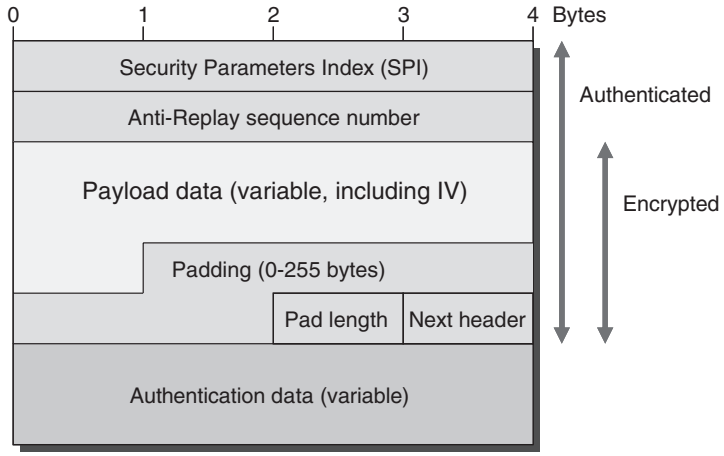

FIGURE 91.3 ESP payload structure.

example, μClinux [9], a free but nevertheless mature IPsec solution is available from the OpenSource Linux FreeS/WAN project [10]. Several commercial IPsec stacks for embedded platforms are also offered on the market. The RAM footprint is usually maintained between 200 and 300 kbytes.

The most serious drawback of IPsec is the complexity involved in setting up protected connections. Although, in principle, the configuration could be done manually by specifying two common SPI values for the two directions plus a set of shared authentication and encryption keys, this procedure would be too error-prone to be feasible in a practical application, especially if frequent rekeying is required. Therefore, an automatic connection setup is preferred using the standardized Internet Key Exchange (IKE) protocol [11], which uses the well-known UDP port 500. IKE is a rather complex protocol comprising a multitude of configuration options. It consists of a Phase 1 called Main Mode where six messages are exchanged in order to establish trust and to compute a common secret key between the two end points. Main Mode is followed by a Quick Mode or Phase 2 negotiation where another three messages are needed to set up the actual connection. A typical Main Mode exchange with mutual authentication based on preshared secrets is shown in Figure 91.4.

- The initiator sends a proposal, listing all supported encryption and authentication algorithms. The responder selects among them one set of common algorithms and sends the selection back to the initiator.
- The second message pair establishes a common secret with the help of a Diffie–Hellman (DH) Key Exchange. In order to prevent replay attacks, a pair of random values N_I and N_R, are also exchanged.
- Starting with the third message exchange, all further IKE communication is encrypted in order to prevent man-in-the-middle attacks. The encryption key is derived from the common DH secret, the random values N_I and N_R, and the preshared secret known only to the two end points. Over the secure channel, an ID string, which establishes the identity and a hash value authenticated with the pre-shared secret, is exchanged.

Another variant of the IKE Main Mode depicted in Figure 91.5 uses RSA public key authentication (only the last two IKE messages are shown, the first four being the same as in Figure 91.4). The use of RSA signatures in connection with X.509 certificates, which are a convenient means of distributing the needed RSA public keys, is the most powerful approach to IPsec, especially if a large number of connections must be maintained.

X.509 certificate support for embedded Linux IPsec solutions is available as a patch [12] developed by the Security Group of the Zurich University of Applied Sciences in Winterthur that can be applied to the

© 2005 by CRC Press LLC

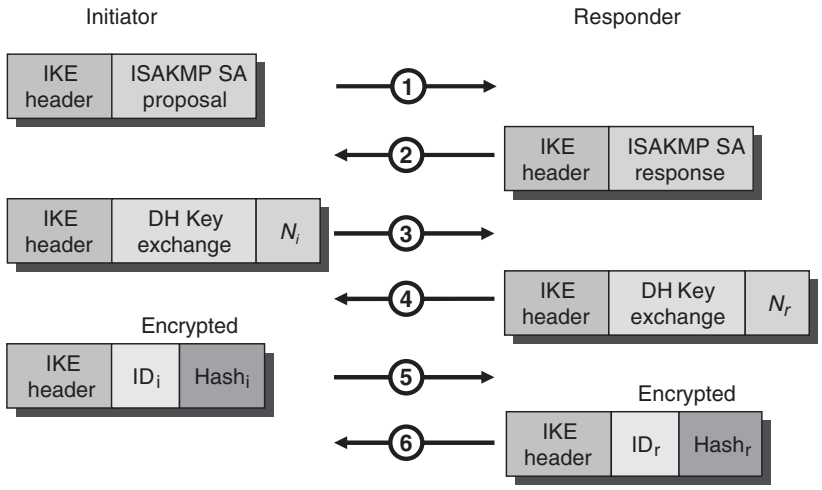

FIGURE 91.4 IKE Main Mode authentication based on preshared secrets.

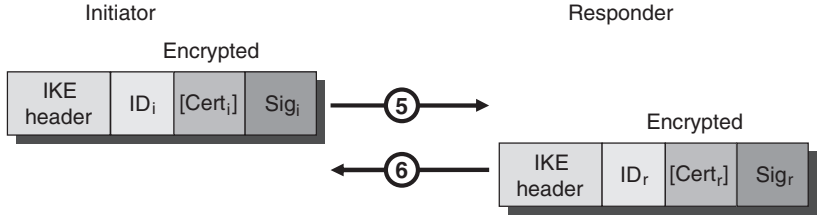

FIGURE 91.5 IKE Main Mode authentication based on X.509 certificates.

FreeS/WAN distribution [10]. Depending on the number of implemented features, an IKE daemon can become quite large. Footprints between 200 kbytes for a very lean client using preshared secrets only and more than 1 Mbytes for a full-fledged IKE implementation are not uncommon.

The complexity of the IKE protocol is the main reason that the use of IPsec is usually restricted to high-end 32-bit embedded platforms that possess the required memory and computational resources.

Transport-Layer Security

The most generic solution at the transport level is the well-known Secure Sockets Layer (SSL) [13, 15], as well as its official IETF successor called Transport Layer Security (TLS) [14, 15] and its lean variant WTLS for wireless applications. The SSL/TLS protocols are layered on top of the reliable TCP transport layer protocol and are typically used in client/server applications, for example, a central controller managing several distributed nodes, but SSL/TLS can also be used for peer-to-peer communication.

By taking a look at Figure 91.6, we see the fundamental difference between network and transport-layer security. Whereas IPsec requires large and potentially dangerous changes in the kernel of the given operating system, SSL/TLS leaves the built-in TCP/IP communications stack untouched because it uses regular TCP sockets. From the application's point of view, IPsec has the major advantage that the interface to the transport layer does not change at all, so that the application program is not even aware of the existence of an additional security layer and any transport protocol (TCP, UDP, ICMP, etc.) can be used. With SSL/TLS, special secure sockets must be opened by the application and TCP is the only transport layer supported. Fortunately, thanks to the widespread popularity of SSL/TLS, many applications now work with secure sockets, which in fact are very similar to normal TCP sockets.

© 2005 by CRC Press LLC

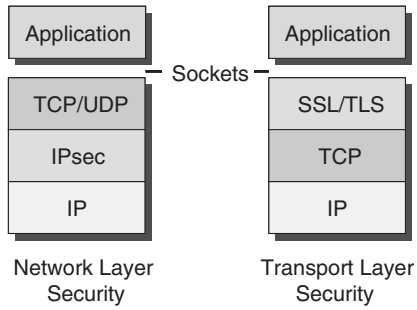

FIGURE 91.6 Comparison; network vs. transport-layer security.

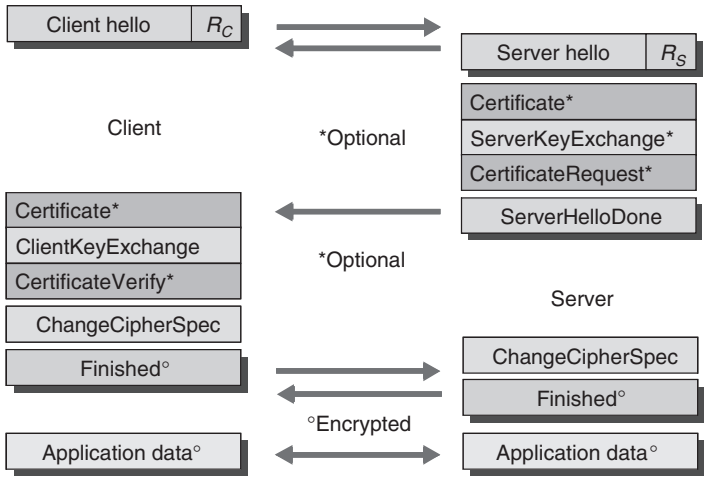

FIGURE 91.7 SSL/TLS handshake protocol.

SSL/TLS uses a record structure to encrypt and authenticate the application data and to embed them into a TCP/IP stream. Similar to IPsec and its companion IKE connection negotiation protocol, the SSL/TLS handshake protocol shown in Figure 91.7 is used to set up a secure SSL/TLS tunnel.

- The handshake is initiated by the client who sends a ClientHello message that lists all its suites of supported encryption, authentication, and compression protocols.
- The server answers by selecting one of the offered suites and includes the decision in a ServerHello message. Both client and server add random values R_C and R_S, respectively, to their hello messages in order to make each session unique, thereby preventing replay attacks.
- A server usually possesses a trusted server certificate, which it sends to the client right after the ServerHello message. By including an optional CertificateRequest, the client can be forced to authenticate itself in turn by requiring it to send a client certificate, too.
- The ServerHelloDone message terminates the first server message block and prompts the client to take over the protocol lead again.
- If requested to do so, the client sends its certificate together with a signature contained in the CertificateVerify message. As mentioned above, client-side authentication is optional and is not used very often.
- The client always generates a 48-byte random premaster secret, encrypts it with the public key extracted from the received server certificate, and puts the protected secret in the ClientKeyExchange message. Based on the premaster secret, the client then computes the master secret and derives all

© 2005 by CRC Press LLC

required encryption and authentication session keys. It then activates the chosen cipher suite, signals this to the server by issuing a ChangeCipherSpec message, and adds an already encrypted Finished message that can be used by the peer side to test the successful establishment of the secure connection.

- The server in turn decrypts the received ClientKeyExchange message using its private key. With the extracted premaster secret, the server can then generate the same master secret and derived sessions keys as the client's. By sending the ChangeCipherSpec and Finished messages, the server signals its readiness to switch over to the secure channel, too.

From this moment on, all application data are exchanged in encrypted and authenticated form.

Every newly opened socket needs to be initialized first using the SSL/TLS handshake protocol. If, for example, the obsolete HTTP 1.0 protocol is used to access a web site, then each graphical element of an HTML page will be downloaded over a socket of its own. This would mean that every time a computationally expensive RSA public key authentication based on a 1024-bit key would have to be executed. In order to avoid a full handshake operation, SSL/TLS offers the possibility to resume or clone an already established session in the abbreviated manner detailed in Figure 91.8.

If the client wants to resume a session or open an additional socket, it sends the session ID of the existing session as part of the ClientHello message. If the server still has the corresponding session data including the premaster secret in its cache then it will reply by immediately sending the ChangeCipherSpec and Finished messages. Nevertheless, using a fresh set of the random values R_C and R_S, a set of new session keys are derived from the cached premaster secret.

A readily available OpenSource SSL/TLS implementation is the popular OpenSSL package [16]. Due to its innumerable options and supported algorithms, the required SSL and crypto libraries add up to a huge size of 1.6 Mbytes. OpenSSL in its direct form is therefore only suitable for high-end 32-bit platforms that usually run an embedded Linux operation system. In Section 91.4 we will demonstrate how a lightweight SSL/TLS stack can be derived from the original OpenSSL library.

Application-Layer Security

A typical example of an application-layer security application is the popular secure shell (ssh) [17], which allows a secure login for administration and monitoring purposes – functions that were classically done by system administrators using the insecure and now deprecated telnet protocol. The authentication mechanisms are similar to those used in the IKE and SSL/TLS handshake protocols. Either raw RSA keys or X.509 certificates are supported.

Another possible security approach at the application level would be to authenticate and encrypt the message bodies using the S/MIME [16] or PGP/GnuPG [18] packages known from secure e-mail. But be aware that additional precautions must be taken to thwart replay attacks using recorded past messages.

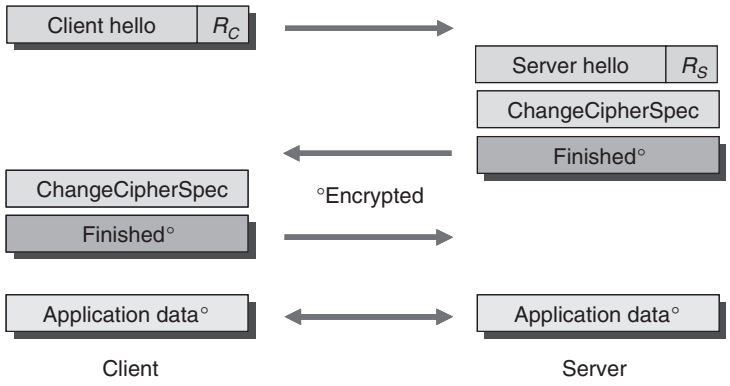

FIGURE 91.8 Resuming SSL/TLS session.

© 2005 by CRC Press LLC

On many embedded systems, a Web server is running by default, allowing the configuration and monitoring of the embedded application via an interactive Web interface. A straightforward approach in this case would be to use the built-in security mechanisms of the HTTP protocol. Two authentication variants are available: Basic and Digest Access Authentication [19], whereas encryption is not supported and must be provided by other means. The Basic Access Authentication scheme defined by the HTTP 1.0 protocol is not secure at all and should not be used because the username/password pair of the client is transmitted in the clear and can easily be intercepted. The Digest Access Authentication introduced by the newer HTTP 1.1 protocol is much more secure because the secret password never crosses the communication channel. Instead, a random challenge string sent by the server is hashed together with the client's username and password to form an MD5 digest, which is sent back as a response to the HTTP server. This digest is vulnerable to brute-force dictionary attacks, though. If a weak password is chosen by the user, then an off-line cracking attempt will find the password in less than an hour if it has been chosen from a multilingual dictionary and has only been slightly modified, for example, by appending a number.

The major advantage of the HTTP Digest Access Authentication is the relative ease of its implementation and use, whereas the drawbacks are the lack of an encryption option and the potential vulnerability of the openly transmitted digest to dictionary attacks due to weakly chosen passwords.

91.3 Key Problems in Embedded Systems

In this section, we will examine two of the key problems that are typical for low-end embedded system platforms. The first topic is the generation of true random material in a low-entropy environment and the second item will concentrate on the computationally intensive operations required by the standard RSA public key cryptosystem as used by IPsec's Internet Key Exchange protocol, the SSL/TLS handshake protocol, and the SSH public key-based authentication.

Generation of True Random Numbers

The security of modern cryptographic algorithms is founded exclusively on the true randomness of the chosen session keys. The same is valid for the challenge/response protocols used for peer authentication that are based on the prerequisite that the challenge strings will never occur twice during the whole lifetime of the system. As a consequence, several random or pseudorandom material must be generated in order to satisfy the demands of a truly secure communication channel.

In a workstation environment, usually sufficient random information can be continuously collected from the timing of keyboard strokes and mouse movements. On unattended servers and firewalls, only disk access timing and arrival times of network packets remain as practical entropy sources, whereas the latter source might raise the concern of some paranoid crypto experts who postulate that the network traffic timing could potentially be manipulated by a malicious attacker. Fortunately, modern Intel-based platforms often possess a chip set [20] with a built-in random generator (RNG) that produces random numbers in copious quantities.

On low-end diskless embedded platforms, it becomes increasingly difficult to gather any random material at all. The usual makeshift solution consists of transferring an initialization file containing about 1024 true random bytes to the target platform during system configuration. This pool of random data is then used as a seed for a pseudorandom generator. After each access to the generator, the new state of the random pool is saved back to the file, thus guaranteeing that the random generator will always start from the last used state and will therefore never repeat itself.

Since embedded systems are often used to control real-time processes, there might be random information readily available at the numerous control inputs. As an alternative, a noise source or some other reliable random device could be attached to some of the unconnected inputs if available. Practical results undertaken at the Zurich University of Applied Sciences in Winterthur, using both a noisy diode and a free-running oscillator have shown that with little hardware effort, a low-cost, low-complexity random number generator can be built suited to low-end embedded platforms. Great care must be taken to

© 2005 by CRC Press LLC

deskew the generated stream of raw random bits, since it is very difficult to achieve a perfectly even distribution of 'zeros' and 'ones.' Either the simple von Neumann de-skewing algorithm [21] can be used or even better, all raw bits gathered from hardware random sources should first be hashed into a random pool using the MD5 or SHA-1 digest algorithms in order to improve the statistical properties of the derived key material.

Public Key Operations

The second obstacle in providing strong cryptography to embedded systems is the extremely time-consuming modular exponentiation operation

$$y = x^e \bmod n$$

that is the corner stone of both the RSA and Diffie–Hellman public key algorithms. Usually, the basis x, the exponent e, and the modulus n are large integers having a size k of 512..2048 bits. Using its RSA private key, an SSL/TLS server running on an embedded system must compute a singular modular exponentiation in order to decrypt the premaster secret that had been previously encrypted by the SSL/TLS client with the server's RSA public key. The processing time needed to execute this crucial RSA decryption operation was measured on the 20 MHz IPC@CHIP platform described in Section 91.4. The results are listed in Table 91.1.

The selected RSA key size k is equivalent to the size of the modulus n used in the modular exponentiation. The observed processing time t varies from a mere 8 sec for the insecure key size k of 512 bits, to 48 sec for the standard RSA key size of 1024 bits, and a horrendous 335 sec for the 2048-bit keys that might be required in a couple of years from now. These execution times listed above are typical values for machine code automatically generated by a standard C compiler. By manually coding the critical parts of the multi-precision multiplication in assembly code, an acceleration of nearly a factor of two can be achieved.

The processing time for the 16-bit IPC@CHIP platform can be well approximated by the formula

$$t \approx \frac{702(k/1024)^3 + 273(k/1024)^2}{f_c[\text{MHz}]}\ [\text{s}]$$

which is plotted together with our measurement data in Figure 91.9. For large key lengths k, the processing time increases with the third power of k. This asymptotic behavior can be easily explained by the fact that the execution time for a multi-precision multiplication of two k bit numbers is proportional to k^2 and that a modular exponentiation with a k bit exponent requires on the average about $k/2$ multi-precision multiplications. Besides the clock frequency, the processor's word size is very decisive for the execution speed. Halving the word size from 16 bits to 8 bits increases the time for a multi-precision multiplication by a factor of four, whereas doubling it to 32 bits decreases it by the same factor.

With the typical system clock of $f_c = 20$ MHz for a low-end embedded processor, an RSA decryption takes 48 sec to execute, whereas with today's 1000 MHz 32-bit Pentium processors, the same operation can be done within well below one second. Such an initial delay of nearly 1 min can be prohibitive in many real-time application, although as a workaround in the particular case of the SSL/TLS protocol, a session can be resumed after a break without the need to encrypt, transmit, and decrypt a new premaster secret.

TABLE 91.1 Processing Time for an RSA Decryption

RSA key Size k (bits)	Processing time t (s)
512	8
768	22
1024	48
1536	150
2048	335

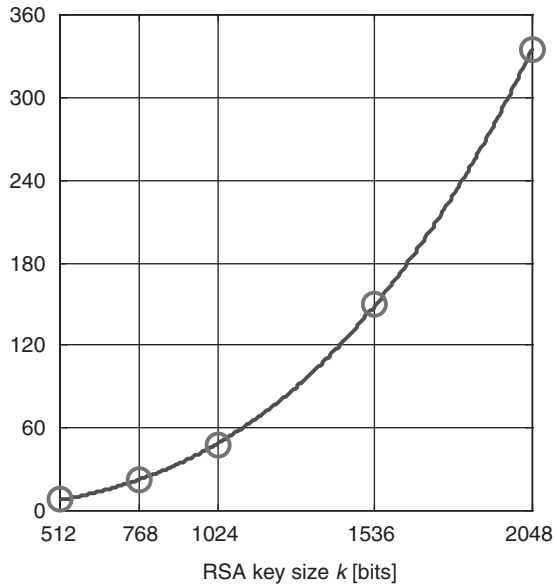

FIGURE 91.9 Processing time in [s] for RSA decryption.

TABLE 91.2 RSA/ECC Key Size Equivalent Strength Comparison (Data from [23])

Time to break in MIPS years	RSA key size (bits)	ECC key size (bits)	RSA/ECC key size ratio
10^4	512	106	5:1
10^8	768	132	6:1
10^{11}	1024	160	7:1
10^{20}	2048	210	10:1

The class of Elliptic Curve Public Key Cryptosystem (ECC) public key algorithms [22] can offer a significant improvement in processing delay, thus making many time-critical applications feasible. The main reason for this speed gain are the much shorter key lengths required (compared to the RSA cryptosystem) to achieve the same cryptographic strength. Table 91.2 shows that a 160-bit ECC key is equivalent in strength to a 1024-bit RSA key. In the years to come, 2048-bit RSA keys might be required to maintain adequate security, which doubles the current RSA key lengths, whereas the ECC key length will have to grow by 50 bits only.

Due to the much shorter key lengths, ECC promises acceleration factors of 10..100 for a 160-bit ECC key, compared to a 1024-bit RSA key [23], especially if the algorithm is realized in special hardware or on a smartcard crypto-coprocessor. ECC software implementations are still not widely deployed, with Certicom being the market leader. Fortunately, thanks to a software donation by Sun Microsystems, the [snapshot] version of the OpenSSL package [16] includes now full ECC support.

91.4 Example of an SSL/TLS-enabled Embedded Platform

In October 2000, the Security Group of the Zurich University of Applied Sciences in Winterthur started its activities in the field of lightweight security protocols by porting the OpenSSL library [16] to the tiny 16-bit 80186-based IPC@CHIP embedded Web server platform shown in Figure 91.10.

The IPC@CHIP is based on a 16-bit little-endian Intel-compatible 80186 processor running with a modest system clock of f_c = 20 MHz. The platform is equipped with 512 kbytes of RAM and 512 kbytes of nonvolatile flash memory and possesses an integrated 10Base-T Ethernet interface. Since about half of

© 2005 by CRC Press LLC

FIGURE 91.10 SSL/TLS-enabled mini Web server.

the flash space is used to store the BIOS comprising a built-in TCP/IP stack, 256 kbytes of free memory are available for the SSL/TLS protocol implementation and the actual application running on the embedded system.

As part of their diploma thesis, the two ZHW students Bernhard Lenzlinger and Andreas Zingg succeeded in stripping the OpenSSL library from the original 1.6 Mbytes down to a mere 580 kbytes. Based on this shrunk 16-bit library, they were able to build an SSL/TLS-enabled Web server application. With its small size of 100 kbytes (after compression, but including the statically linked OpenSSL library), the SSL/TLS server fitted without problems into the available flash memory.

The features offered by the mini Web server depicted in Figure 91.10 are as follows:

- Support of the SSL 3.0 and TLS 1.0 protocols.
- File-based initialization of the random seed.
- MD5 and SHA-1 hash used for message authentication.
- RC4 stream cipher with 128-bit symmetric key used for encryption.
- X.509 certificate used for server authentication.
- 1024-bit RSA key embedded in the X.509 server certificate used for the encrypted transmission of the premaster secret from client to server.
- Secure client-side authentication based on HTTP passwords after SSL/TLS link has been successfully established.
- Single HTTP session supported, no multithreading.

Multiple sessions could be cached making session resuming possible, but only a single concurrent TCP/IP socket was supported.

Encouraged by the success of this lightweight SSL/TLS rapid prototype, the Security Group of the Zurich University of Applied Sciences in Winterthur decided to launch the project "*Secure Communications in Distributed Embedded Systems*" in July 2002, with the following extended objectives:

- Implementation of a modular and lightweight SSL 3.0 / TLS 1.0 protocol stack that can be quickly ported with little or no modifications to a large variety of 16- and 32-bit embedded platforms possessing limited memory resources and processing power.
- Support of the fast AES [24] with 128-bit symmetric keys, which is much more secure than the current default RC4 stream cipher.
- Support of the fast ECC [22] in addition to the traditional RSA Public Key Cryptosystem.
- Multithreading capability allowing multiple concurrent TCP/IP sockets.

The design of this extended and modular SSL/TLS stack will be tailored to the needs of a large percentage of the existing embedded system platforms, spanning the whole range from the low-end 16-bit microcontrollers with proprietary operating systems up to the powerful 32-bit processors running under embedded Linux.

© 2005 by CRC Press LLC

91.5 Conclusions

In this chapter, we have shown that secure communications in distributed embedded systems can be implemented in nearly all layers of the communications stack, but we express a pronounced preference for the network and transport layers. A practical implementation of an SSL/TLS stack on a low-end 16-bit embedded platform has clearly demonstrated that lightweight security protocols are feasible. For high-end, embedded Linux-based platforms, IPsec might be the optimum choice due to the maximum flexibility that can achieved. With the advent of the fast AES and ECC algorithms, the speed handicap incurred by low-cost and low-power processors will be alleviated and time-critical applications will become feasible. In special cases, hardware acceleration using a crypto coprocessor might be required. Such devices are available, for example, in the form of smart card crypto coprocessors. For pure console-based applications, the ssh is certainly the right choice. And if your security requirements are not so stringent and encryption of the payload is not mandatory, then HTTP Digest Access Authentication might be the appropriate option.

92.1 Introduction

"System-on-Chip" is a phrase that has been much bandied about in recent years [1]. It is more than a design style, more than an approach to the design of application-specific integrated circuits (ASICs), more than a methodology. Rather, System-on-Chip (SoC) represents a major revolution in IC design — a revolution enabled by the advances in process technology allowing the integration of all or most of the major components and subsystems of an electronic product onto a single chip, or integrated chipset. [2] This revolution in design has been embraced by many designers of complex chips, as the performance, power consumption, cost, and size advantages of using the highest level of integration made available have proven to be extremely important for many designs. In fact, the design and use of SoCs is arguably one of the key problems in designing real-time embedded systems.

The move to SoC began sometime in the mid-1990s. At this point, the leading CMOS-based semiconductor process technologies of 0.35 and 0.25 microns were sufficiently capable of allowing the integration of many of the major components of a second-generation wireless handset or a digital set-top box

© 2005 by CRC Press LLC

onto a single chip. The digital baseband functions of a cellphone — a Digital Signal Processor (DSP), hardware support for voice encoding and decoding, and an RISC processor — could all be placed onto a single die. Although such a baseband SoC was far from the complete cellphone electronics — there were major components such as the RF transceiver, the analog power control, analog baseband, and passives that were not integrated — the evolutionary path with each new process generation, to integrate more and more onto a single die, was clear. Today's chipset would become tomorrow's chip. The problems of integrating hybrid technologies involved in making up a complete electronic system would be solved. Thus, eventually, SoC could encompass design components drawn from the standard and more adventurous domains of digital, analog, RF, reconfigurable logic, sensors, actuators, optical, chemical, microelectronic mechanical systems, and even biological and nanotechnology.

With this viewpoint, of continued process evolution leading to ever-increasing levels of integration into ever-more-complex SoC devices, the issue of an SoC being a single *chip* at any particular point in time is somewhat moot. Rather, the word "system" in SoC is more important than "chip." What is most important about an SoC whether packaged as a single chip, or integrated chipset, or System-in-Package (SiP) or System-on-Package (SoP) is that it is designed as an integrated *system*, making design tradeoffs across the processing domains and across the individual chip and package boundaries.

92.2 SoC

Let us define a SoC as a complex integrated circuit, or integrated chipset, which combines the major functional elements or subsystems of a complete end-product into a single entity. These days, all interesting SoC designs include at least one programmable processor, and very often a combination of at least one RISC control processor and one DSP. They also include on-chip communications structures — processor bus(es), peripheral bus(es), and perhaps a high-speed system bus. A hierarchy of on-chip memory units, and links to off-chip memory are important especially for SoC processors (cache, main memories, very often separate instruction, and data caches are included). For most signal-processing applications, some degree of hardware-based accelerating functional units are provided, offering higher performance and lower energy consumption. For interfacing to the external, real world, SoCs include a number of peripheral processing blocks, and due to the analog nature of the real world, this may include analog components as well as digital interfaces (e.g., to system buses at a higher packaging level). Although there is much interesting research in incorporating MEMS-based sensors and actuators, and in SoC applications incorporating chemical processing (lab-on-a-chip), these are, with rare exceptions, research topics only. However, future SoCs of a commercial nature may include such subsystems, as well as optical communications interfaces.

Figure 92.1 illustrates what a typical SoC might contain for consumer applications.

One key point about SoC that is often forgotten for those approaching them from a hardware-oriented perspective is that all interesting SoC designs encompass both hardware and software components, that is, programmable processors, real-time operating systems, and other aspects of hardware-dependent software such as peripheral device drivers, as well as middleware stacks for particular application domains, and possibly optimized assembly code for DSPs. Thus, the design and use of SoCs cannot remain a hardware-only concern — it involves aspects of system-level design and engineering, hardware-software tradeoff and partitioning decisions, and software architecture, design, and implementation.

92.3 System-on-a-Programmable-Chip

Recently, attention has increased in the SoC world from SoC implementations using custom, ASIC, or application-specific standard part (ASSP) design approaches, to include the design and use of complex reconfigurable logic parts with embedded processors and other application-oriented blocks of intellectual property. These complex Field-Programmable Gate Arrays (FPGAs) are offered by several vendors, including Xilinx (Virtex-II PRO Platform FPGA) and Altera (SOPC), but are referred to by several names: highly programmable SoCs, system-on-a-programmable-chip, and embedded FPGAs. The key idea behind this approach to SoC is to combine large amounts of reconfigurable logic with embedded RISC processors (either custom laid-out, "hardened" blocks, or synthesizable processor cores), in order to allow

© 2005 by CRC Press LLC

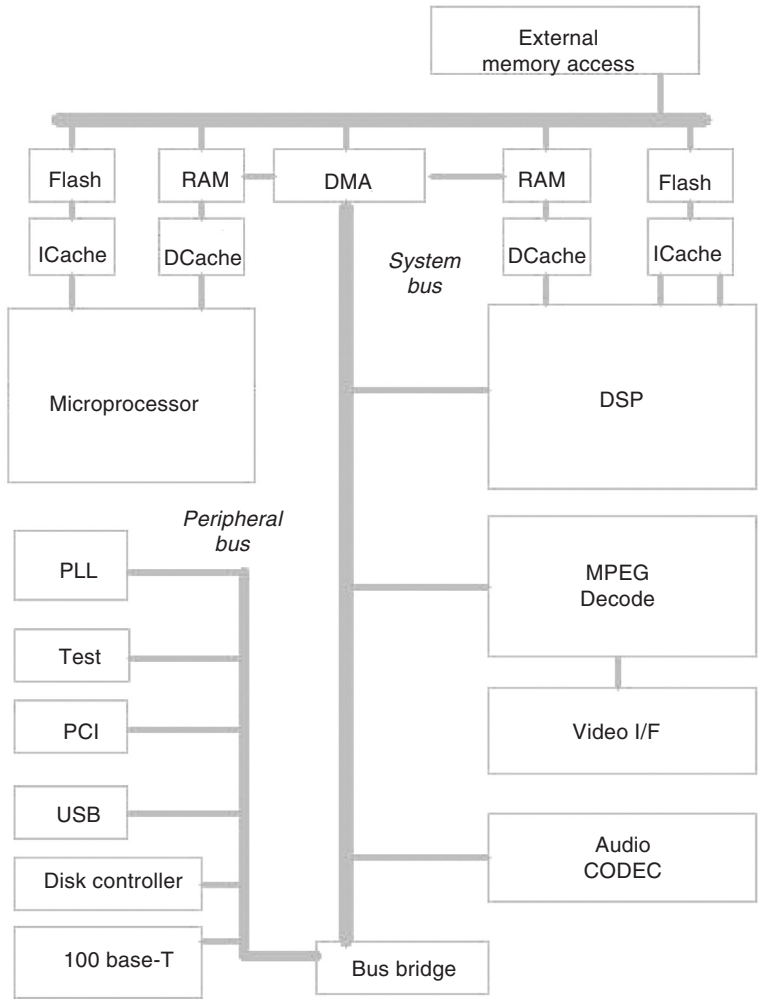

FIGURE 92.1 A typical SoC device for consumer applications.

very flexible and tailorable combinations of hardware and software processing to be applied to a particular design problem. Algorithms that consist of significant amounts of control logic, plus significant quantities of dataflow processing, can be partitioned into the control RISC processor (e.g., in Xilinx Virtex-II PRO, a PowerPC processor) and reconfigurable logic offering hardware acceleration. Although the resulting combination does not offer the highest performance, lowest energy consumption, or lowest cost, in comparison with custom IC or ASIC/ASSP implementations of the same functionality, it does offer tremendous flexibility in modifying the design in the field and avoiding expensive Non-Recurring Engineering (NRE) charges in the design. Thus, new applications, interfaces, and improved algorithms can be downloaded to products working in the field using this approach.

Products in this area also include other processing and interface cores, such as multiply-accumulate (MAC) blocks that are specifically aimed at DSP-type dataflow signal and image-processing applications, and high-speed serial interfaces for wired communications such as serializer/deserializer (SERDES) blocks. In this sense, system-on-a-programmable-chip SoCs are not exactly application-specific, but not completely generic either.

It remains to be seen whether system-on-a-programmable chip SoCs are going to be a successful way of delivering high-volume consumer applications, or will end up restricted to the two main applications

© 2005 by CRC Press LLC

for high-end FPGAs: rapid prototyping of designs that will be retargeted to ASIC or ASSP implementations, and used in high-end, relatively expensive parts of the communications infrastructure that require in-field flexibility and can tolerate the tradeoffs in cost, energy consumption, and performance. Certainly, the use of synthesizable processors on more moderate FPGAs to realize SoC style designs is one alternative to the cost issue. Intermediate forms, such as the use of metal-programmable gate-array style logic fabrics together with hard-core processor subsystems and other cores, such as is offered in the "Structured ASIC" offerings of LSI Logic (RapidChip) and NEC (Instant Silicon Solutions Platform) represents an intermediate form of SoC between the full-mask ASIC and ASSP approach and the field-programmable gate array approach. Here, the tradeoffs are a much slower design creation (a few weeks rather than a day or so), higher NRE than FPGA (but much lower than a full set of masks), and better cost, performance, and energy consumption than FPGA (perhaps 15–30% worse than an ASIC approach). Further interesting compromises or hybrid style approaches, such as ASIC/ASSP with on-chip FPGA regions, are also emerging to give design teams more choices.

92.4 IP Cores

The design of SoC would not be possible if every design started from scratch. In fact, the design of SoC depends heavily on the reuse of Intellectual Property blocks — what are called "IP Cores." IP reuse has emerged as a strong trend over the last 8–9 years [3] and has been one key element in closing what the International Technology Roadmap for Semiconductors [4] calls the "design productivity gap" — the difference between the rate of increase of complexity offered by advancing semiconductor process technology, and the rate of increase in designer productivity offered by advances in design tools and methodologies.

But reuse is not just important to offer ways of enhancing designer productivity — although it has dramatic impacts on this. It also provides a mechanism for design teams to create SoC products that span multiple design disciplines and domains. The availability of both hard (laid-out and characterized) and soft (synthesizable) processor cores from a number of processor IP vendors allows design teams who would not be able to design their own processor from scratch to drop them into their designs and thus add RISC control and DSP functionality to an integrated SoC without having to master the art of processor design within the team. In this sense, the advantages of IP reuse go beyond productivity — it offers both a large reduction in design risk, and also a way for SoC designs to be done that would otherwise be infeasible due to the length of time it would take to acquire expertise and design IP from scratch.

This ability when acquiring and reusing IP cores — to acquire, in a *prepackaged* form, design domain expertise outside one's own design team's set of core competencies, is a key requirement for the evolution of SoC design going forward. Up to this point, SoC has concentrated in large part on integrating digital components together, perhaps with some analog interface blocks that are treated as black boxes. The hybrid SoCs of the future, incorporating domains unfamiliar to the integration team, such as RF or MEMS, requires the concept of "drop-in" IP to be extended to these new domains. We are not yet at that state — considerable evolution in the IP business and the methodologies of IP creation, qualification, evaluation, integration, and verification are required before we will be able to easily specify and integrate truly heterogeneous sets of disparate IP blocks into a complete hybrid SoC.

However, the same issues existed at the beginning of the SoC revolution in the digital domain. They have been solved to a large extent, through the creation of standards for IP creation, evaluation, exchange, and integration — primarily for digital IP blocks but also extending to analog/mixed-signal (AMS) cores. Among the leading organizations in the identification and creation of such standards has been the Virtual Socket Interface Alliance (VSIA) [5], formed in 1996 and having at its peak membership more than 200 IP, systems, semiconductor, and Electronic Design Automation (EDA) corporate members. Although often criticized over the years for a lack of formal and acknowledged adoption of its IP standards, VSIA has had a more subtle influence on the electronics industry. Many companies instituting reuse programs internally, many IP, systems, and semiconductor companies engaging in IP creation and exchange, and many design groups have used VSIA IP standards as a key starting point for

© 2005 by CRC Press LLC

developing their own standards and methods for IP-based design. In this sense, use of VSIA outputs has enabled a kind of IP reuse in the IP business.

VSIA, for example, in its early architectural documents of 1996–1997, helped define the strong industry-adopted understanding of what it meant for an IP block to be considered to be in "hard" or "soft" form. Other important contributions to design included the widely read system-level design model taxonomy created by one of its working groups. Its standards, specifications, and documents thus represent a very useful resource for the industry.

Other important issues for the rise of IP-based design and the emergence of a third party industry in this area (which has taken much longer to emerge than originally hoped in the mid-1990s) are the business issues surrounding IP evaluation, purchase, delivery, and use. Organizations such as the Virtual Component Exchange (VCX) [6] emerged to look at these issues and provide solutions. Although still in existence, it is clear that the vast majority of IP business relationships between firms occurs within a more *ad hoc* supplier to customer business framework.

92.5 Virtual Components

The VSIA has had a strong influence on the nomenclature of the SoC- and IP-based design industry. The concept of the "virtual socket" — a description of all the design interfaces that an IP core must satisfy, and design models and integration information that must be provided with the IP core, required to allow it to be more easily integrated or "dropped into" an SoC design, comes from the concept of Printed Circuit Board (PCB) design where components are sourced and purchased in a prepackaged form and can be dropped into a board design in a standardized way.

The dual of the "virtual socket" then becomes the "virtual component." Specifically in the VSIA context, but also more generally in the interface, an IP core represents a design block that *might* be reusable. A virtual component represents a design block that is *intended* for reuse, and that has been *developed* and *qualified* to be highly reusable. The things that separate IP cores from virtual components are in general as follows:

- Virtual components conform in their development and verification processes to well-established design processes and quality standards.
- Virtual components come with design data, models, associated design files, scripts, characterization information, and other deliverables that conform to one or other well-accepted standards for IP reuse — for example, the VSIA deliverables, or another internal or external set of standards.
- Virtual components in general should have been fabricated at least once, and characterized post-fabrication to ensure that they have validated claims.
- Virtual components should have been reused at least once by an external design team, and usage reports and feedback should be available.
- Virtual components should have been rated for quality using an industry standard quality metric such as OpenMORE (created by Synopsys and Mentor Graphics) or the VSI Quality standard (which has OpenMORE as one of its inputs).

To a large extent, the developments over the last decade in IP reuse have been focused on defining the standards and processes to turn the *ad hoc* reuse of IP cores into a well-understood and reliable process for acquiring and reusing virtual components, thus enhancing the analogy with PCB design.

92.6 Platforms and Programmable Platforms

The emphasis in the preceding sections has been on IP (or virtual component) reuse on a somewhat *ad hoc* block-by-block basis in SoC design. Over the past several years, however, a more integrated approach to the design of complex SoCs and the reuse of virtual components has arisen — what has been called "Platform based design." This will be dealt with at a much greater length in another chapter in this book. Much more information is available in the references [7–10]. Suffice it here to define platform-based design in the SoC context from one perspective.

© 2005 by CRC Press LLC

We can define platform-based design as a planned design methodology, which reduces the time and effort required, and risk involved, in designing and verifying a complex SoC. This is accomplished by extensive reuse of combinations of hardware and software IP. As an alternative to IP reuse in a block-by-block manner, platform-based design assembles groups of components into a reusable platform architecture. This reusable architecture, together with libraries of preverified and precharacterized, application-oriented HW and SW virtual components is an SoC integration platform.

There are several reasons for the growing popularity of the platform approach in industrial design. These include the increase in design productivity, the reduction in risk, the ability to utilize preintegrated virtual components from other design domains more easily, and the ability to reuse SoC architectures created by experts. Industrial platforms include full application platforms, reconfigurable platforms, and processor-centric platforms [11]. Full application platforms, such as Philips Nexperia and TI OMAP provide a complete implementation vehicle for specific product domains [12]. Processor-centric platforms, such as ARM PrimeXsys, concentrate on the processor, its required bus architecture and basic sets of peripherals, along with RTOS and basic software drivers. Reconfigurable or "highly programmable" platforms such as the Xilinx Platform FPGA and Altera's SOPC deliver hardcore processors plus reconfigurable logic along with associated IP libraries and design tool flows.

92.7 Integration Platforms and SoC Design

The use of SoC integration platforms changes the SoC design process in two fundamental ways:

1. The basic platform must be designed, using whatever *ad hoc* or formalized design process for SoC that the platform creators decide on. The next section outlines some of the basic steps required to build an SoC, whether building a platform or using a block-based more *ad hoc* integration process. However, when constructing an SoC platform for reuse in derivative design, it is important to remember that it may not be necessary to take the whole platform and its associated HW and SW component libraries through complete implementation. Enough implementation must be done to allow the platform and its constituent libraries to be fully characterized and modeled for reuse. It is also essential that the platform creation phase produce in an archivable and retrievable form all the design files required for the platform and its libraries to be reused in a derivative design process. This must also include the setup of the appropriate configuration programs or scripts to allow automatic creation of a configured platform during derivative design.
2. A design process must be created and qualified for all the *derivative* designs, which will be created based on the SoC integration platform. This must include processes for retrieving the platform from its archive, for entering the derivative design configuration into a platform configurator, the generation of the design files for the derivative, the generation of the appropriate verification environment(s) for the derivative, the ability for derivative design teams to select components from libraries, to modify these components and validate them within the overall platform context, and, to the extent supported by the platform, to create new components for their particular application.

Reconfigurable or highly programmable platforms introduce an interesting addition to the platform-based SoC design process [13]. Platform FPGAs and SOPC devices can be thought of as a "meta-platform": a platform for creating platforms. Design teams can obtain these devices from companies such as Xilinx and Altera, containing a basic set of more generic capabilities and IP — embedded processors, on-chip buses, special IP blocks such as MACs and SERDES, and a variety of other pre-qualified IP blocks. They can then customize the meta-platform to their own application space by adding application domain-specific IP libraries. Finally, the combined platform can be provided to derivative design teams, who can select the basic meta-platform and configure it within the scope intended by the intermediate platform creation team, selecting the IP blocks needed for their exact derivative application. More on platform-based design will be found in another chapter in this book.

92.8 Overview of the SoC Design Process

The most important thing to remember about SoC design is that it is a multidisciplinary design process, which needs to exercise design processes from across the spectrum of electronics. Design teams must gain some fluency with all these multiple disciplines, but the integrative and reuse nature of SoC design means that they may not need to become deep experts in all of them. Indeed, avoiding the need for designers to understand all methodologies, flows and domain-specific design techniques are one of the key reasons for reuse and enablers of productivity. Nevertheless, from DFT through digital and analog HW design, from verification through system-level design, from embedded SW through IP procurement and integration, from SoC architecture through IC analysis, a wide variety of knowledge is required by the team, if not every designer.

Figure 92.2 illustrates some of the basic constituents of the SoC design process.

We will now define each of these steps as illustrated:

SoC requirements analysis is the basic step of defining and specifying a complex SoC, based on the needs of the end product into which it will be integrated. The primary input into this step is the marketing definition of the end product and the resulting characteristics of what the SoC should be: both functional and nonfunctional (e.g., cost, size, energy consumption, performance: latency and throughput, package selection). This process of requirements analysis must ultimately answer the question: is the product feasible? Is the desired SoC feasible to design, and with what effort and in what timeframe? How much reuse will be possible? Is the SoC design based on legacy designs of previous generation products (or, in the case of platform-based design, to be built based on an existing platform offering)?

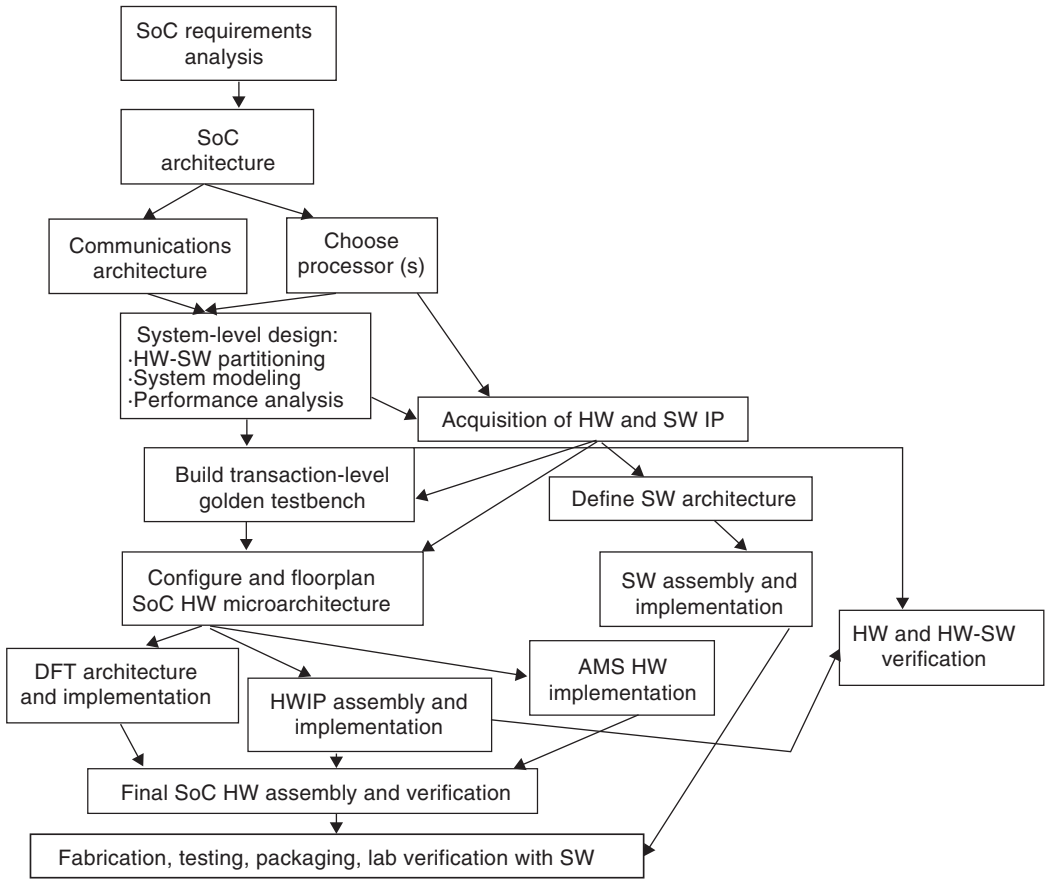

FIGURE 92.2 Steps in the SoC design process.

© 2005 by CRC Press LLC

SoC architecture: In this phase, the basic structure of the desired SoC is defined. It is vitally important to decide on the *communications architecture* that will be used as the backbone of the SoC on-chip communications network. An inadequate communications architecture will cripple the SoC and have as large an impact as the use of an inappropriate processor subsystem. Of course, the choice of communications architecture is impossible to divorce from making the basic *processor(s) choice* — for example, do I use an RISC control processor? Do I have an on-board DSP? How many of each? What are the processing demands of my SoC application? Do I integrate the bare processor core, or use a whole processor subsystem provided by an IP company (most processor IP companies have moved from offering just processor cores, to whole processor subsystems including hierarchical bus fabrics tuned to their particular processor needs)? Do I have some ideas, based on legacy SoC design in this space, as to how SW and HW should be partitioned? What memory hierarchy is appropriate? What are the sizes, levels, performance requirements, and configurations of the embedded memories most appropriate to the application domain for the SoC?

System-level design is an important phase of the SoC process — but one that is often done in a relatively *ad hoc* way. The whiteboard and the spreadsheet are as much used by the SoC architects as more capable toolsets. However, *ad hoc* C/C++- based models have long been in use for the system design phase — to validate basic architectural choices. And designers of complex signal processing algorithms for voice and image processing have long adopted dataflow models and associated tools to define their algorithms, define optimal bit-widths, and validate performance whether destined for hardware or software implementation. A flurry of activity in the last few years on different C/C++ modeling standards for system architects has consolidated on SystemC [14]. The *system* nature of SoC demands a growing use of system-level design modeling and analysis as these devices grow more complex. The basic processes carried out in this phase include HW–SW partitioning (the allocation of functions to be implemented in dedicated HW blocks, in SW on processors (and the decision of RISC vs. DSP), or a combination of both, together with decisions on the communications mechanisms to be used to interface HW and SW, or HW–HW, and SW–SW). In addition, the construction of system-level models, and the analysis of correct functioning, performance, and other nonfunctional attributes of the intended SoC through simulation and other analytical tools, is necessary. Finally, all additional IP blocks required that can be sourced outside, or reused from the design group's legacy, must be identified — both HW and SW. The remaining new functions will need to be implemented as a part of the overall SoC design process.

After system-level design and the identification of the processors and communications architecture, and other HW or SW IP required for the design, the group must undertake an *IP acquisition* stage. To a large extent, this can be done at least in part in parallel with other work such as system-level design (assuming early identification of major external IP is made) or building golden transaction-level testbench models. Fortunate design groups will be working in companies with both a large legacy of existing well-crafted IP (rather, "virtual components") organized in easy to search databases, or those with access via supplier agreements to large external IP libraries, or at least those with experience at IP search, evaluation, purchase, and integration. For these lucky groups, the problems at this stage are greatly ameliorated. Others with less experience or infrastructure will need to explore these processes for the first time, hopefully making use of IP suppliers' experience with the legal and other processes required. Here, the external standards bodies such as VSIA and VCX have done much useful work that will smooth the path, at least a little. One key issue in IP acquisition is to conduct rigorous and thorough incoming inspection of IP to ensure its completeness and correctness to the greatest extent possible prior to use, and to resolve any problems with quality early with suppliers — long before SoC integration. Every hour spent on this at this stage will pay back in avoiding much longer schedule slip later. The IP quality guidelines discussed earlier are a foundation level for a quality process at this point.

Build a transaction-level golden testbench: The system model built up during the system-level design stage can form the basis for a more elaborated design model, using "transaction-level" abstractions [15], which represents the underlying HW–SW architecture and components in more detail — sufficient detail to act as a functional virtual prototype for the SoC design. This golden model can be used at this stage to verify the microarchitecture of the design and to verify detailed design models for HW IP at the Hardware Description Language (HDL) level within the overall system context. It thus can be reused all the way down the SoC design and implementation cycle.

© 2005 by CRC Press LLC

Define the SoC *SW architecture*. SoC is, of course, not just about HW [16]. In addition to often defining the right on-chip communications architecture, the choice of processor(s) and the nature of the application domain have a very strong influence on the SW architecture. For example, Real-Time Operating System (RTOS) choice is limited by the processor ports that have been done and by the application domain (OSEK is an RTOS for automotive systems; Symbian OS for portable wireless devices; PalmOS for Personal Digital Assistants, etc.). In addition to the basic RTOS, every SoC peripheral device will need a device driver, hopefully based on reuse and configuration of templates. Various middleware application stacks (e.g., telephony, multimedia image processing) are important parts of the SW architecture; voice and image encoding and decoding on portable devices often is based on assembly code IP for DSPs. There is thus a strong need in defining the SoC to fully elaborate the SW architecture to allow reuse, easy customization, and effective verification of the overall HW–SW device.

Configure and floorplan SoC microarchitecture: At this point, we are beginning to deal with the SoC on a more physical and detailed logical basis. Of course, during high-level architecture and system-level design, the team has been looking at physical implementation issues (although our design process diagram shows everything as a waterfall kind of flow; in reality, SoC design like all electronics design is more of an iterative, incremental process — that is, more akin to the famous "spiral" model for SW). But before beginning detailed HW design and integration, it is important that there is agreement among the team on the basic physical floorplan, that all the IP blocks are properly and fully configured, that the basic microarchitectures (test, power, clocking, bus, timing) have been fully defined and configured, and that HW implementation can proceed. In addition, this process should also generate the downstream verification environments that will be used throughout the implementation processes — whether SW simulation based, emulation based, using rapid prototypes, or other hybrid verification approaches.

DFT architecture and implementation: The test architecture is only one of the key microarchitectures that must be implemented; it is complicated by IP legacy and the fact that it is often impossible to impose one Design-for-Test style (such as BIST or SCAN) on all IP blocks. Rather, wrappers or adaptations of standard test interfaces (such as JTAG ports) may be necessary to fit all IP blocks together into a coherent test architecture and plan.

AMS HW implementation: Most SoCs incorporating AMS blocks use them to interface to the external world. VSIA, among other groups, has done considerable work in defining how AMS IP blocks should be created to allow them to be more easily integrated into mainly digital SoCs (the "Big D/little a" SoC), and guidelines and rules for such integration. Experiences with these rules and guidelines and extra deliverables have been on the whole promising — but they have more impact between internal design groups today than on the industry as a whole. The "Big A/Big D" mixed-signal SoC is still relatively rare.

HW IP assembly and integration: This design step is in many ways the most traditional. Many design groups have experience in assembling design blocks done by various designers or subgroups in an incremental manner, into the agreed on architectures for communications, bussing, clocking, power, etc. The main difference with SoC is that many of the design blocks may be externally sourced IP. To avoid difficulties at this stage, the importance of rigorous qualification of incoming IP and the early definition of the SoC microarchitecture, to which all blocks must conform, cannot be overstated.

SW assembly and implementation: Just as with HW, the SW IP, together with new or modified SW tasks created for the particular SoC under design, must be assembled together and validated as to conformance to interfaces and expected operational quality. It is important to verify as much of the SW in its normal system operating context as possible (see below).

HW and HW–SW verification: Although represented as a single box on the diagram, this is perhaps one of the largest consumers of design time and effort and the major determinant of final SoC quality. Vital to effective verification is the setup of a targeted SoC verification environment, reusing the golden testbench models created at higher levels of the design process. In addition, highly capable, multi-language, mixed simulation environments are important (e.g., SystemC models and HDL implementation models need to be mixed in the verification process and effective links between them are crucial). There are a large number of different verification tools and techniques [17], ranging from SW-based simulation environments, to HW emulators, HW accelerators, and FPGA and bonded-core-based rapid prototyping approaches. In addition,

© 2005 by CRC Press LLC

formal techniques such as equivalence checking, and model/property checking have enjoyed some successful usage in verifying parts of SoC designs, or the design at multiple stages in the process.Mixed approaches to HW–SW verification range from incorporating Instruction Set Simulators (ISSs) of processors in SW-based simulation to linking HW emulation of the HW blocks (compiled from the HDL code) to SW running natively on a host workstation, linked in an *ad hoc* manner by design teams or using a commercial mixed verification environment. Alternatively, HDL models of new HW blocks running in an SW simulator can be linked to emulation of the rest of the system running in HW — a mix of emulation and use of bonded-out processor cores for executing SW. It is important that as much of the system SW be exercised in the context of the whole system as possible, using the most appropriate verification technology that can get the design team close to real-time execution speed (no more than 100X slower is the minimum to run significant amounts of software). The trend to transaction-based modeling of systems, where transactions range in abstraction from untimed functional communications via message calls, through abstract bus communications models, through cycle-accurate bus functional models, and finally to cycle and pin-accurate transformations of transactions to the fully detailed interfaces, allows verification to occur at several levels or with mixed levels of design description. Finally, a new trend in verification is assertion-based verification, using a variety of input languages (PSL/Sugar, e, Vera, or regular Verilog and VHDL) to model design properties, which can then be monitored during simulation, either to ensure that certain properties will be satisfied, or certain error conditions never occur. Combinations of formal property checking and simulation-based assertion checking have been created, viz. "semi-formal verification." The most important thing to remember about verification is that armed with a host of techniques and tools, it is essential for design teams to craft a well-ordered verification process, which allows them to definitively answer the question "how do we know that verification is done?" and thus allow the SoC to be fabricated.

Final SoC HW assembly and verification: Often done in parallel or overlapping "those final few simulation runs" in the verification stage, the final SoC HW assembly and verification phase includes final place and route of the chip, any hand-modifications required, and final physical verification (using design rule checking and layout-vs.-schematic (netlist) tools), as well as important analysis steps for issues that occur in advanced semiconductor processes such as IR drop, signal integrity, power network integrity, as well as satisfaction and design transformation for manufacturabilty (OPC, etc.).

Fabrication, testing, packaging, and lab verification: When an SoC has been shipped to fabrication, it would seem time for the design team to relax. Instead, this is an opportunity for additional verification to be carried out — especially more verification of system software running in the context of the hardware design — and for fixes, either of software, or of the SoC HW on hopefully no more than one expensive iteration of the design, to be determined and planned. When the tested packaged parts arrive back for verification in the lab, the ideal scenario is to load the software into the system and have the SoC and its system booted up and running software within a few hours. Interestingly, the most advanced SoC design teams, with well-ordered design methodologies and processes, are able to achieve this quite regularly.

92.9 System-Level Design

As we touched on earlier, when describing the overall SoC design flow, system-level design and SoC are essentially made for each other. A key aim of IP reuse and of SoC techniques such as platform-based design is to make the "back end" (RTL to GDS II) design implementation processes easier, fast and with low-risk, and to shift the major design phase for SoC up in time and in abstraction level to the system level. This also means that the back-end tools and flows for SoC designs do not necessarily differ from those used for complex ASIC, ASSP, and custom IC design — it is the methodology of how they are used, and how blocks are sourced and integrated, that overlays the underlying design tools and flows, which may differ for SoC. However, the fundamental nature of IP-based design of SoC has a stronger influence on the system level.

It is at the system level that the vital tasks of deciding on and validating the basic system architecture and choice of IP blocks are carried out. In general, this is known as "design space exploration." As part of this exploration, SoC platform customization for a particular derivative is carried out, should the SoC platform approach be used. Essentially, one can think of platform design space exploration (DSE) as

© 2005 by CRC Press LLC

being a task similar to general DSE, except that the scope and boundaries of the exploration are much more tightly constrained — the basic communications architecture and platform processor choices may be fixed, and the design team may be restricted to choosing certain customization parameters and choosing optional IP from a library. Other tasks include HW–SW partitioning, usually restricted to decisions about key processing tasks, which might be mapped into either HW or SW form and that have a large impact on system performance, energy consumption, on-chip communications bandwidth consumption, or other key attributes. Of course, in multi-processor systems, there are "SW–SW" partitioning or codesign issues as well, deciding on the assignment of SW tasks to various processor options. Again, perhaps 80–95% of these decisions can or are made *a priori*, especially if an SoC is either based on a platform or an evolution of an existing system; such codesign decisions are usually made on a small number of functions that have critical impact.

Because partitioning, codesign, and DSE tasks at the system level involve much more than HW–SW issues, a more appropriate term for this is "function-architecture codesign" [18, 19]. In this codesign model, systems are described on two equivalent levels:

- The functional intent of the system — for example, a network of applications, decomposed into individual sets of functional tasks, which may be modeled using a variety of models of computation such as discrete event, finite state machine, or dataflow.
- The architectural structure of the system — the communications architecture, major IP blocks such as processor(s), memorie(s), and HW blocks, captured or modeled, for example, using some kind of IP or platform configurator.

The methodology implied in this approach is then to build explicit mappings between the functional view of the system and the architectural view, which carry within them the implicit partitioning that is made for both computation and communications. This hybrid model can then be simulated, the results analyzed, and a variety of ancillary models (e.g., cost, power, performance, communications bandwidth consumption, etc.) can be utilized in order to examine the suitability of the system architecture as a vehicle for realizing or implementing the end-product functionality.

The function–architecture codesign approach has been implemented and used in both research and commercial tools [20] and forms the foundation of many system-level codesign approaches going forward. In addition, it has been found to be extremely suitable as the best system-level design approach for platform-based design of SoC [21].

92.10 Interconnection and Communication Architectures for Systems on Chip

This topic is dealt with in more detail in other chapters in this book. Suffice it to say here that current SoC architectures deal in fairly traditional hierarchies of standard on-chip buses: for example, processor-specific buses, high-speed system buses, and lower-speed peripheral buses, using standards such as ARM's AMBA and IBM's CoreConnect [12], and traditional master–slave bus approaches. Recently, there has been considerable interest in network-on-chip communications architectures, based on packet-sw, and a number of approaches have been reported in the literature but this remains primarily a research topic both in universities and industrial research labs. [22]

92.11 Computation and Memory Architectures for Systems on Chip

The primary processors used in SoC are embedded RISCs such as ARM processors, PowerPCs, MIPS architecture processors and some of the configurable processors, designed specifically for SoC such as Tensilica and ARC. In addition, embedded DSPs from traditional suppliers as TI, Motorola, ParthusCeva, and others are also quite common in many consumer applications, for embedded signal processing for

© 2005 by CRC Press LLC

voice and image data. Research groups have looked at compiling or synthesizing application-specific processors or coprocessors [23, 24] and these have interesting potential in future SoCs, which may incorporate networks of heterogeneous configurable processors collaborating to offer large amounts of computational parallelism. This is an especially interesting prospect given the wider use of reconfigurable logic that opens up the prospect of dynamic adaptation of SoC to application needs. However, most multi-processor SoCs today involve at most 2–4 processors of conventional design; the larger networks are more often found today in the industrial or university lab.

Although several years ago most embedded processors in early SoCs did not use cache memory-based hierarchies, this has changed significantly over the years, and most RISC and DSP processors now involve significant amounts of Level 1 Cache memory, as well as higher level memory units both on and off chip (off-chip flash memory is often used for embedded software tasks which may be only infrequently required). System design tasks and tools must consider the structure, size, and configuration of the memory hierarchy as one of the key SoC configuration decisions that must be made.

92.12 IP Integration Quality and Certification Methods and Standards

We have emphasized the design reuse aspects of SoC and the need for reuse of both internal and externally sourced IP blocks by design teams creating SoCs. In the discussion of the design process above, we mentioned issues such as IP quality standards and the need for incoming inspection and qualification of IP. The issue of IP quality remains one of the biggest impediments to the use of IP-based design for SoC [25]. The quality standards and metrics available from VSIA and OpenMORE, and their further enhancement help, but only to a limited extent. The industry could clearly use a formal certification body or lab for IP quality that would ensure conformance to IP transfer requirements and the integration quality of the blocks. Such a certification process would be of necessity quite complex due to the large number of configurations possible for many IP blocks and the almost infinite variety of SoC contexts into which they might be integrated. Certified IP would begin to deliver the "virtual components" of the VSIA vision.

In the absence of formal external certification (and such third-party labs seem a long way off, if they ever emerge), design groups must provide their own certification processes and real reuse quality metrics, based on their internal design experiences. Platform-based design methods help due to the advantages of prequalifying and characterizing groups of IP blocks and libraries of compatible domain-specific components. Short of independent evaluation and qualification, this is the best that design groups can do currently.

One key issue to remember is that IP not created for reuse, with all the deliverables created and validated according to a well-defined set of standards, is inherently not reusable. The effort required to make a reusable IP block has been estimated to be 50–200% more effort than that required to use it once; however, assuming the most conservative extra cost involved implies positive payback with three uses of the IP block. Planned and systematic IP reuse and investment in those blocks with greatest SoC use potential gives a high chance of achieving significant productivity soon after starting a reuse program. But *ad hoc* attempts to reuse existing design blocks not designed to reuse standards have failed in the past and are unlikely to provide the quality and productivity desired.

92.13 Summary

In this chapter, we have defined System-on-a-Chip and have surveyed a large number of the issues involved in its design. An outline of the important methods and processes involved in SoC design define a methodology that can be adopted by design groups and adapted to their specific requirements. Productivity in SoC design demands high levels of design reuse, and the existence of third-party and internal IP groups and the chance to create a library of reusable IP blocks (true virtual components) are all possible for most design groups today. The wide variety of design disciplines involved in SoC mean that unprecedented collaboration between designers of all backgrounds — from systems experts through

© 2005 by CRC Press LLC

embedded software designers through architects through HW designers — is required. But the rewards of SoC justify the effort required to succeed.

93.1 Introduction

The motivations behind *Platform-Based Design* [10] originate in the *disaggregation of the electronic industry,* a phenomenon that has been evolving over the past decade and whose ultimate result consists in the move from a vertically oriented model into a horizontally oriented one. In the past, electronic companies used to maintain full control of the production cycle from product definition to final manufacturing. Nowadays, the identification of a new market opportunity, the definition of the detailed system specifications, the development of the components, the assembly of these components, and the manufacturing of the final product are tasks that are mostly performed by distinct organizations. In fact, the complexity of electronic designs and the number of technologies that must be mastered to bring to market winning products have forced electronic companies to focus on their core competence. In this scenario, the integration of the design chain becomes a serious problem, whose most delicate aspects occur at the *hand-off points* from one company to another. These must be unambiguously defined to avoid the risk of costly redesigns. Furthermore, each organization that contributes a component to the final product naturally strives for a position that allows it to make continuous adjustments and accomodate last-minute engineering changes. A most dramatic consequence of this quest for flexibility is the rise of standardized chips at the expense of custom and ASIC solutions. In fact, due to the increasing cost of mask ownership, only high-volume ASICs remain economically feasible for those semiconductor companies that both design and manufacture silicon. Instead, standardized chips that are highly reconfigurable (in hardware) and programmable (in software) provide the advantage of spreading the multimillion-dollar cost of a design across a range of applications. This shift toward reconfigurable and programmable solutions is a defining characteristic of embedded system design.

© 2005 by CRC Press LLC

Platform-based design addresses the above challenges by providing the following advantages:

It lays the foundation for developing economically feasible design flows because it is a structured methodology *that theoretically limits the space of exploration, yet still achieves superior results in the fixed time constraints of the design*. A platform is an abstraction layer in the design flow that facilitates a number of possible refinements into a subsequent abstraction layer in the design flow. The design process progresses through a series of platforms and each platform layer defines bounds for what is achievable by mapping into it, while offering a faster design and lower risk.

It provides a formal mechanism to identify the most critical hand-off points in the design chain: the hand-off point between system companies and IC design companies and the one between IC design companies and manufacturing companies represent the *articulation points* of the overall design process. For instance, semiconductor companies need to minimize risks when designing standardized chips. Hence, they need to have a fairly complete characterization of the application spaces that they wish to target together with the associated constraints in terms of affordable costs and performance levels. By the same token, system companies need to have an accurate characterization of the capabilities of the chips in terms of performance such as power consumption, size and timing, as well as *"Application Program Interfaces" (APIs)* that allow the mapping of their application into the chip at a fairly abstract level. APIs must then support a number of tools to ease the possibly automatic generation of the personalization of the programmable components of the chips.

It eliminates costly design iterations because it enables *derivative design,* that is, the technique of building an application-specific product by assembling and configuring platform components in a rapid and reliable manner. For instance, a hardware platform is a family of architectures satisfying a set of constraints imposed to allow reuse of hardware and software components. Then, an API platform can be developed to effectively extend the hardware platform toward the application software, thus enabling quick, reliable, and derivative design.

This paper is organized as follows. In Section 93.2, we define the main principles of platform-based design. Since the term "platform" has been used in several ways by the various segments of the electronic industry, our goal is to provide a precise reference that may be used as the basis for reaching a common understanding in the electronic system and circuit design community. In the following sections, we discuss the use of these principles in system design and in silicon implementation. First, we revisit the discussion on the platforms that define the articulation points between system definition and implementation (Section 93.3). Then, we discuss network platforms, which are an important example of application of *pure* system design (Section 93.4) and analog platforms, which are destined to have a key role in determining the overall design time and effort of silicon implementations (Section 93.5).

93.2 Platform-Based Design

The basic tenets of platform-based design are:

- The identification of design as a *meeting-in-the-middle process,* where successive refinements of specifications meet with abstractions of potential implementations.
- The identification of precisely defined layers where the refinement and abstraction processes take place. Each layer supports a design stage providing an opaque abstraction of lower layers that allows accurate performance estimations. This information is incorporated in appropriate parameters that annotate design choices at the present layer of abstraction. These layers of abstraction are called *platforms* to stress their role in the design process and their solidity.

In practice, a platform is a library of components that can be assembled to generate a design at that level of abstraction. This library not only contains *computational* blocks that carry out the appropriate computation but also *communication* components that are used to interconnect the functional components. Each element of the library has a characterization in terms of performance parameters, together with the functionality it can support. For every platform level, there is a set of methods used to map the upper layers of abstraction into the platform and a set of methods used to estimate performances of

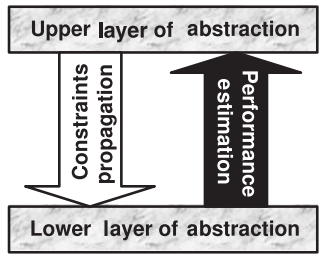

FIGURE 93.1 Interactions between abstraction layers.

lower level abstractions. As illustrated in Figure 93.1, the meeting-in-the-middle process is a combination of two efforts:

- top-down: map an instance of the top platform into an instance of the lower platform and propagate constraints;
- bottom-up: build a platform by defining the *library* that characterizes it and a performance abstraction (e.g., number of literals for tech. independent optimization, area and propagation delay for a cell in a standard cell library).

A *platform instance* is a set of architecture components that are selected from the library and whose parameters are set. Often, the combination of two consecutive layers and their "filling" can be interpreted as a unique abstraction layer with an "upper" view, the top abstraction layer, and a "lower" view, the bottom layer. A *platform stack* is a pair of platforms, along with the tools and methods that are used to map the upper layer of abstraction into the lower level. Note that we can allow a platform stack to include several substacks if we wish to span a large number of abstractions.

Platforms should be defined to eliminate large loop iterations for affordable designs: they should restrict design space via new forms of regularity and structure that surrender some design potential for lower cost and first-pass success. The library of function and communication components is the design space that we can explore at the appropriate level of abstraction. Establishing the number, location, and components of intermediate platforms is the essence of platform-based design. In fact, designs with different requirements and specification may use different intermediate platforms, hence different layers of regularity and design-space constraints. A critical step of the platform-based design process is the definition of intermediate platforms to support *predictability,* which enables the abstraction of implementation detail to facilitate higher-level optimization, and *verifiability,* that is, the ability to formally ensure correctness. On the other hand, when design-time and product volume permit it, it may be useful to skip intermediate platforms. This is equivalent to enlarge the design space and, therefore, can potentially produce a superior design. However, even if a "large-step-across-platform flow" can be adopted, there is still a benefit, from an evaluation standpoint, in having a lower bound on the optimality of the feasible design as the one that can be provided by a more constrained and predictable flow. Naturally, the larger the step across platforms, the more difficult it is to predict the performance, optimize at system level, and provide a tight lower bound. In fact, the design space for this approach may actually be smaller than the one obtained with smaller steps because it becomes harder to explore meaningful design alternatives and the restriction on search impedes complete design space exploration. Ultimately, predictions/abstractions may be so inaccurate that design optimizations are misguided and the lower bounds are incorrect.

It is important to emphasize that the Platform-Based Design paradigm applies to all levels of design. While it is rather easy to grasp the notion of a programmable hardware platform, the concept is completely general and should be exploited through the entire design flow to solve the design problem. In the following sections, we will show that platforms can be applied to low levels of abstraction such as analog components, where flexibility is minimal and performance is the main focus, as well as to very high levels of abstraction such as networks, where platforms have to provide connectivity and services. In the former case, platforms abstract hardware to provide (physical) implementation, while in the latter communication services abstract software layers (protocol) to provide global connectivity.

93.3 Platforms at the Articulation Points of the Design Process

As we mentioned above, the key to the application of the design principle is the careful definition of the platform layers. Platforms can be defined at several point of the design process. Some levels of abstraction are more important than others in the overall design trade-off space. In particular, the articulation point between system definition and implementation is a critical one for design quality and time. Indeed, the very notion of platform-based design originated at this point (see [1, 5–7]). In studying this articulation point (see [10] for full details), we have discovered that at this level there are indeed two distinct platforms that form the *system platform stack* that need to be defined together with the methods and tools necessary to link the two: an *architecture platform* and an API platform. The API platform allows system designers to use the *services* that a (micro-) architecture offers them. In the world of Personal Computers, this concept is well known and is the key to the development of application software on different hardware that share some commonalities allowing the definition of a unique API.

(Micro-) Architecture Platforms

Integrated circuits used for embedded systems will most likely be developed as an instance of a particular (*micro-*) *architecture platform.* That is, rather than being assembled from a collection of independently developed blocks of silicon functionalities, they will be derived from a specific *family of micro-architectures,* possibly oriented toward a particular class of problems, which can be extended or reduced by the system developer. The elements of this family are a kind of "hardware denominator" that could be shared across multiple applications. Hence, an architecture platform is a family of micro-architectures that share some commonality, the library of components that are used to define the micro-architecture. Every element of the family can be obtained quickly through the personalization of an appropriate set of parameters controlling the micro-architecture. Often,the family may have additional constraints on the components of the library that can or should be used. For example, a particular micro-architecture platform may be characterized by the same programmable processor and the same interconnection scheme, while the peripherals and the memories of a particular implementation may be selected from the predesigned library of components depending on the particular application. Depending on the implementation platform that is chosen, each element of the family may still need to go through the standard manufacturing process, including mask making. This approach then conjugates the need of saving design time with the optimization of the element of the family for the application at hand. Although it does not solve the mask cost issue directly, it should be noted that the mask cost problem is primarily due to generating multiple mask sets for multiple design spins, which is addressed by the architecture platform methodology.

The less constrained the platform, the more freedom a designer has in selecting an instance and the more potential there is for optimization, if time permits. However, more constraints mean stronger standards and easier addition of components to the library that defines the architecture platform (as with PC platforms). Note that the basic concept is similar to the cell-based design layout style, where regularity and the reuse of library elements allow faster design time at the expense of some optimality. The trade-off between design time and design "quality" needs to be kept in mind. The economics of the design problem must dictate the choice of design style. The higher the granularity of the library, the more leverage we have in shortening the design time. Given that the elements of the library are reused, there is a strong incentive to optimize them. In fact, we argue that the "macro-cells" should be designed with great care and attention to area and performance. It makes also sense to offer a variation of cells with the same functionality but with implementations that differ in performance, area and power dissipation. Architecture platforms are, in general, characterized by (but not limited to) the presence of programmable components. That means that each of the platform instances that can be derived from the architecture platform maintains enough flexibility to support an application space that guarantees the production volumes required for economically viable manufacturing.

The library that defines the architecture platform may also contain reconfigurable components. Reconfigurability comes in two flavors. With runtime reconfigurability, FPGA blocks can be customized by the user without the need of changing mask set, thus saving both design cost and fabrication cost. With design-time reconfigurability, where the silicon is still application-specific, only design time is reduced.

© 2005 by CRC Press LLC

An *architecture platform instance* is derived from an architecture platform by choosing a set of components from the architecture platform library and/or by setting parameters of reconfigurable components of the library. The flexibility, or the capability of supporting different applications, of a platform instance is guaranteed by programmable components. Programmability will ultimately be of various forms. One is software programmability to indicate the presence of a microprocessor, DSP, or any other software-programmable component. Another is hardware programmability to indicate the presence of reconfigurable logic blocks such as FPGAs, whereby logic function can be changed by software tools without requiring a custom set of masks. Some of the new architecture and/or implementation platforms being offered on the market mix the two into a single chip. For example, Triscend, Altera, and Xilinx are offering FPGA fabrics with embedded hard processors. Software programmability yields a more flexible solution, since modifying software is, in general, faster and cheaper than modifying FPGA personalities. On the other hand, logic functions mapped on FPGAs execute orders of magnitude faster and with much less power than the corresponding implementation as a software program. Thus, here the trade-off is between flexibility and performance.

API Platform

The concept of architecture platform by itself is not enough to achieve the level of application software reuse we require. The architecture platform has to be abstracted at a level where the application software "sees" a high-level interface to the hardware that we call API or Programmers' Model. A software layer is used to perform this abstraction. This layer wraps the essential parts of the architecture platform:

- the programmable cores and the memory subsystem via a Real Time Operating System (RTOS),
- the I/O subsystem via the device drivers, and
- the network connection via the network communication subsystem.

In our framework, the API or Programmers' Model is a unique abstract representation of the architecture platform via the software layer. With an API thus defined, the application software can be reused for every platform instance. Indeed, the Programmers' Model (API) is a platform itself that we can call the API platform. Of course, the higher the abstraction level at which a platform is defined, the more instances it contains. For example, to share source code, we need to have the same operating system but not necessarily the same instruction set, while to share binary code, we need to add the architectural constraints that force us to use the same ISA, thus greatly restricting the range of architectural choices.

The RTOS is responsible for the scheduling of the available computing resources and of the communication between them and the memory subsystem. Note that in several embedded system applications, the available computing resources consist of a single microprocessor. In others, such as wireless handsets, the combination of an RISC microprocessor or controller and DSP has been used widely in 2G, now for 2.5G and 3G, and beyond. In set-top boxes, an RISC for control and a media processor has also been used. In general, we can imagine a multiple core architecture platform where the RTOS schedules software processes across different computing engines.

System Platform Stack

The basic idea of system platform stack is captured in Figure 93.2. The vertex of the two cones represents the combination of the API or Programmers' Model and the architecture platform. A system designer maps its application into the abstract representation, which "includes" a family of architectures that can be chosen to optimize cost, efficiency, energy consumption, and flexibility. The mapping of the application into the actual architecture in the family specified by the Programmers' Model or API can be carried out, at least in part, automatically if a set of appropriate software tools (e.g., software synthesis, RTOS synthesis, device-driver synthesis) is available. It is clear that the synthesis tools have to be aware of the architecture features as well as of the API. This set of tools makes use of the software layer to go from the API platform to the architecture platform. Note that the system platform effectively decouples the application development process (the upper triangle) from the architecture implementation process (the lower triangle). Note also

© 2005 by CRC Press LLC

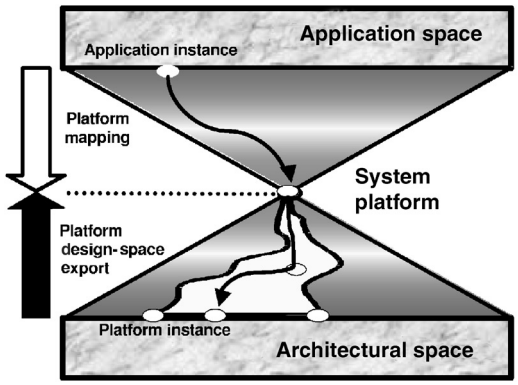

FIGURE 93.2 System platform stack.

that, once we use the abstract definition of "API" as described above, we may obtain extreme cases such as traditional PC platforms on the one hand and full hardware implementation on the other. Of course, the programmer model for a full custom hardware solution is trivial, since there is a one-to-one map between functions to be implemented and physical blocks that implement them. In this latter case, platform-based design amounts to adding to traditional design methodologies some higher level of abstractions.

93.4 Network Platforms

In distributed systems, the design of the communication protocols and channels that support the communication among the system components is a difficult task due to the tight constraints on performances and cost. To make the communication design problem more manageable, designers usually decompose the communication function into distinct protocol layers, and design each layer separately. According to this approach, of which the OSI Reference Model [12] is a particular instance, each protocol layer together with the lower layers defines a platform that provides communication services to the upper layers and to the application-level components. Identifying the most effective layered architecture for a given application requires one to solve a tradeoff between performance, which usually increases by minimizing the number of layers, and design manageability, which improves with the number of the intermediate steps. Present embedded system applications, due to their tight constraints, increasingly demand the codesign of protocol functions (e.g., MAC and routing protocols in sensor networks) that were traditionally assigned to different layers and designed separately. The definition of an optimal layered architecture, the design of the correct functionality for each protocol layer, and the design space exploration for the choice of the physical implementation must be supported by tools and methodologies that allow to evaluate the system performance and guarantee the satisfaction of the constraints after each step. For these reasons, we believe that the Platform-Based Design principles and methodology outlined above provide the right framework to design communication networks. In this section, first we formalize the concept of Network Platform, and then we outline a methodology for selecting, composing, and refining Network Platforms (NPS) [11].

Definitions

A *NP* is a library of resources that can be selected and composed together to form a Network Platform Instance (NPI) and support the interaction among a group of interacting components.

The structure of an NPI is defined by abstracting computation resources as nodes and communication resources as links. Ports interface nodes with links or with the environment of the NPI. The structure of an NPI is defined by a set of nodes and the links connecting them; the structure of a node or a link is defined by its input and output ports.

© 2005 by CRC Press LLC

The behaviors and the performances of an NPI are defined in terms of the type and the quality of the communication services it offers. We formalize the behaviors of an NPI using the Tagged Signal Model [8]. NPI components are modeled as processes, and events model the instances of the send and receive actions of the processes. An event is associated with a message that has a type and a value and with tags that specify attributes of the corresponding action instance (e.g., when it occurs in time). The set of behaviors of an NPI is defined by the intersection of the behaviors of the component processes.

A NPI is defined as a tuple $NPI = (L,N, P,S)$, where

- $L = \{L_1, L_2, ...,L_{Nl}\}$ is a set of directed links.
- $N = \{N_1, N_2, ...,N_{Nn}\}$ is a set of nodes.
- $P = \{P_1,P_2, ...,P_{Np}\}$ is a set of ports. A port P_i is a triple (N_i,L_i,d), where $N_i \in N$ is a node, $L_i \in L \cup Env$ is a link or the NPI environment and $d = in$ if it is an input port, $d = out$ if it is an output port. The ports that interface the NPI with the environment define the sets $P^{in} \subseteq P$ (input ports), $P^{out} \subseteq P$ (output ports).
- $S = \cap_{Nn+Nl} R_i$ is the set of behaviors, where R_i indicates the set of behaviors of a resource that can be a link in L or a node in N.

The basic services provided by an NPI are called *Communication Services* (*CS*). A CS consists of a sequence of message exchanges through the NPI from its input to its output ports. A CS can be accessed by NPI users through the invocation of send and receive *primitives,* whose instances are modeled as events. An *NPI API* consists of the set of primitives that can be invoked by the NPI users to access the CS. For the definition of an NPI API, it is essential to specify not only the service primitives but also the type of CS they provide access to (e.g., reliable send, out-of-order delivery, etc.). Formally, a CS is a tuple $(\overline{P}^{in}, \overline{P}^{out}, M, E, h, g, <^t)$, where $\overline{P}^{in} \subseteq P^{in}$ is a nonempty set of NPI input ports, $\overline{P}^{out} \subseteq P^{out}$ is a nonempty set of NPI output ports, M is a nonempty set of messages, E is a nonempty set of events, h is a mapping $h : E \rightarrow (\overline{P}^{in} \cup \overline{P}^{out})$ that associates each event with a port, g is a mapping $g : E \rightarrow M$ associating each event with a message, and $<^t$ is a total order on the events in E.

A CS is defined in terms of the number of ports, that determine, for example, if it is a unicast, multicast or broadcast CS, the set M of messages representing the exchanged information, the set E including the events that are associated with the messages in M and model the instances of the send and receive method invocations. The CS concept allows to express a *correlation* among events, and explicit, for example, if two events are from the same source or are associated with the same message.

Quality of Service

NPIs can be classified according to the type, the quality, and the cost of the CS they offer. Rather than in terms of event sequences, a CS is more conveniently described using *QoS parameters* like error rate, latency, throughput, jitter, and *cost parameters* like consumed power and manufacturing cost of the NPI components. QoS parameters can be defined using annotation functions that associate individual events with quantities, such as the time when an event occurs and the power consumed by an action. Then, one can compare the values of pairs of input and output events associated with the same message to quantify the error rate, or compare the timestamp of events observed at the same port to compute the delay or the jitter. The most relevant QoS parameters are defined below using a notation where $e^{i,j} \in e^{M,(\overline{P}^{in} \cup \overline{P}^{out})}$ indicates an event carrying the ith message and observed at the jth port, $v(e)$ and $t(e)$ represents, respectively, the value of the message carried by event e and the timestamp of the action modeled by event e.

delay: The communication delay of a message is given by the difference between the timestamps of the input and output events carrying that message. Assuming that the ith message is transferred from input port j_1 to output port j_2, the delay Δ_i of the ith message, the average delay Δ_{Av} and the peak delay Δ_{Peak} are defined, respectively, as $\Delta_i = t(e^{i,j_2}) - t(e^{i,j_1})$, $\Delta_{Av} = \sum_{i=1}^{|M|} t(e^{i,j_2}) - t(e^{i,j_1}) / |M|$ *and* $\Delta_{peak} = max_i \{t(e^{i,j_2}) - t(e^{i,j_1})\}$.

© 2005 by CRC Press LLC

Throughput: The throughput is given by the number of output events in an interval (t_0,t_1), that is, the cardinality of the set $\Theta = \{e_i \in E | h(e_i) \in \overline{P}^{out}, t(e_i) \in (t_0, t_1)\}$.

Error rate: The message error rate (MER) is given by the ratio between the number of lost or corrupted output events and the total number of input events. Given $LostM = \{e_i \in E | h(e_i) \in \overline{P}^{in}, \neg \exists e_j \in E \text{ s.t. } h(e_j) \in \overline{P}^{out}, g(e_j)=g(e_i)\}$, $CorrM = \{e_i \in E | h(e_i) \in \overline{P}^{in}, \exists e_j \in E \text{ s.t. } h(e_j) \in \overline{P}^{out}, g(e_j)=g(e_i), v(e_j) \neq v(e_i)\}$, and $InM = \{e_i \in E | h(e_i) \in \overline{P}^{in}\}$, the message error rate $MER = (\text{Lost M}|+|\text{CorrM})/|InM|$. Using information on message encoding, MER can be converted to Packet and Bit Error Rate.

The number of CS that an NPI can offer is large; thus, the concept of Class of Communication Services (CCS) is introduced to simplify the description of an NPI. CCS define a new abstraction (and therefore another platform) that groups together CS of similar type and quality. For example, a CCS may include all the CS that transfer a periodic stream of messages with no errors, and another CCS all the CS that transfer a stream of input messages arriving at a bursty rate and with a 10^{-6} bit error rate. CCS can be identified based on the type of messages (e.g., packets, audio samples, video pixels, etc.), the input arrival pattern (e.g., periodic, bursty, etc.), and the range of QoS parameters. For each NPI supporting multiple CS, there are several ways to group them into CCS. It is task of the NPI designer to identify in each case the most useful CCS and provide the proper abstractions to facilitate the use of the NPI.

Design of Network Platforms

The design methodology we have defined derives an NPI implementation by successive refinement from the specification of the behaviors of the interacting components and the declaration of the constraints that the NPI implementation must satisfy. The most abstract NPI is defined by a set of end-to-end direct logical links connecting pairs of interacting components. Communication refinement of an NPI defines at each step a more detailed NPI' by replacing one or multiple links in the original NPI with a set of components or NPIs. During this process, another NPI can be used as a resource to build other NPIs. A correct refinement procedure generates an NPI' that provides CS equivalent to those offered by the original NPI with respect to the constraints defined at the upper level. A typical communication refinement step requires to define both the structure of the refined NPI', that is, its components and topology, and the behavior of these components, that is, the protocols deployed at each node. One or more NP components (or predefined NPIs) are selected from a library and composed to create CS of higher quality. Two types of compositions can be used. One type consists of choosing an NPI and extending it with a protocol layer to create CS at a higher level of abstraction (vertical composition). The other type is based on the concatenation of NPIs at the same abstraction level using an adapter (or gateway) that maps sequences of events between the ports being connected (horizontal composition). This design methodology has been applied to the design of Picoradio sensor networks as discussed in [11].

93.5 Analog Platforms

Emerging applications such as multimedia devices (video cell phones, digital cameras, wireless PDAs, to mention but a few) are driving the SoC market toward the integration of analog components in almost every system. Even when analog solutions could be functionally replaced by digital ones, power consumption or performance requirements may be so tight that the digital approach is out of the question. Moreover, we are experiencing a growing lag between the design of large digital blocks and the design of smaller (sometimes much smaller) analog components. The problem is that analog design has traditionally been the most difficult discipline of IC design. There are several reasons for this, ranging from the effects that physical implementations have on the functionality of analog circuits to the lack of abstraction levels and estimation mechanisms. In the digital case, functionality depends on discrete sequences of discrete (binary) signals. Not so in the analog case, where continuous sequences (waveforms) of continuous values encode the information that we need to manipulate and use. For this reason, any second-order physical effect may have a significant impact on the function and performance of an analog circuit. In order to overcome these issues, the design of analog components has been pivoted around low-level,

© 2005 by CRC Press LLC

nonsystematic "clever tricks" that involve transistor layout and parameter selection, thus making it virtually impossible to use higher levels of abstraction.

Today, system-level analog design is a design process dominated by heuristics. Given a set of specifications/requirements that describes the system to be realized, the selection of a feasible (let alone optimal) implementation architecture comes mainly out of experience. Usually, what is achieved is just a feasible point at the system level, while optimality is sought locally at the circuit level. The reason for this is the difficulty in the analog world of knowing whether something is realizable without actually attempting to design the circuit. The number of effects to consider and their complex interrelations make this problem approachable only through the experience of past designs. Platform-based design can provide the necessary insight to develop a methodology for analog components that takes into consideration system-level specifications and can choose among a set of possible solutions including digital approaches wherever it is feasible to do so. If the "productivity gap" between analog and digital components is not overcome, time-to-market and design quality of SoC will be seriously affected by the small analog sections required to interface with the real world. Moreover, SoC designs will expose system-level explorations that would be severely limited if the analog section is not provided with a proper abstraction level that allows system performance estimation in an efficient way and across the analog/digital boundary. Therefore, there is a strong need to develop more abstract design techniques that can encapsulate analog design into a methodology that could shorten design time without compromising the quality of the solutions, leading to a *hardware/software/analog* codesign paradigm for embedded systems.

Definitions

The term *Analog Platform* (AP) indicates an architectural resource to map analog functionalities during system-level exploration phases and constrain exploration to the feasible space of the considered implementation (or set of implementations). Therefore, an AP consists of a set of behavioral models and of matching performance models. *Behavioral models* are parameterized mathematical models of the analog functionality that introduce at the functional level a number of nonidealities attributable to the implementation and not intrinsic in the functionality itself, such as distortion, bandwidth limitations, and noise. Nonideal effects, as well as the principal performance figures of the functionality (e.g., gain, power consumption, and area) are embedded in the behavioral models in the form of parameters. *Performance models* constrain these parameters to satisfy a mathematical relation so that only feasible instances of the behavioral model (models with a complete set of parameter values) can be selected with respect to the considered architecture. Performance parameters for APs are derived bottom-up from simulation data. Different from common approaches that rely on regression schemes, relations on performance parameters are directly modeled by means of characteristic functions. Performance model can be formally defined with the following definitions:

1. *Input space* $\mathcal{I}$: Given a circuit $\mathcal{C}$ and m parameters controlling its instances, $\mathcal{I}_\mathcal{C} \subseteq \mathbb{R}^m$ is the set of m-tuples (parameter values) over which we want to characterize $\mathcal{C}$.
2. *Output space* $\mathcal{O}$: Given a circuit $\mathcal{C}$ and n performance figures completely characterizing its behavioral model, $\mathcal{O}_\mathcal{C} \subseteq \mathbb{R}^n$ is the set of m-tuples (per formance values) that are achievable by $\mathcal{C}$.
3. *Evaluation function* ϕ: Given a circuit $\mathcal{C}$, $\mathcal{I}_\mathcal{C}$, and $\mathcal{O}_\mathcal{C}$, $\phi_\mathcal{C} : \mathcal{I} \rightarrow \mathcal{O}$ allows translating a parameter m-tuple set into a performance n-tuple set.
4. *Performance relation* $\mathcal{P}$: Given a circuit $\mathcal{C}$, $\mathcal{I}_\mathcal{C}$, $\mathcal{O}_\mathcal{C}$, and, ϕ, we define the performance relation of $\mathcal{C}$ given $\mathcal{I}_\mathcal{C}$ and $\phi_\mathcal{C}$ to be $\mathcal{P}_\mathcal{C}$ on $\mathbb{R}^n$ that hold only for points $o \in \mathcal{O}_\mathcal{C}$. With a little abuse in notation, we will denote both the performance relation characteristic function $\chi_\mathcal{P}(x) : \mathbb{R}^n \rightarrow \{0,1\}$ and the relation itself with $\mathcal{P}_\mathcal{C}(x)$.

For example, in the Low Noise Amplifier (LNA) shown in Figure 93.3, we may define $\mathcal{I}$ as $\{W_{in}, L_{in}, I_{bias}\}$, where the first two quantities are related to the input transistor and *Ibias* is the bias current. A platform instance defines specific values for $\{W^\star_{in}, L^\star_{in}, I^\star_{bias}\}$, that is, the actual circuit to be considered. Continuing with the LNA example, the output space $\mathcal{O}$ can be defined as{*Gain, Power, Noise*}. Finally, ϕ can be defined by circuit simulation and/or circuit equations. The LNA platform performances are then

© 2005 by CRC Press LLC

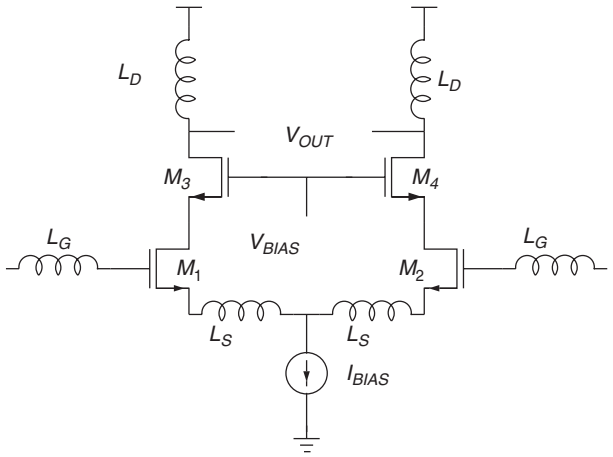

FIGURE 93.3 Schematics for the LNA used for generating the performance model $\mathcal{P}$ shown in Figure 93.4.

represented by $\mathcal{P}$ (*Gain, Power, Noise*) = 1, which are satisfied only by those *n*-tuples of performance figures that are actually obtainable. In this way, it is possible to capture all the interrelations among the different performance figures and annotate behavioral models consequently.

A key concept of APs is that only $\mathcal{O}$ has to be exported at the current level of abstraction *(platform opaqueness),* because the function $\phi(\cdot)$ and $\mathcal{I}$ are not necessary to evaluate the performances of mapped behaviors. Because of this, APs are also suitable candidates to protect sensitive data when exporting IPs.

In order to allow hierarchical exploitation of platform instances, the following operations have to be defined and implemented in terms of $\mathcal{P}$*'s:*

- Abstraction — given a platform relation $\mathcal{P}$(*Gain, Power, Noise, IP3, SR*) = 1, we may want to derive an abstracted view of the platform (*virtual* platform) that only relates a subset of performance figures, for example, $\mathcal{P}'$(*Gain, Power, Noise*) = 1 $\Leftrightarrow$ $\exists IP3^{\star}$, $SR^{\star}$ s.t. $\mathcal{P}$*(Gain,Power, Noise, IP3*, SR*)*=1. This operation is needed every time we use models at higher levels of abstraction (see Figure 93.5).
- Composition — given two platforms *A* and *B* with parameters ζ_a and ζ_b and some interface parameters λ (e.g., the output load for *A*/input load for *B*), we may want to derive $\mathcal{P}_{AoB}(\zeta_a,\zeta_b)=1$ $\Leftrightarrow$ $\exists\lambda$ s.t. $\mathcal{P}_A(\zeta_a,\lambda)=1$ and $\mathcal{P}_B(\zeta_b,\lambda)=1$. $\mathcal{P}_{AoB}$ represents the set of compatible performances of the composition *AoB*.
- Merge — given *n* platforms for the same functionality, a super-set platform can be defined by or-ing the respective $\mathcal{P}$ after moving to a common level of abstraction. $\mathcal{P}_{merge} = 1 \Leftrightarrow \exists i$ s.t. $\mathcal{P}_i=1$.
- Closure — given a system implemented with a set of APs, closure generates a new platform at a different level of abstraction so as to implement system platform stacks.

The generation of platform performance models $\mathcal{P}s$ is in general accomplished through sampling $\phi(\cdot)$ over the input space $\mathcal{I}$. This is because in the general case $\phi(\cdot)$ is a complex nonlinear function, and no explicit representation for it might be available (in order to provide accurate characterizations, $\phi(\cdot)$ may be implicitly defined by circuit simulation). The goal is to obtain a smooth continuous approximation of the performance relation $\mathcal{P}$. This phase constitutes the bottom-up phase for building a platforms library and is the crucial step for achieving accurate performance annotations. The characterization of a platform over its input space is exponentially complex with the dimensionality of $\mathcal{I}$. Also, the characterization process generates large amounts of data that need to be effectively represented. The first problem requires some hints from the analog designer to limit the dimensionality of $\mathcal{I}$, that is, which "knobs" are most meaningful for defining the platform and which constraints on the value of each parameter can be exploited to prune the characterization space. Furthermore, the parameter space $\mathcal{I}$ of a circuit is usually much smaller than its

© 2005 by CRC Press LLC

bounding hypercube. For example, given n MOS sharing the same bias current $\mathcal{I}_{bias}$, their physical dimensions have to allow all of them to operate in saturation in order for the circuit to be functional. Therefore, the performance model is not affected if we limit $\mathcal{I}$ to some kind of "manifold" defined by a set of constraints over the variables in $\mathcal{I}$. Examples of constraints are correct biasing conditions, DC levels, or minimum gain/bandwidth required. The design of experiments techniques may also be used to achieve optimal accuracy/complexity tradeoffs. Even so, large numbers of multi-dimensional samples may be generated, on the order of thousands or tens of thousands. As Figure 93.4 illustrates, an effective way of representing the information provided by these simulations is to use machine learning techniques, in particular, Support Vector Machines (SVMs). As shown in [3], SVMs make it possible to store only a small portion of the original data (typically 10% or lower) while providing multidimensional approximation that enables the extrapolation of performance figures out of the available data based on some continuity assumptions on ϕ.

Analog Platform Stacks

An Analog Platform Stack contains several layers of abstraction with the appropriate representation at each level. In the analog world, finding a model for a platform is a complex matter. Behavioral models allow fast simulations, thus enabling more extensive explorations/optimizations. Furthermore, they are tailored for a specific platform to include specific idiosyncrasies of the platform at the behavioral level. By constraining models to reflect platform performances, that is, constraining model parameters to satisfy the platform $\mathcal{P}$, a mapping of functionality onto architecture is achieved.

Analog Platform Stacks provide hierarchies of behavioral models at different levels of abstraction to reflect the refinement process typical of top-down flows. In order to promote design space exploration, all the models are derived from root models characterized by functionality families (see Figure 93.5). For example, we can have LNA, mixer and PLL families, which in turn generate trees of models at different levels of abstraction. The nodes of these trees represent higher-level platforms and the leaves represent implementation platforms. By exploiting the abstraction and merge operations defined above, all

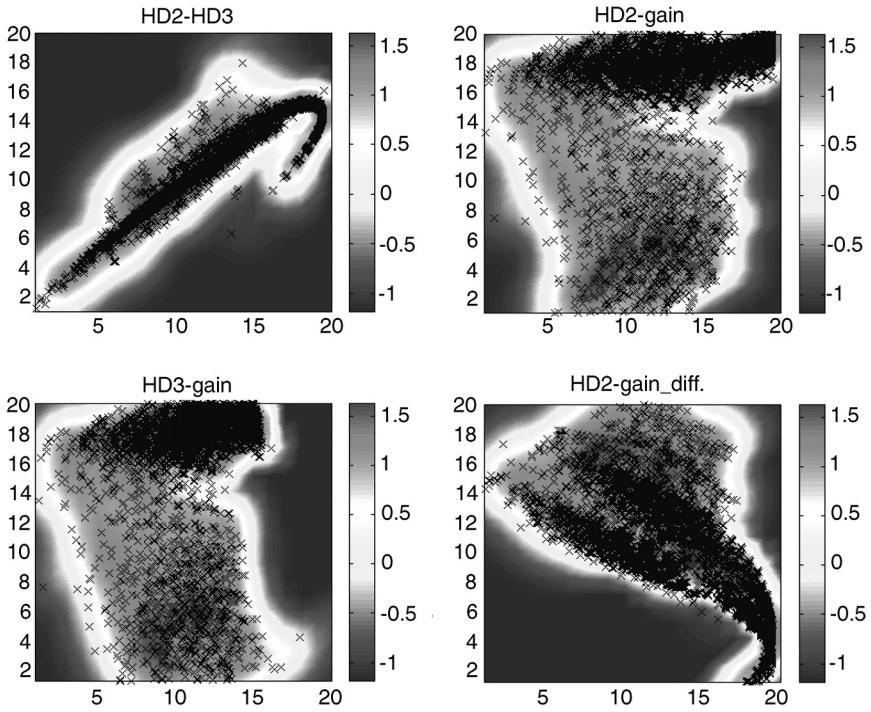

FIGURE 93.4 Projections of a seven-dimensional $\mathcal{P}$ for an LNA.

© 2005 by CRC Press LLC

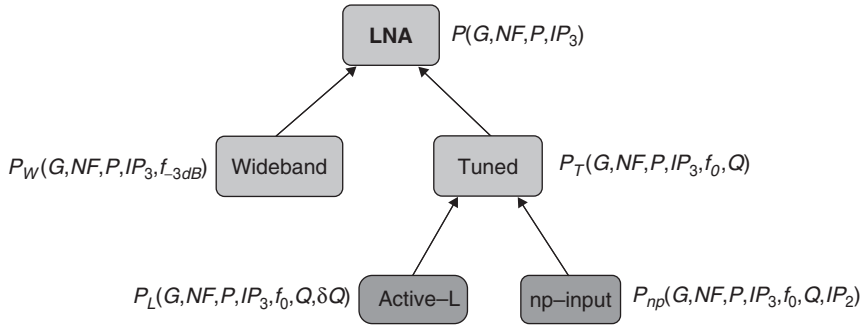

FIGURE 93.5 Sample model hierarchy for an LNA platform. The root node provides performance constraints for a generic LNA, which is then refined by more detailed $\mathcal{P}$ for specific classes of LNAs.

platforms in a given family can be included in a tree originating from the same root model (the most abstract platform). The refinement process proceeds by selecting branches in the tree and, therefore, more detailed platforms, transforming constraints from a more abstract platform to a more detailed platform (exactly as described in the digital case). The mapping process ends with the selection of a platform instance of a particular platform.

Platforms require to explicitly model communication. Communication is a main actor in APs, with even more emphasis than in the digital case. In fact, interactions between communication and computation in analog blocks are much more involved than for digital blocks. We can consider the communication between two blocks as well as the respective behaviors to be the fixed-point solution of the composition of the blocks. Because of this, orthogonalization becomes harder for detailed platforms and communication has to be modeled together with behavior. Therefore, the semantics of the component families requires to specify the allowed block interconnections. In this sense, the communication at the output of an LNA is modeled with respect to the mixer that is supposed to follow the LNA. At the most detailed level, this means that a given LNA can work with some mixers and not with others. Of course, different domains of application may require different compositional characteristics among the component families.

APs can be hierarchically composed to generate new APs at a higher level of abstraction. PLLs provide examples of hierarchical composition since their complexity allows them to be considered as systems *per se.* The result of the composition is a new AP that needs to be endowed with a set of behavioral models. The process of deriving new platforms is the same as deriving platform for circuits *(fractal nature of design),* where $\phi(\cdot)$now refers to the composition of APs in place of simple circuits. Therefore, hierarchical composition provides a more general way to generate more abstract platforms other than the abstraction/merge operations previously defined.

Design Flow with APs

The platform paradigm can be effectively used to drive exploration and eventually optimization at the system level. We call *exploration* the process of defining the set of optimal specifications compatible with the considered implementation architectures and the available performance models. In this sense, exploration can be cast as an optimization problem on the current level of abstraction.

The design process starts with the collection/generation of a suitable platform library for system implementation. The platform concept is extremely flexible in terms of encapsulation of design components. For example, schematics coming from previous designs, module generators, analog IPs, and eventually new solutions can be used to generate a platform library. Since the exploration phase leverages automatic optimization, an operative metric to measure optimality of a design has to be defined. Multiobjective optimization schemes may be adopted, for example, min max or weighted sums objective functions [4]. A number of test vectors (simulation scenarios) have to be defined in order to evaluate system

© 2005 by CRC Press LLC

performance under meaningful conditions (e.g., as dictated by a standard). A behavioral model of the system is then built, and exploration is performed having platform performance models as constraints to enforce feasibility. Since no mathematical properties are generally available for the optimization problem, global optimization schemes such as simulated annealing or genetic algorithms are exploited. Even if these schemes are potentially very expensive, the number of optimization parameters available at the system level is usually low (a few tens) and behavioral simulations are expected to be very efficient.

Since different implementation architectures may actually be merged at proper levels of abstraction (see Figure 93.5), platform-based analog design allows exploring a wide architectural space (depending on the platform library) while decomposing system specifications into block requirements. The selection of platform performances may have different implications on subsequent refinements: either the selected performance set is achievable by only one architecture (then the architecture has been selected), or by more than one architecture (which indicates that at the current abstraction level and with the current metrics, the selected platforms are equivalent). In the latter case, going to more detailed models or refining the metrics selects a proper architecture. Also, platforms may be locally refined to expand the design space or to explore interesting design corners with improved accuracy.

The result of the exploration phase is a set of specifications for each platform in the system. The exploration process can then be iterated over single subsystems. Eventually, the evaluation scheme used to estimate platform performances (e.g., simulation) can be inverted so that specifications get converted in to suitable configuration parameters. In practice, this task can be accomplished with some regression scheme on the performance data used to approximate the performance model. A vanilla implementation would simply return the configurations whose performances are closest to the requested specifications (nearest neighbors). This set of potential solutions could then be used as initial points of a local detailed optimization process, such as finalizing the circuit sizing and layout. From here on, it is up to the IP provider to generate an implementation with the required performances or up to designers to size the schematic and generate the layout. The novelty of the approach consists in the fact that the use of $\mathcal{P}s$ guarantees by construction that the set of specifications generated is feasible, thus drastically reducing the number of iterations required to obtain feasible specifications and achieving optimal points over larger parameter spaces.

APs also separate the design of individual blocks from system design, thus allowing more effective explorations and optimizations at higher levels of abstraction where the design space is much larger. The introduction of the platform concept enables the integration of heterogeneous IPs, and does not put any constraint on analog designers for developing new circuit solutions for sensitive blocks. In this sense, APs may be exploited as a fast evaluation method for new solutions, generating coarse performance regions at first to evaluate the basic performances of a new solution at the system level, and, then, refining both the architecture and the functionality to take full advantage of the new solution (if convenient). This process can be pictorially represented by the classic Y chart that is essentially the same as in the digital case (Figure 93.6).

APs can also be used to model programmable fabrics. In the digital implementation platform domain, functionality with digital signal processings (FPGAs) provide a very intuitive example of platform, for example, including microprocessors on chip. The appearance of Field Programmable Analog Arrays [9] constitutes a new attempt to build reconfigurable AP. A platform stack can be built by exploiting the software tools that allow mapping complex functionalities (filters, amplifiers, triggers, and so on) directly on the array. The top-level platform, then, provides an API to map and configure analog functionalities, exposing analog hardware at the software level. By exploiting this abstraction, not only design exploration is greatly simplified, but new synergies between higher layers and analog components can be leveraged to further increase the flexibility/reconfigurability and optimize the system. From this abstraction level, implementing a functionality with digital signal processing (FPGA) or analog processing (FPAA) becomes subject to system-level optimization while exposing the same abstract interface. Moreover, very interesting tradeoffs can be explored exploiting different partitionings between analog and digital components and leveraging the reconfigurability of the FPAA. For example, limited analog performances can be mitigated by proper reconfiguration of the FPAA, so that a tight interaction between analog and digital subsystems can provide a new optimum from the system-level perspective.

93.6 Concluding Remarks

We have defined platform-based design as an all-encompassing intellectual framework in which scientific research, design tool development, and design practices can be embedded and justified. A platform is an abstraction layer that hides the details of the several possible implementation refinements of the underlying layer. Platform-based design allows us to trade off various components of manufacturing, NRE, and design costs while sacrificing potential design performance as little as possible . We presented examples of these concepts at different key articulation points of the design process, including network platforms, implementation platforms, and analog platforms. The principles of platform-based have been applied in the development of the Metropolis design environment [2], a federation of integrated analysis, verification, and synthesis tools supported by a rigorous mathematical theory of metamodels and agents.

94.1 Introduction

Modern system-on-chip (SoC) design shows a clear trend toward integration of multiple processor cores. The SoC System Driver section of the "International Technology Roadmap for Semiconductors [1]" predicts that the number of processor cores will increase fourfold per technology node in order to match the processing demands of the corresponding applications. Typical multiprocessor SoC (MPSoC) applications like network processors, multimedia hubs, and base-band telecom circuits have particularly tight time-to-market and performance constraints that require a very efficient design cycle.

Our conceptual model of the MPSoC platform is composed of four kinds of components: software tasks, processor and intellectual property (IP) cores, and a global on-chip interconnect IP (see Figure 94.1a). Moreover, to complete the MPSoC platform, we must also include hardware and software elements that adapt platform components to each other. MPSoC platforms are quite different from single-master processor SoCs (SMSoCs). For instance, their implementation of system communication is more

© 2005 by CRC Press LLC

complicated since heterogeneous processors may be involved and complex communication protocols and topologies may be used. The hardware adaptation layer must deal with some specific issues:

1. In SMSoC platforms, most peripherals (excluding DMA controllers) operate as slaves with respect to the shared communication interconnect. MPSoC platforms may use many different types of processor cores; in this case, sophisticated synchronization is needed to control shared communication between several heterogeneous masters.
2. While SMSoC platforms use simple master/slave shared-bus interconnections, MPSoC platforms often use several complex system buses or micro-networks as global interconnect. In MPSoC platforms, we can separate computation and communication design by using communication coprocessors and profiting from the multi-master architecture. Communication coprocessors/controllers (masters) implement high-level communication protocols in hardware and execute them in parallel with the computation executed on processor cores.

Application software is generally organized as a stack of layers that runs on each processor core (see Figure 94.1b). The lowest layer contains drivers and low-level routines to control/configure the platform. For the middle layer, we can use any commercial embedded OS and configure it according to the application. The upper layer is an application-programming interface (API), which provides some pre-defined routines to access the platform. All these layers correspond to the software adaptation layer in Figure 94.1a, coding application software can then be isolated from the design of the SoC platform (software coding is not the topic of this chapter and will be omitted). One of the main contributions of this work is to consider this layered approach also for the dedicated software (often-called firmware). Firmware is the software that controls the platform, and, in some cases, executes some nonperformance-critical application functions. In this case, it is not realistic to use a generic OS as the middle layer due to code size and performance reasons. A lightweight custom OS supporting an application- and platform-specific API is required.

Software and hardware adaptation layers isolate platform components enabling concurrent development as shown in Figure 94.1c. With this scheme, the software design team uses APIs for both application and dedicated software development. The hardware design team uses abstract interfaces provided by communication coprocessors/controllers. SoC design team can concentrate on implementing hardware and software abstraction layers for the selected communication interconnect IP. Designing these hardware/software (HW/SW) abstraction layers represents a major effort, and design tools are lacking. Established EDA tools are not well adapted to this new MPSoC design scenario, and consequently many challenges are emerging; some major issues are as follows:

1. *Higher abstraction level is needed*: the register-transfer level (RTL) is too time consuming to model and verify the interconnection between multiple processor cores.
2. *Higher-level programming is needed*: MPSoCs will include hundred thousands lines of dedicated software (firmware). This software cannot be programmed at the assembler level as today.

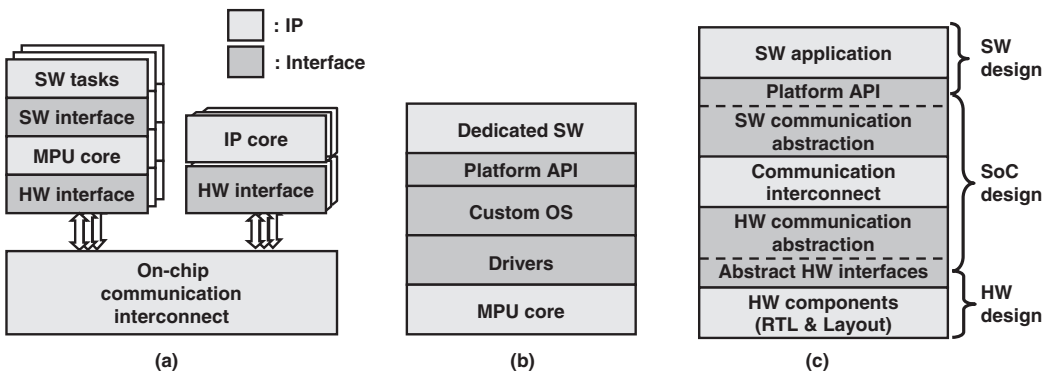

FIGURE 94.1 MPSoC platform (a), software stack (b), and concurrent development environment (c).

© 2005 by CRC Press LLC

3. *Efficient HW/SW interfaces are required*: microprocessor interfaces, bank of registers, shared memories, software drivers, and operating systems must be optimized to each application.

This chapter presents a component-based design automation approach for MPSoC platforms. Section 94.2 introduces the basic concepts for MPSoC design and discusses some related platform- and component-based approaches. Section 94.3 details IP-based methodologies for hardware and software IP integration. Section 94.4 details our specification model and design flow. Section 94.5 presents the application of this flow for the design of a VDSL circuit and the analysis of the results.

94.2 System-on-Chip Design

System-Level Design Flow

This section gives an overview of current SoC design methodologies using a template design flow (see Figure 94.2). The basic theory behind this flow is the separation between communication and computation refinement for platform- and component-based design [2,3]; it has five main design steps:

1. *System specification*: system designers and the end-customer must agree on an informal model containing all application's functionality and requirements. Based on this model, system designers build a more formal specification that can be validated by the end-customer.
2. *Architecture exploration*: system designers build an executable model of the specification and iterate through a performance analysis loop to decide the HW/SW partitioning for the SoC architecture. This executable specification uses an abstract platform composed of abstract models for HW/SW components. For instance, an abstract software model can concentrate on I/O execution profiles, or most frequent use cases, or worst-case scheduling. Abstract hardware can be described using transaction-level models or behavioral models. This step produces the "golden" architecture model,

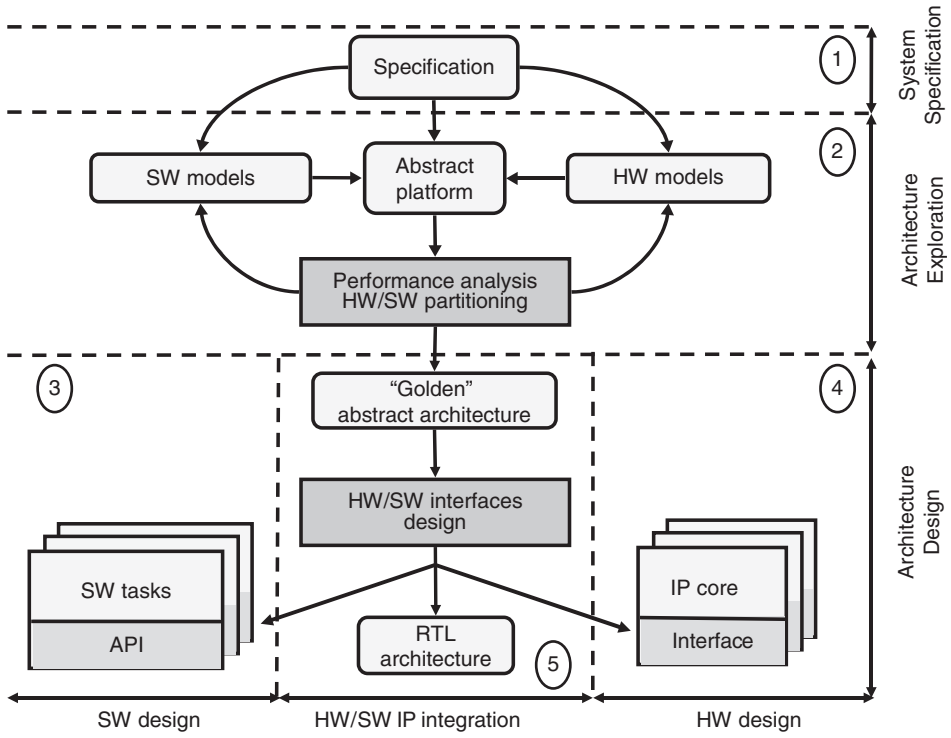

FIGURE 94.2 System-level design flow for SoC.

© 2005 by CRC Press LLC

which is the customized SoC platform or a new architecture created by system designers after selecting processors, the global communication interconnect, and other IP components. Once HW/SW partitioning is decided, software and hardware development can be done concurrently.

3. *Software design*: since the final hardware platform will not be available during software development, some kind of hardware abstraction layer (HAL) or API must be provided to the software design team.
4. *Hardware design*: hardware IP designers implement the functionality described by the abstract hardware models at the RT level. Hardware IPs can use specific interfaces for a given platform or standard interface as defined by Virtual Socket Interface Alliance (VSIA [4]).
5. *HW/SW IP integration*: SoC designers create HW/SW interfaces to the global communication interconnect. The golden architecture model must specify performance constraints to assure a good HW/SW integration. Software and hardware communication interfaces are designed to conform to these constraints.

SoC Design Automation — An Overview

Many academic and industrial works propose tools for SoC design automation covering many, but not all, design steps presented before. Most approaches can be classified into three groups: system-level synthesis, platform-based design, and component-based design.

System-level synthesis methodologies are top-down approaches; the SoC architecture and software models are produced by synthesis algorithms from a system-level specification. COSY [5] proposes an HW/SW communication refinement process that starts with an extended Kahn Process Network model on design step (1), uses VCC [6] for step (2), callback signals over a standard RTOS for the API in (3), and VSIA interfaces for steps (4) and (5). SpecC [7] starts with an untimed functional specification model written in extended C on design step (1), uses performance estimation for a structural architecture model for step (2), HW/SW interface synthesis based on a timed bus-functional communication model for step (5), synthesized C code for step (3), and behavioral synthesis for step (4).

Platform-based design is a meet-in-the-middle approach that starts with a functional system specification and a predesigned SoC platform. Performance estimation models are used to try different mappings between the set of application's functional modules and the set of platform components. During these iterations, designers can try different platform customizations and functional optimizations. VCC [6] can produce a performance model using a functional description of the application and a structural description of the SoC platform for design steps (1) and (2). CoWare N2C [8] is a good complement for VCC for design steps (4) and (5). Still, the API for software components and many architecture details must be implemented manually.

Section 94.3 discusses hardware and software IP integration in the context of current IP-based design approaches. Most IP-based design approaches build SoC architectures from the bottom-up using predesigned components with standard interfaces and/or a standard bus. For instance, IBM defined a standard bus called CoreConnect [9], Sonics proposes a standard on-chip network called Silicon Backplane μNetwork [10], and VSIA defined a standard component protocol called VCI. When needed, wrappers adapt incompatible buses and/or component interfaces. Frequently, internally developed components are tied to inhouse (nonpublic) standards; in this case, adopting public standards implies a large effort to redesign interfaces or wrappers for old components.

Section 94.4 introduces a higher-level IP-based design methodology for HW/SW interface design called component-based design. This methodology defines a virtual architecture model composed of HW/SW components and uses this model to automate design step (5), by providing automatic generation of hardware interfaces (4), device drivers, operating systems, and application programming interfaces (3). Even if this approach does not provide much help in automating design steps (1) and (2), it provides a considerable reduction of design time for design steps (3)–(5) and facilitates component reuse. The key improvements over other state-of-art platform and component-design approaches are:

1. *Strong support for software design and integration*: the generated API completely abstracts the hardware platform and OS services. Software development can be concurrent to and independent of platform customization.

© 2005 by CRC Press LLC

2. *Higher-level abstractions*: the use of a virtual architecture model allows designers to deal with HW/SW interfaces at a high abstraction level. Behavior and communication are separated in the system specification; thus, they can be refined independently.
3. *Flexible HW/SW communication*: automatic HW/SW interfaces generation is based on the composition of library elements. It can be used with a variety of IP interconnect components by adding the necessary supporting library.

94.3 HW/SW IP Integration

There are two major approaches for the integration of HW/SW IP components into a given design. In the first one, component interfaces follow a given standard (such as a bus or core interface, for hardware components, or a set of high-level communication primitives, for software components) and can be thus directly connected to each other. In the second approach, components are heterogeneous in nature and their integration requires the generation of hardware and/or software wrappers. In both cases, an RTOS must be used to provide services that are needed in order that the application software fits into the SoC architecture. This section describes different solutions to the integration of HW/SW IP components.

Introduction to IP Integration

The design of an embedded SoC starts with a high-level functional specification, which can be validated. This specification must already follow a clear separation between computation and communication [11], in order to allow their concurrent evolution and design. An abstract architecture is then used to evaluate this functionality based on a mapping that assigns functional blocks to architectural ones. This high-level architectural model abstracts away all low-level implementation details. A performance evaluation of the system is then performed, by using estimates of the computation and communication costs. Communication refinement is now possible, with a selection of particular communication mechanisms and a more precise performance evaluation.

According to the platform-based design approach [2], the abstract architecture follows an architectural template that is usually domain-specific. This template includes both a hardware platform, consisting of a given communication structure and given types of components (processors, memories, hardware blocks), and a software platform, in the form of a high-level API. The target-embedded SoC will be designed as a derivative of this template, where the communication structure, the components, and the software platform are all tailored to fit the particular application needs.

The IP-based design approach follows the idea that the architectural template may be implemented by assembling reusable HW/SW IP components, maybe even delivered by third-party companies.

The IP integration step comprises a set of tasks that are needed to assemble predesigned components in order to fulfill system requirements. As shown in Figure 94.3, it takes as inputs the abstract architecture and a set of HW/SW IP components that have been selected to implement the architectural blocks. Its output is a micro-architecture where hardware components are described at the RT level with all cycle-and-pin accurate details that are needed for a further automatic synthesis. Software components are described in an appropriate programming language, such as C, and can be directly compiled to the target processors of the architecture.

In an ideal situation, IP components would fit directly together (or to the communication structure) and exactly match the desired SoC functionality. In a more general situation, the designer may need to adapt each component's functionality (a step called IP derivation) and synthesize HW/SW wrappers to interconnect them. For programmable components, although adaptation may be easily performed by programming the desired functionality, the designer may still need to develop software wrappers (usually device and/or bus drivers) to match the application software to the communication infrastructure. The generation of HW/SW wrappers is usually known as interface or communication synthesis. Besides these, application software may also need to be retargeted to the processors and OS of the chosen architecture.

© 2005 by CRC Press LLC

In the following subsections, different approaches to IP integration are introduced and their impact on the possible integration subtasks is analyzed.

Bus- and Core-Based Approaches

In the bus-based design approach [9,12,13], IP components communicate through one or more buses (interconnected by bus bridges). Since the bus specification can be standardized, libraries of components whose interfaces directly match this specification can be developed. Even if components follow the bus standard, very simple bus interface adapters may still be needed [14]. For components that do not directly match the specification, wrappers have to be built. Companies offer very rich component libraries and specialized development and simulation environments for designing systems around their buses.

A somewhat different approach is the core-based design, as proposed by the VSIA VCI standard [4] and by the OCP-IP organization [15]. In this case, IP components are compliant to a bus-independent and standardized interface and can thus be directly connected to each other. Although the standard may support a wide range of functionalities, each component may have an interface containing only the functions that are relevant for it. These components may also be interconnected through a bus, in which case standard wrappers can adapt the component interface to the bus. Sonics [13] follows this approach, proposing wrappers to adapt the bus-independent OCP socket to the MicroNetwork bus.

For particular needs, the SoC may be built around a sophisticated and dedicated network-on-chip (NoC) [16] that may deliver a very high performance for connecting a large number of components. Even in this case, a bus- or core-based approach may be adopted to connect the components to the network.

Bus- and core-based design methodologies are integration approaches that depend on standardized component or bus interfaces. They allow the integration of homogeneous IP components that follow these standards and can be directly connected to each other, without requiring the development of complex wrappers. The problem we face is that many *de facto* standards exist, coming from different companies or organizations, thus preventing a real interchange of libraries of IP components developed for different substandards.

Integrating Software IP

Programmable components are important in a reusable architectural platform, since it is very cost-effective to tailor a platform to different applications by simply adapting the low-level software and maybe only configuring certain hardware parameters, such as memory sizes and peripherals.

As illustrated in Figure 94.3, the software view of an embedded system shows three different layers:

1. The bottom layer is composed of services directly provided by hardware components (processor and peripherals) such as instruction sets, memory and peripheral accesses, and timers.

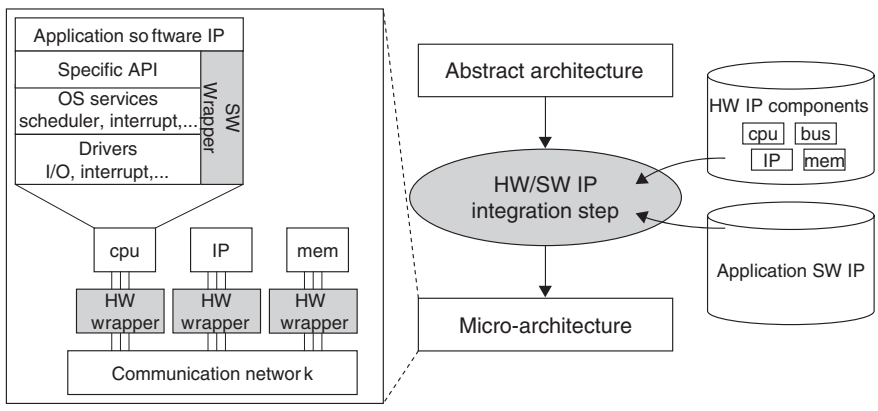

FIGURE 94.3 The HW/SW IP integration design step.

© 2005 by CRC Press LLC

2. The top layer is the application software, which should remain completely independent of the underlying hardware platform.
3. The middle layer is composed of three different sub-layers, as seen from bottom to top:
   (a) hardware-dependent software (HdS), consisting, for instance, of device drivers, boot code, parts of an RTOS (such as context switching code and configuration code to access the MMU), and even some domain-oriented algorithms that directly interact with the hardware;
   (b) hardware-independent software, typically high-level RTOS services, such as task scheduling and high-level communication primitives; and
   (c) the API , which defines a system platform that isolates the application software from the hardware platform and from all basic software layers, and enables their concurrent design.

The standardization of this API, which can be seen as a collection of services usually offered by an operating system, is essential for software reuse above and below it. At the application software level, libraries of reusable software IP components can implement a large number of functions that are necessary for developing systems for given application domains. If, however, one tries to develop a system by integrating application software components that do not directly match a given API, software retargeting to the new platform will be necessary. This can be a very tedious and error-prone manual process, which is a candidate for an automatic software synthesis technique.

Nevertheless, reuse can also be obtained below the API. Software components implementing the hardware-independent parts of the RTOS can be more easily reused, especially if the interface between this layer and the HdS layer is standardized. Although the development of reusable HdS may be harder to accomplish, because of the diversity of hardware platforms, it can be at least obtained for platforms aimed at specific application domains.

There are many academic and industrial alternatives providing RTOS services. The problem with most approaches, however, is that they do not consider specific requirements for SoC, such as minimizing memory usage and power consumption. Recent research efforts propose the development of application-specific RTOS containing only the minimal set of functions needed for a given application [17,18] or including dynamic power management techniques [19]. IP integration methodologies should thus consider the generation of application-specific RTOS that are compliant to a standard API and optimized for given system requirements.

In recent years, many standardization efforts aimed at hardware IP reuse have been developed. Similar efforts for software IP reuse are now needed. VSIA [4] has recently created working groups to deal with HdS- and platform-based design.

Communication Synthesis

Solutions for the automatic synthesis of communication wrappers to connect hardware IP components that have incompatible interfaces have already been proposed. In the PIG tool [20], component interfaces are specified as protocols described as regular expressions, and an FSM interface for connecting two arbitrary protocols is automatically generated. The Polaris tool [21] generates adapters based on state machines for converting component protocols into a standard internal protocol, together with send and receive buffers and an arbiter.

These approaches, however, do not address the integration of software IP components. The TEReCS tool [18] synthesizes communication software to connect software IP components, given a specification of the communication architecture and a binding of IP components to processors. In the IPChinook environment [22], abstract communication protocols are synthesized into low-level bus protocols according to the target architecture. While the IPChinook environment also generates a scheduler for a given partitioning of processes into processors, the TEReCS approach is associated to the automatic synthesis of a minimal OS, assembled from a general-purpose library of reusable objects that are configured according to application demands and the underlying hardware.

Recent solutions uniformly handle HW/SW interfaces between IP components. In the COSY approach [5], design is performed by an explicit separation between function and architecture. Functions are then

© 2005 by CRC Press LLC

mapped to architectural components. Interactions between functions are modeled by high-level transactions and then mapped to hardware–software communication schemes. A library provides a fixed set of wrapper IPs, containing hardware and/or software implementations for given communication schemes.

IP Derivation

Hardware IP components may come in several forms [23]. They may be hard, when all gates and interconnects are placed and routed, soft, with only an RTL representation, or firm, with an RTL description together with some physical floorplanning or placement. The integration of hard IP components cannot be performed by adapting their internal behavior and/or structure. If they have the advantage of a more predictable performance, in turn they are less flexible and therefore less reusable than adaptable components.

Several approaches for enhancing reusability are based on adaptable components. Although one can think of very simple component configurations (for instance, by selecting a bit width), a higher degree of reusability can be achieved by components whose behavior can be more freely modified. Object-orientation is a natural vehicle for high-level modeling and adaptation of reusable components [24,25]. This approach, which can be better classified as IP derivation, is adequate for not only firm and soft hardware IP components but also for software IP [26]. Although component reusability is enhanced by this approach, the system integrator has a greater design effort, and it becomes more difficult to predict IP performance.

IP derivation and communication synthesis are different approaches to solve the same problem of integration between heterogeneous IP components, which do not follow standards (or the same substandards). IP derivation is a solution usually based on object-oriented concepts coming from the software community. It can be applied to the integration of application software components and for hardware soft and firm components, but it cannot be used for hard IP components. Communication synthesis, on the other hand, follows the path of the hardware community on automatic logic and high-level synthesis. It is the only solution to the integration of heterogeneous hard IP components, although it can also be used for integrating software IP and soft and firm hardware IP. While IP derivation is essentially a user-guided manual process, communication synthesis is an automatic process, with no user intervention.

94.4 Component-Based SoC Design

This section introduces the component-based design methodology, a high-level IP-based methodology aimed at the integration of heterogeneous HW/SW IP components. It follows an automatic communication synthesis approach, generating both HW/SW wrappers. It also generates a minimal and dedicated OS for programmable components. It uses a high-level API, which isolates the application software from the implementation of a hardware–software solution for the system platform, such that software retargeting is not necessary.

This approach enables the automatic integration of heterogeneous (components that do not follow a given bus or core standard) and hard IP components (whose internal behavior or structure is not known). However, the approach is also very well suited to the integration of homogeneous and soft IP components. The methodology has been conceived to fit to any communication structure, such as an NoC [16] or a bus.

The component-based methodology is based on a clear definition of three abstraction levels that are also adopted by other current approaches: system (pure functional), macro-architecture, and micro-architecture (RTL). These levels constitute clear "interfaces" between design steps, promoting reuse of both components and tools for design tasks at each of these levels.

Design Methodology Principles

The design flow starts with a virtual architecture model that corresponds to the "golden" architecture in Figure 94.2, and allows automatic generation of wrappers, device drivers, operating systems, and application programming interfaces. The goal is to produce a synthesizable RTL model of the MPSoC platform that is composed of processor cores, IP cores, the communication interconnect IP, and HW/SW wrappers.

© 2005 by CRC Press LLC

The latter are automatically generated from the interfaces of virtual components (as indicated by the arrows in Figure 94.4). Software written for the virtual architecture specification runs without modification on the implementation because the same APIs are provided by the generated custom OSs.

The input abstract architecture (see Figure 94.4a) is composed of virtual modules (VM), corresponding to processing and memory IPs, connected by any communication structure, also encapsulated within a VM. This abstract architecture model clearly separates computation from communication, allowing independent and concurrent implementation paths for components and for communication. Virtual modules that correspond to processors may be hierarchically decomposed into submodules containing software tasks assigned to this processor. Virtual modules communicate through virtual ports, which are sets of hierarchical internal and external ports through which services are requested and provided. The separation between internal and external ports makes possible the connection of modules described at different abstraction levels.

Virtual Architecture

The virtual architecture represents a system as an abstract netlist of virtual components (see Figure 94.4a). It is described in VADeL, a SystemC [27] extension that includes a platform-independent API offering high-level communication primitives. This API abstracts the underlying hardware platform, thus enhancing the free development of reusable components. In the abstract architecture model, the interfaces of software tasks are the same for SW–SW and SW–HW connections, even if the software tasks are executed by different

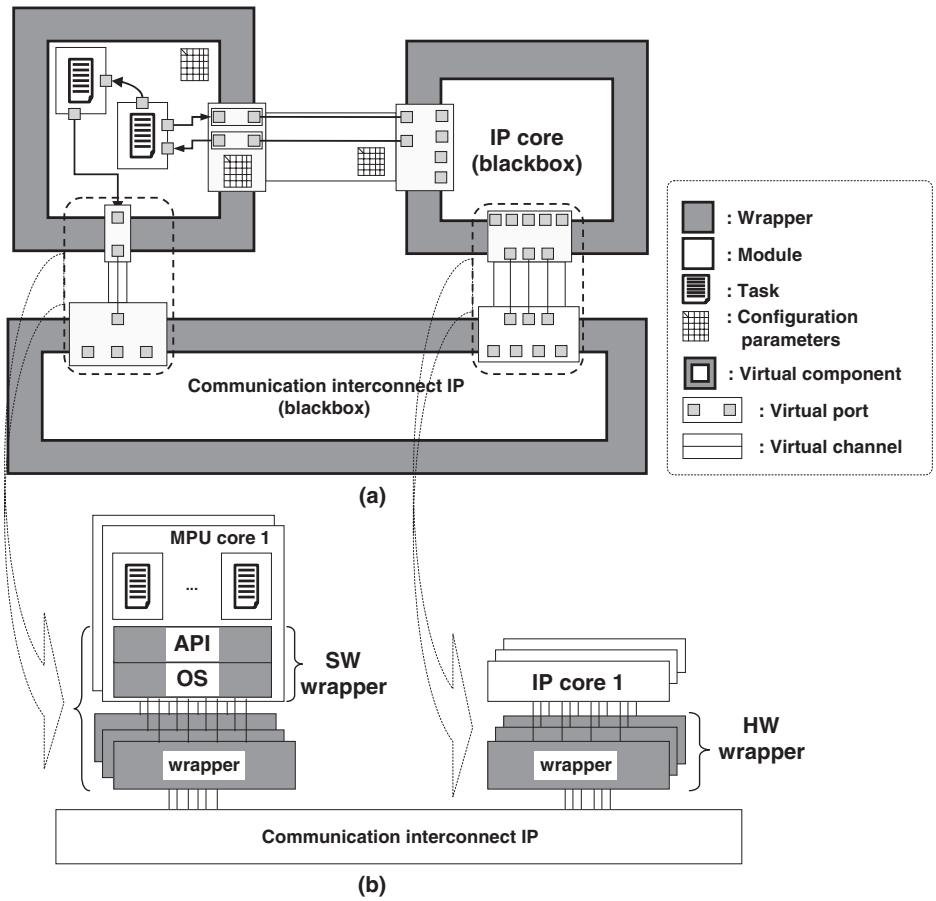

FIGURE 94.4 MPSoC design flow: virtual architecture (a) and target MPSoC platform (b).

© 2005 by CRC Press LLC

processors. Different hardware/software realizations of this API are possible. Architectural design space exploration can thus be achieved without influencing the functional description of the application.

Virtual components use wrappers to adapt accesses from the internal component (a set of software tasks or a hardware function) to the external channels. The wrapper is modeled as a set of virtual ports that contain internal and external ports that can be different in terms of: (1) communication protocol, (2) abstraction level, and/or (3) specification language. This model is not directly synthesizable or executable because wrapper's behavior is not described. These wrappers can be generated automatically, in order to produce a detailed architecture that can be both synthesized and simulated.

The required SystemC extensions implemented in VADeL are:

1. virtual module: consists of a module and its wrapper;
2. virtual port: groups some internal and external ports that have a conversion relationship. The wrapper is the set of virtual ports for a given virtual module;
3. virtual channel: groups several channels having a logical relationship (e.g., multiple channels belonging to the same communication protocol); and
4. parameters: used to customize hardware interfaces (e.g., buffer size and physical addresses of ports), operating systems, and drivers.

In VADeL, there are also predefined ports with special semantics called Service Access Ports (SAP). They can be used to access some services that are implemented by hardware or software wrapper components. For instance, the *timer* SAP can be used to request an interrupt from a hardware timer after a given delay.

Target MPSoC Architecture Model

We use a generic MPSoC architecture where processors and other IP cores are connected to a global communication interconnect IP via wrappers (see Figure 94.4b). In fact, processors are separated from the physical communication IP by wrappers that act as communication coprocessors or bridges, freeing processors from communication management and enabling parallel execution of computation tasks and communication protocols. Software tasks also need to be isolated from hardware through an OS that plays the role of an SW wrapper. When defining this model, our goal was to have a generic model where both computation and communication may be customized to fit the specific needs of the application. For computation, we may change the number and kind of components and, for communication, we can select specific communication IP and protocols. This architecture model is suitable to a wide domain of applications; more details can be found in [31].

HW/SW Wrapper Architecture

Wrappers are automatically generated as point-to-point adapters between each VM and the communication structure, as shown in Figure 94.4b [31]. This approach allows the connection of components to standard buses as well as point-to-point connections between cores.

Wrappers may have HW/SW parts. The internal architecture of a wrapper on the hardware side is shown in Figure 94.5b. It consists of a processor adapter, one or more channel adapters, and an internal bus. The number of channel adapters depends on the number of channels that are connected to the corresponding virtual module. This architecture allows the easy generation of multi-point, multi-protocol wrappers. The wrapper dissociates communication from computation, since it can be considered as a communication coprocessor that operates concurrently with other processing functions.

On the software side [17], as shown in Figure 94.5a, wrappers provide the implementation of the high-level communication primitives (available through the API) used in the system specification and drivers to control the hardware. If required, the wrapper will also provide sophisticated OS services such as task scheduling and interrupt management minimally tailored for the particular application.

The synthesis of wrappers is based on libraries of basic modules from which hardware wrappers and dedicated OSs are assembled. These libraries may be easily extended with modules that are needed to build wrappers for processors, memories, and other components that follow various bus and core standards.

Design Tools

Figure 94.6 shows an overall view of our design environment, which is called *ROSES*. The input model may be imported from a specification analysis tools (e.g., [6]) or manually coded using our extended SystemC library. All design tools use a unified design model that contains an abstract HW/SW netlist annotated with parameters (Colif [28]). Hardware wrapper generation [31] transforms the input model into a synthesizable architecture. The software wrapper generator [17] produces a custom OS for each processor on the target platform. For validation, we use the cosimulation wrapper generator [30] to produce simulation models. Details about these tools can be found in the references; only their principles will be discussed here.

Hardware wrapper generation assembles library components using the architecture template presented before (Figure 94.5b) to produce the RTL architecture. This library contains generalized descriptions of hardware components in a macro language (**m4** like); it has two parts: the processor library and the protocol library. The former contains local template architectures for processors with four types of

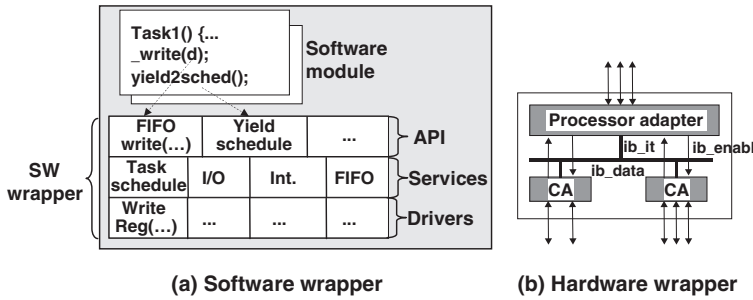

FIGURE 94.5 HW/SW wrapper architecture.

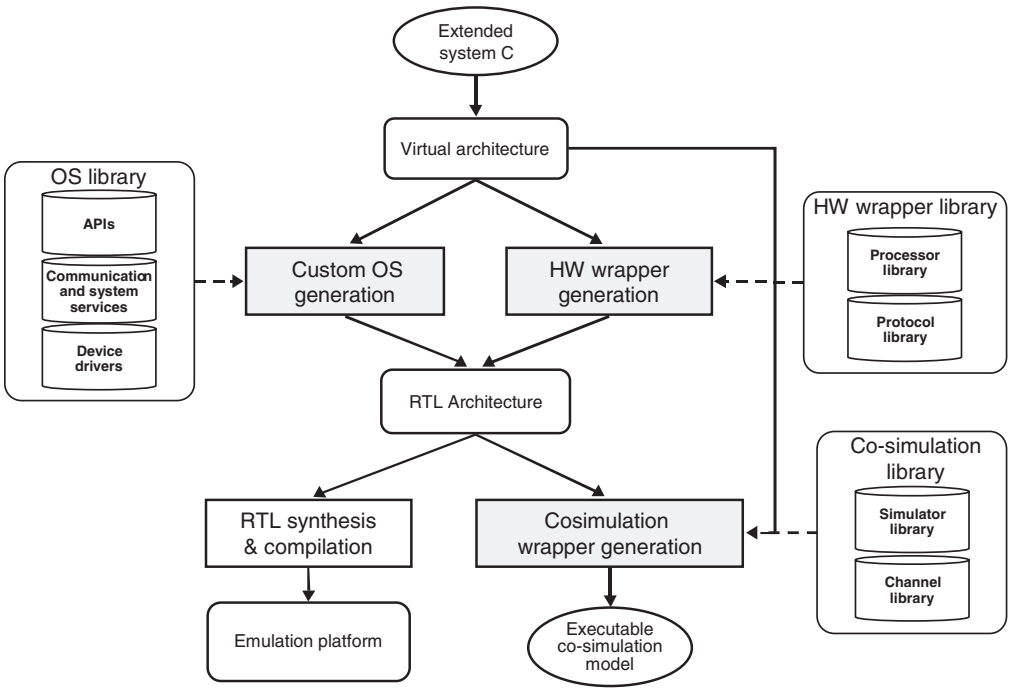

FIGURE 94.6 Design automation tools for MPSoC.

© 2005 by CRC Press LLC

elements: processor cores, local buses, local IP components (e.g., local memory, address decoder, coprocessors, etc.), and processor adapters. The latter consists of a list of channel adapters. Each channel adapter has simulation, estimation, and synthesis models that are parameterized (by the channel parameters, e.g., direction, storage size, and data type) as the elements in the processor library.

The software wrapper generator produces operating systems streamlined and preconfigured for the software module(s) that run(s) on each target processor. It uses a library organized in three parts: APIs, communication/system services, and device drivers. Each part contains elements that will be used in a given software layer in the generated OS. The generated OS provides services: communication services (e.g., FIFO communication), I/O services (e.g., AMBA bus drivers), memory services (e.g., cache or virtual memory usage), etc. Services have dependency between them, for instance, communication services are dependent on I/O services. Elements of the OS library also have dependency information. This mechanism is used to keep the size of the generated OS at a minimum; the elements that provide unnecessary services are not included.

There are two types of service code: re-usable (or existing) code and expandable code. As an example of existing code, AMBA bus-master service code can exist in the OS library in the form of C language. As an example of expandable code, OS kernel functions can exist in the OS library in the form of macrocode (**m4** like). There are several preemptive schedulers available in the OS library such as round-robin scheduler, priority-based scheduler, etc. In the case of round-robin scheduler, time-slicing (i.e., assigning different CPU load to tasks) is supported. To make the OS kernel very small and flexible, (1) the task scheduler can be selected from the requirements of the application code and (2) a minimal amount (less than 10% of kernel code size) of processor-specific assembly code is used (for context switching and interrupt service routines).

The cosimulation wrapper generator [30] produces an executable model composed of a SystemC simulator that acts as a master for other simulators. A variety of simulators can participate in this cosimulation: SystemC, VHDL, Verilog, and Instruction-set simulators. Cosimulation wrappers have the same structure as hardware wrappers (see Figure 94.5b), with simulation adapters in the place of processor adapters and simulation models of channel adapters. In the cosimulation wrapper library, there are simulation adapters for the different simulators supported and channel adapters that implement all supported protocols in different languages.

In terms of functionality, the cosimulation wrapper transforms channel access(es) via internal port(s) to channel access(es) via external port(s) using the following functional chain: channel interface, channel resolution, data conversion, and module communication behavior. Internal ports use channel functions (e.g., FIFO available, FIFO write) to exchange data. Channel interface provides the implementation of these channel functions. Channel resolution maps N-to-M correspondence between internal and external ports. Data conversion is required since different abstraction levels can use different data types to represent the same data. Module communication behavior is required to exchange data via external port(s), that is, to call port functions of external ports.

Defining IP-Component Interfaces

Hardware and software component interfaces must be composed using basic elements of the hardware wrapper and software wrapper generators libraries (respectively). Table 94.1 lists some API functions available for different kinds of software task interfaces and some services provided by channel adapters available to be used in hardware component interfaces.

Software tasks must communicate through API functions provided by the software-wrapper generator library. For instance, the shared-memory API (SHM) provides read/write functions for intertask communication. The guarded-shared memory API (GSHM) adds semaphores services to the SHM API by providing lock/unlock functions.

Hardware IP components must communicate through communication primitives provided by the channel adapters of the hardware-wrapper generator library. For instance, FIFO channel adapters (sender and receiver) implement a buffered two-phase handshake protocol (Put/Get) and provide Full/Empty functions for accessing the state of the buffer. ASFIFO channel adapters use instead a single-phase handshake protocol and can generate an interrupt for signaling the full and empty state of the buffer.

© 2005 by CRC Press LLC

A recurrent problem in library-based approaches is library size explosion. In ROSES, this problem is minimized by the use of layered library structures where a service is factorized so that its implementation uses elements of different layers. This scheme increases reuse of library elements since the elements of the upper layers must use the services provided by the elements in the immediate lower layer.

Designers are able to extend ROSES libraries since they are implemented in an open format. This is an important feature since it enables the support of different standards while reusing most of the basic elements in the libraries.

Table 94.2 shows some of the existing hardware and software components in the current ROSES IP library and gives the type of communication they use in their interfaces.

Figure 94.7 a shows the "stream" software IP and part of its code to demonstrate the utilization of the communication APIs. Its interface is composed of four ports: two for the FIFO API (P3 and P4), one for the signal API (P2), and one for the GSHM API (P1). In line 7 of Figure 94.4a, the stream IP uses P1 to lock the access to the shared memory that contains the data that will be streamed. P2 is used to suspend the task that fills up the shared memory (line 8). Then, some header information is obtained from the input FIFO using P3 (line 11) and streamed to the output FIFO using P4 (line 12). When streaming is finished, P1 is used to unlock the access to the shared memory (line 14).

TABLE 94.1 HW/SW communication APIs

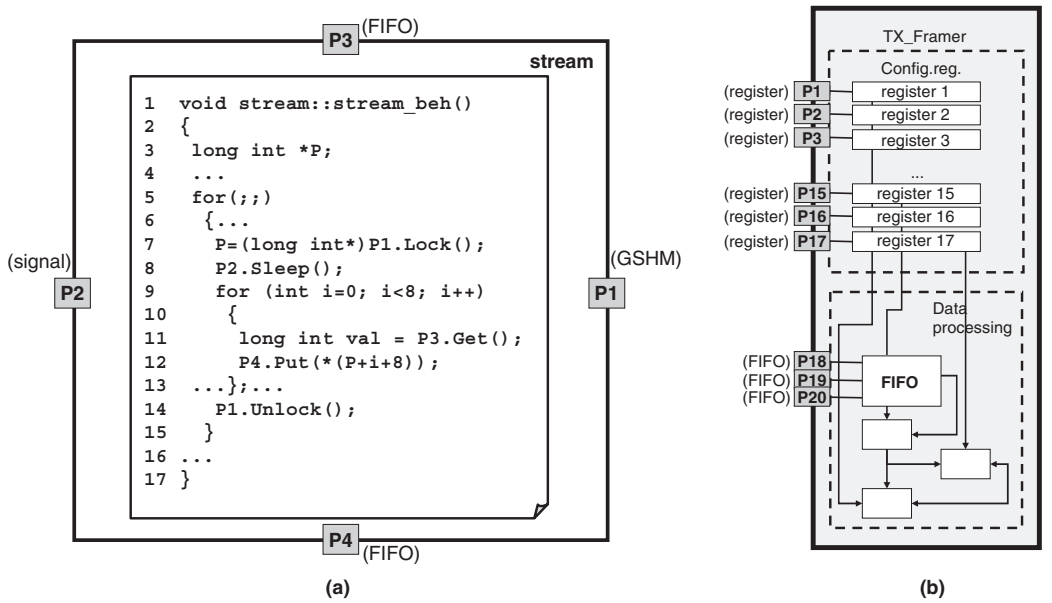

FIGURE 94.7 The stream software IP (a) and the TX_Framer hardware IP (b).

Figure 94.7b shows the "TX_Framer" hardware IP, which is part of a VDSL modem and responsible for packaging data into ATM-network-compatible frames. Its interface is composed of 17 configuration registers (P1–P17) and one single-handshake input FIFO (P18–P20). The registers are used to configure the IP functionality and have bit sizes varying from 2 to 11, while the FIFO is used to store data packets that will be inserted into specific places in the output ATM frames. These ports are driven directly by the compatible outputs from register and ASFIFO channel adapters that are generated by the hardware wrapper generator.

94.5 Component-Based Design of a VDSL Application

Specification

The design presented in this section illustrates the IP integration capabilities of ROSES. We redesigned part of a VDSL modem that was prototyped by Diaz-Nava and Okvist [29] using discrete components (the shaded part in Figure 94.8a). The block diagram for the modem subset used in the rest of this paper is shown in Figure 94.8b. It corresponds to a deframing/framing unit (DFU), composed of two ARM7 processors and the TX_Framer. The TX_Framer is part of the VDSL Protocol Processor. In this experiment, it is used as a hard IP component described at the RT level. The partition of processors/tasks was suggested by the design team of the VDSL-modem prototype.

Processors exchange data using three asynchronous FIFO buffers. The TX_Framer IP has some configuration registers and input a data stream through a synchronous FIFO buffer. Tasks use a variety of control and data-transmission protocols to communicate. For instance, a task can block/unblock the execution of other tasks by sending them an OS signal. Tasks use for data transmission: a FIFO memory buffer, two shared memories (with or without semaphores), and direct register access. Despite representing only a subset of the VDSL modem, the design of the DFU remains quite challenging. In fact, it uses two processors executing parallel tasks. The control over the three modules of the specification is fully distributed. All three modules act as masters when interacting with their environment. Additionally, the application includes multipoint communication channels requiring sophisticated OS services.

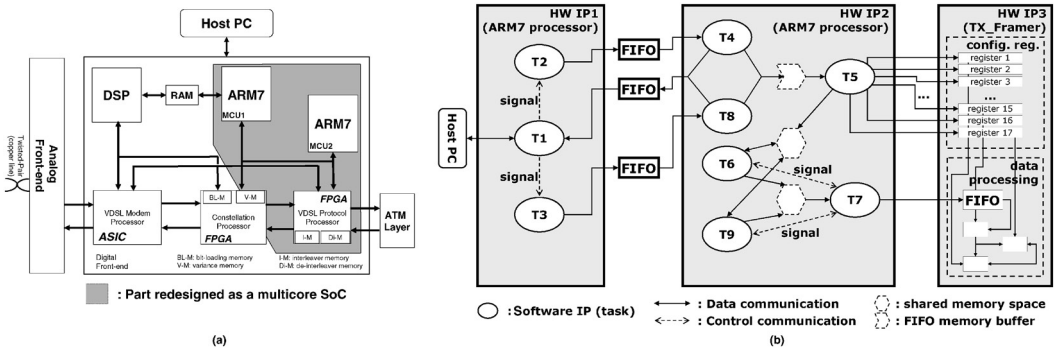

FIGURE 94.8 VDSL modem prototype (a) and DFU block diagram (b).

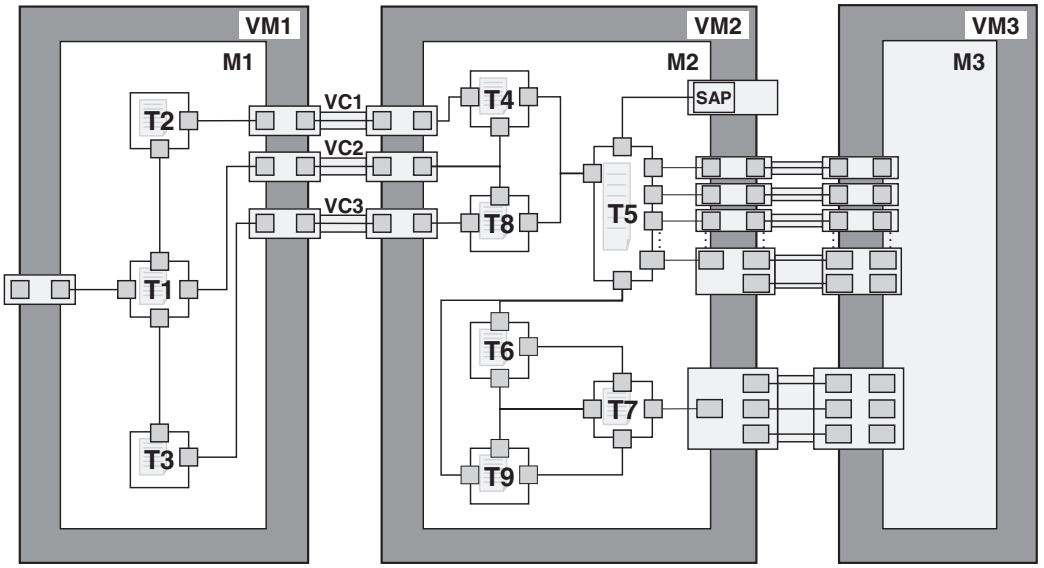

FIGURE 94.9 DFU abstract architecture specification.

DFU Abstract Architecture

Figure 94.9 shows the abstract architecture model that captures the DFU specification with point-to-point communications between the three main IP cores. *VM1* and *VM2* are two virtual processors, and *VM3* corresponds to the TX_Framer function. VM1 and VM2 include several submodules corresponding to software tasks *T1–T9* assigned to these processors. This abstract model can be mapped onto different concrete micro-architectures depending on the selected IP components and on desired performance, area, and power constraints. For instance, the three point-to-point connections (*VC1–VC3*) between VM1 and VM2 can be mapped onto a bus or onto a shared memory.

MPSoC RTL Architecture

For the implementation of the DFU virtual architecture, two hardware IP cores have been selected: an ARM7 processor and the TX_Framer. The application software has been built by reusing several available software IP components for implementing tasks T1–T9. Table 94.3 lists the selected IP components and indicates their correspondence to the virtual modules and submodules in the DFU virtual architecture.

© 2005 by CRC Press LLC

TABLE 94.3 HW/SW IP utilization

IP	Description	Use
SW		
Host-if	Host PC interface	T1
Rand	Random number generator	T2, T3
mult-tx	Multipoint FIFO data transmission	T4, T8
reg-config	Register configuration	T5
shm-sync	Shared memory synchronization	T6, T9
Stream	FIFO data streaming	T7
HW		
ARM7	Processor core	VM1, VM2
TX_Framer	Data package framing	VM3

The interfaces of the selected software IP components in Table 94.3 (see Table 94.2) match the communication type of the software tasks of the virtual architecture in Figure 94.8b.

Figure 94.10 shows the RTL micro-architecture obtained after HW/SW wrapper generation. It is important to notice that, from an abstract target architecture containing an "abstract" ARM7 processor, ROSES automatically generates a "concrete" ARM7 local architecture containing additional IP components, which implement local memory, local bus, and address decoder.

Each software wrapper (custom OS) is customized to the set of software IPs corresponding to the tasks executed by the processor core. For example, software IPs running on VM2 access the custom OS using communication primitives available through the API: Register is used to write/read to/from the configuration/status registers inside the TX_Framer block, while SHM and GSHM are used to manage shared-memory communication. Each OS contains a round-robin scheduler (Sched) and resource management services (Sync, IT). The driver layer contains low-level code to access the channel adapters within the hardware wrappers (e.g., Pipe LReg for the HNDSHK channel adapter), and some low-level kernel routines.

Results

The manual design of a full VDSL modem requires several person-years; the presented DFU was estimated as a more than five persons-year effort. When using the ROSES IP integration capabilities, the overall experiment took only one person during four months, including all validation and verification time (but not counting the effort to develop library components and to debug design tools). This corresponds to a 15-times reduction in design effort (a more detailed presentation can be found in [32]).

Application code and generated OS are compiled and linked together to be executed on each ARM7 processor. The HW wrapper can be synthesized using RTL synthesis. As can be seen in Table 94.4, most OS code is generated in C; only a small part of it is in assembly and includes some low-level routines (e.g., context switching and processor boot) that are specific to each processor. If we compare the numbers presented in Table 94.4 with commercial embedded operating systems, the results are still very good. The minimum size for such operating systems is around 4 kbytes; but with this size, few of them could provide the required functionality. Table 94.5 shows the numbers obtained after RTL synthesis of the HW wrappers using a CMOS 0.35 μm technology. These are good results because wrappers account for less than 5% of the ARM7s core surface and have a critical path that corresponds to less than 15% of the clock cycle for the 25 MHz ARM7 processors used in this case study.

Evaluation

Results show that the component-based approach can generate HW/SW interfaces and operating systems that are as efficient as the manually coded/configured ones. The HW/SW frontier in wrapper

implementation can be easily displaced by changing some library components. This choice is transparent to the final user since everything that implements the interconnect API is generated automatically (the API does not change only its implementation does). Furthermore, correctness and coherence can be verified inside tools and libraries against the API semantics without having to impose fixed boundaries to the HW/SW frontier (in contrast to standardized component interfaces and/or buses).

The utilization of layered library components provides considerable flexibility; the design environment can be easily adapted to accommodate different languages to describe system behavior, different task scheduling and resource management policies, different global communication interconnect topologies and protocols, a diversity of processor cores and IP cores, and different memory architectures. In most cases, inserting a new design element into this environment only requires to add the appropriate library components. Layered library components are at the roots of the methodology; the principle followed is to contain a unique functionality, and to respect well-defined interfaces that enable easy composition. This layered structure prevents library size explosion since composition is used to implement complex functionality and to increase component reutilization.

© 2005 by CRC Press LLC

As explained in this chapter and illustrated by the design case study, ROSES use a component-based methodology that presents a unique combination of features:

It implements a general approach for the automatic integration of heterogeneous and hard IP components, although it easily accommodates the integration of homogeneous and soft IP components.

It offers an architectural-independent API, integrated into SystemC, containing high-level communication primitives and enhancing the free development of reusable components. Application software accessing this API does not need to be retargeted to each system implementation.

It adopts a library-based approach to wrapper generation. As long as components communicate through a known protocol, communication synthesis can be done automatically, without any additional design effort. In a formal-based approach, instead, the designer must describe the component interface by some appropriate formalism, such as an FSM [21] or a regular expression [20].

It uniformly addresses the generation of hardware and software parts of communication wrappers for programmable components. While some approaches consider only hardware [20, 21] or software [18, 22] wrappers, others also consider hardware and software parts but are restricted to predefined wrapper libraries for given communication schemes [5]. The library-based approach of ROSES, in turn, allows the synthesis of software interfaces for various communication schemes.

It can be used with any architectural template and communication structure, such as a bus, an NoC, or point-to-point connections between components. It is also configurable to synthesize wrappers for any bus or core standard.

94.6 Conclusions

Reuse of IP components is a major requirement for the design of complex embedded SoCs. However, reuse is a complex process that involves many steps, requires support from specialized tools and methodologies, and influences current design practices. The integration of IP components into a particular design is may be the most complex step of the reuse process. Many design approaches, such as bus-, core-, and platform-based designs, are aimed at an easier IP integration. Nevertheless, many problems are still open, in particular, the automatic synthesis of hardware and software wrappers between heterogeneous and hard IP components.

The chapter has shown that the component-based design methodology provides a complete, generic, and efficient solution to the hardware/software interfaces design problem. Starting from a high-level function specification and an abstract architecture, design tools can automatically generate hardware and software wrappers that are necessary to integrate heterogeneous IP components that have been selected to implement the application. Designers do not need to design any low-level interfacing details manually. The chapter has also shown how HW/SW component interfaces can be decomposed and easily adapted to different communication structures and bus and core standards.

95.1 Introduction

The increasing integration densities made available by shrinking device geometries will have to be exploited to meet the computational requirements of parallel applications such as multimedia processing, automotive, multi-window TV, ambient intelligence, etc.

As an example, systems designed for ambient intelligence will be based on high-speed digital signal processing with computational loads ranging from 10 MOPS for lightweight audio processing, 3 GOPS for video processing, 20 GOPS for multilingual conversation interfaces, and up to 1 TOPS for synthetic video generation. This computational challenge will have to be addressed at manageable power levels and affordable costs [1].

Such a performance cannot be provided by a single processor, but requires a heterogeneous on-chip multi-processor system containing a mix of general-purpose programmable cores, application-specific processors, and dedicated hardware accelerators.

In this context, performance of gigascale *Systems-on-Chip* (SoCs) will be communication dominated, and only an interconnect-centric system architecture will be able to cope with this problem. Current on-chip interconnects consist of low-cost shared arbitrated buses, based on the serialization of bus access requests; only one master at a time can be granted access to the bus. The main drawback of this solution is its lack of scalability, which will result in unacceptable performance degradation for complex SoCs (more than a dozen of integrated cores). Moreover, the connection of new blocks to a shared bus increases its associated load capacitance, resulting in more energy-consuming bus transactions.

© 2005 by CRC Press LLC

A scalable communication infrastructure that better supports the trend of SoC integration consists of an on-chip micro-network of interconnects, generally known as *Network-on-Chip* (NoC) architecture [2,6,7]. The basic idea is borrowed from the wide-area networks domain, and envisions router (or switch)-based networks on which on-chip packetized communication takes place, as depicted in Figure 95.1. Cores access the network by means of proper interfaces, and have their packets forwarded to destination through a certain number of hops.

The scalable and modular nature of NoCs and their support for efficient on-chip communication potentially lead to NoC-based multi-processor systems characterized by high structural complexity and functional diversity. On the one hand, these features need to be properly addressed by means of new design methodologies [3], while on the other more efforts have to be devoted to modeling on-chip communication architectures and integrating them into a single modeling and simulation environment combining both processing elements and communication infrastructures [4,9,10]. These efforts are needed to include on-chip communication architecture in any quantitative evaluation of system design during design space exploration [8,11], to enable the assessment of the impact of the interconnect on achieving a target system performance.

An important design decision for NoCs regards the choice of topology. Several researchers [7,12,3,13] envision NoCs as regular tile-based topologies (such as mesh networks and fat trees), which are suitable for interconnecting homogeneous cores in a chip multiprocessor. However, SoC component specialization (used by designers to optimize performance at low power consumption and competitive cost) leads to the on-chip integration of heterogeneous cores having varied functionality, size, and communication requirements. If a regular interconnect is designed to match the requirements of a few communication-hungry components, it is bound to be largely overdesigned with respect to the needs of the remaining components. This is the main reason why most current SoCs use irregular topologies like bridged buses and/or dedicated point-to-point links [14].

This chapter introduces the basic principles and guidelines for the NoC design. At first, the motivation for the design paradigm shift of SoC communication architectures from shared buses to NoCs is examined. Then, the chapter goes into the details of NoC building blocks (switch, network interface, and switch-to-switch links), discussing the design guidelines and presenting a case study where some of the most advanced concepts in NoC design have been applied to a real NoC architecture (called *Xpipes* and developed at University of Bologna [15]).

Finally, the challenging issue of heterogeneous NoC design will be addressed, and the effects of mapping the communication requirements of an application onto a domain-specific NoC, instead of a network with regular topology, will be detailed by means of an illustrative example.

95.2 Design Challenges for On-Chip Communication Architectures

SoC design challenges that are driving the evolution of traditional bus architectures toward NoCs can be outlined as follows:

Technology issues: While gate delays scale down with technology, global wire delays typically increase or remain constant as repeaters are inserted. It is estimated that in 50 nm technology, at a clock frequency of 10 GHz, a global wire delay can be up to 6–10 clock cycles [2]. Therefore, limiting the on-chip distance traveled by critical signals will be key to guarantee the performance of the overall system, and will be a common design guideline for all kinds of system interconnects. On the contrary, other challenges posed by deep sub-micron technologies are leading to a paradigm shift in the design of SoC communication architectures. For instance, global synchronization of cores on future SoCs will be unfeasible due to deep submicron effects (clock skew, power associated with clock distribution tree, etc.), and an alternative scenario consists of self-synchronous cores that communicate with one another through a network-centric architecture [16]. Finally, signal integrity issues (cross-talk, power supply noise, soft errors, etc.) will lead to more transient and permanent failures of signals, logic values, devices, and interconnects, thus raising the reliability concern for on-chip communication [17]. In many cases, on-chip networks can be designed as regular structures, allowing electrical parameters of wires to be optimized and well controlled. This leads to lower communication failure probabilities, thus enabling the use of low swing signaling techniques [18], and to the capability of exploiting performance optimization techniques such as wavefront pipelining [19].

Performance issues: In traditional buses, all communication actors share the same bandwidth. As a consequence, performance does not scale with the level of system integration, but degrades significantly, although once the bus is granted to a master, access occurs with no additional delay. On the contrary, NoCs can provide a much better performance scalability. No delays are experienced for accessing the communication infrastructure, since multiple outstanding transactions originating from multiple cores can be handled at the same time, resulting in a more efficient network resources utilization. However, given a certain network dimension (e.g., the number of instantiated switches), large latency fluctuations for packet delivery could be experienced as a consequence of network congestion. This is unacceptable when hard real-time constraints of an application have to be met, and two solutions are viable: network overdimensioning (for NoCs designed to support best-effort traffic only) or implementation of dedicated mechanisms to provide guarantees for timing-constrained traffic (e.g., loss-less data transport, minimal bandwidth, bounded latency, minimal throughput, etc.) [20].

Design productivity issues: It is well known that synthesis and compiler technology development do not keep up with IC manufacturing technology development [21]. Moreover, times-to-market need to be kept as low as possible. Reuse of complex preverified design blocks is an efficient means to increase productivity, and considers both computation resources and the communication infrastructure [22]. It would be highly desirable to have processing elements that could be used in different platforms by means of a plug-and-play design style. To this end, a scalable and modular on-chip network represents a more efficient communication infrastructure compared with shared bus-based architectures. However, the reuse of processing elements is facilitated by the definition of standard network interfaces, which also make the modularity property of the NoC effective. The *Virtual Socket Interface Alliance* (VSIA) has attempted to set the characteristics of this interface industrywide [23]. OCP [24] is another example of standard interface sockets for cores. It is worth remarking that such network interfaces also decouple the development of new cores from the evolution of new communication architectures. The core developer will not have to make assumptions about the system, when the core will be plugged into. Similarly, designers of new on-chip interconnects will not be constrained by the knowledge of detailed interfacing requirements for particular legacy SoC components. Finally, let us observe that NoC components (e.g., switches or interfaces) can be instantiated multiple times in the same design as opposed to the arbiter of traditional shared buses (which is instance-specific) and reused in a large number of products targeting a specific application domain.

© 2005 by CRC Press LLC

The developments of NoC architectures and protocols are fueled by the aforementioned arguments, in spite of the challenges represented by the need for new design methodologies and an increased complexity of system design.

95.3 Related Work

The need to progressively replace on-chip buses with micro-networks was extensively discussed in [2,7]. A number of NoC architectures have been proposed in the literature so far.

Sonics MicroNetwork [25] is an on-chip network making use of communication architecture-independent interface sockets. The *MicroNetwork* is an example of evolutionary solutions [26], which move from a physical implementation as a shared bus, and propose generalizations to support a higher bandwidth (such as partial and full crossbars).

STBUS interconnect from STMicroelectronics is another example of evolutionary architecture, which provides designers with the capability to instantiate both shared bus or partial or full crossbar interconnect configurations.

Even though these architectures provide a bandwidth higher than simple buses, addressing the wiring delay and scalability challenge in the long term requires more radical solutions.

One of the earliest contributions in this area is the *Maia* heterogeneous signal processing architecture, proposed by Zhang et al., [27] based on a hierarchical mesh network. Unfortunately, *Maia*'s interconnect is fully instance-specific. Furthermore, routing is static at configuration time: network switches are programmed once and for all for a given application (as in an FPGA). Thus, communication is based on circuit switching, as opposed to packet switching.

In this direction, Dally and Lacy sketch the architecture of a VLSI multi-computer using 2009 technology [35]. A chip with 64 processor-memory tiles is envisioned. Communication is based on packet switching. This seminal work draws upon past experiences in designing parallel computers and reconfigurable architectures (FPGAs and their evolutions) [28–30].

Most proposed NoC platforms are packet switched and exhibit a regular structure. An example is a mesh interconnection, which can rely on a simple layout and the switch independence on the network size. The *NOSTRUM* network described in [3] adopts this approach: the platform includes both a mesh architecture and the design methodology. The *Scalable Programmable Integrated Network (SPIN)* described in [31] is another regular, fat-tree-based network architecture. It adopts cut-through switching to minimize message latency and storage requirements in the design of network switches. The *Linkoeping SoCBUS* [32] is a two-dimensional mesh network, which uses a *packet connected circuit* (PCC) to set up routes through the network: a packet is switched through the network locking the circuit as it goes. This notion of virtual circuit leads to deterministic communication behavior but restricts routing flexibility for the rest of the communication traffic.

The need to map communication requirements of heterogeneous cores may lead to the adoption of irregular topologies. The motivation for such architectures lies in the fact that each block can be optimized for a specific application (e.g., video or audio processing), and link characteristics can be adapted to the communication requirements of the interconnected cores. Supporting heterogeneous architectures requires a major design effort and leads to coarser-granularity control of physical parameters. Many recent heterogeneous SoC implementations are still based on shared buses (such as the single chip MPEG-2 codec reported in [33]), but the growing complexity of customizable media-embedded processor architectures for digital media processing will soon require NoC-based communication architectures and proper hardware/software development tools. The *Aethereal* NoC design framework presented in [34] aims at providing a complete infrastructure for developing heterogeneous NoC with end-to-end quality of service guarantees. The network supports *guaranteed throughput* (GT) for real-time applications and *best-effort* (BE) traffic for timing unconstrained applications.

Support for heterogeneous architectures requires highly configurable network building blocks, customizable at instantiation time for a specific application domain. For instance, the *Proteo* NoC [36]

© 2005 by CRC Press LLC

consists of a small library of predefined, parameterized components that allow the implementation of a large range of different topologies, protocols, and configurations.

Xpipes interconnect [15] and its synthesizer *XpipesCompiler* [41] push this approach to the limit, by instantiating an application-specific NoC from a library of composable soft macros (network interface, link, and switch). The components are highly parameterizable and provide a reliable and latency-insensitive operation.

95.4 Network-on-Chip Architecture

Most of the terminology for on-chip packet switched communication is adapted from computer network and multiprocessor domain. Messages that have to be transmitted across the network are usually partitioned into fixed-length packets. Packets in turn are often broken into message flow control units called *flits*. In the presence of channel width constraints, multiple physical channel cycles can be used to transfer a single flit. A *phit* is the unit of information that can be transferred across a physical channel in a single step. Flits represent logical units of information, as opposed to phits that correspond to physical quantities. In many implementations, a flit is set to be equal to a phit. The basic building blocks for packet-switched communication across NoCs are:

I. network link
II. switch
III. network interface

and will be described hereafter.

Network Link

The performance of interconnect is a major concern in scaled technologies. As geometries shrink, gate delay improves much faster than the delay in long wires. Therefore, the long wires increasingly determine the maximum clock rate, and hence performance, of the entire design. The problem becomes particularly serious for domain-specific heterogeneous SoCs, where the wire structure is highly irregular and may include both short and extremely long switch-to-switch links. Moreover, it has been estimated that only a fraction of the chip area (between 0.4 and 1.4%) will be reachable in one clock cycle [42].

A solution to overcome the interconnect-delay problem consists of pipelining interconnects [37,38]. Wires can be partitioned into segments (or relay stations, which have a function similar to the one of latches on a pipelined data path), whose length satisfies predefined timing requirements (e.g., desired clock speed of the design). In this way, link delay is changed into latency, but data introduction rate is not bounded by the link delay any more. Now, the latency of a channel connecting two modules may end up being more than one clock cycle. Therefore, if the functionality of the design is based on the sequencing of the signals and not on their exact timing, then link pipelining does not change the functional correctness of the design. This requires the system to be composed of modules whose behavior does not depend on the latency of the communication channels (latency-insensitive operation). As a consequence, the use of interconnect pipelining can be seen as a part of a new and more general methodology for *deep submicron* (DSM) designs, which can be envisioned as synchronous distributed systems composed of functional modules that exchange data on communication channels according to a latency-insensitive protocol. This protocol ensures that functionally correct modules behave correctly independent of the channel latencies [37]. The effectiveness of the latency-insensitive design methodology is strongly related to the ability of maintaining a sufficient communication throughput in the presence of increased channel latencies.

The *International Technology Roadmap for Semiconductors* (ITRS) 2001 [16] assumes that interconnect pipelining is the strategy of choice in its estimates of achievable clock speeds for MPUs. Some industrial designs already make use of interconnect pipelining. For instance, the NETBURST micro-architecture of Pentium 4 contains instances of a stage dedicated exclusively to handle wire delays: in fact, a so-called drive stage is used only to move signals across the chip without performing any computation and, therefore, can be seen as a physical implementation of a relay station [39].

© 2005 by CRC Press LLC

Xpipes interconnect makes use of pipelined links and of a latency-insensitive operation in the implementation of its building blocks. Switch-to-switch links are subdivided into basic segments whose length guarantees that the desired clock frequency (i.e., the maximum speed provided by a certain technology) can be used. In this way, the system operating frequency is not bound by the delay of long links. According to the link length, a certain number of clock cycles are needed by a flit to cross the interconnect. If network switches are designed in such a way that their functional correctness depends on the flit arriving order and not on their timing, input links of the switches can be different and of any length. These design choices are the bases of latency-insensitive operation of the NoC and allow the construction of an arbitrary network topology and hence support for heterogeneous architectures.

Figure 95.2 illustrates the link model, which is equivalent to a pipelined shift register. Pipelining has been used both for data and control lines. The figure also illustrates how pipelined links are used to support latency-insensitive link-level error control, ensuring robustness against communication errors. The retransmission of a corrupted flit between two successive switches is represented. Multiple outstanding flits propagate across the link during the same clock cycle. When flits are correctly received at the destination switch, an ACK is propagated back to the source. After at least $2N$ clock cycles since transmission (where N is the length of the link expressed in number of repeater stages), the flit will be discarded from the buffer of the source

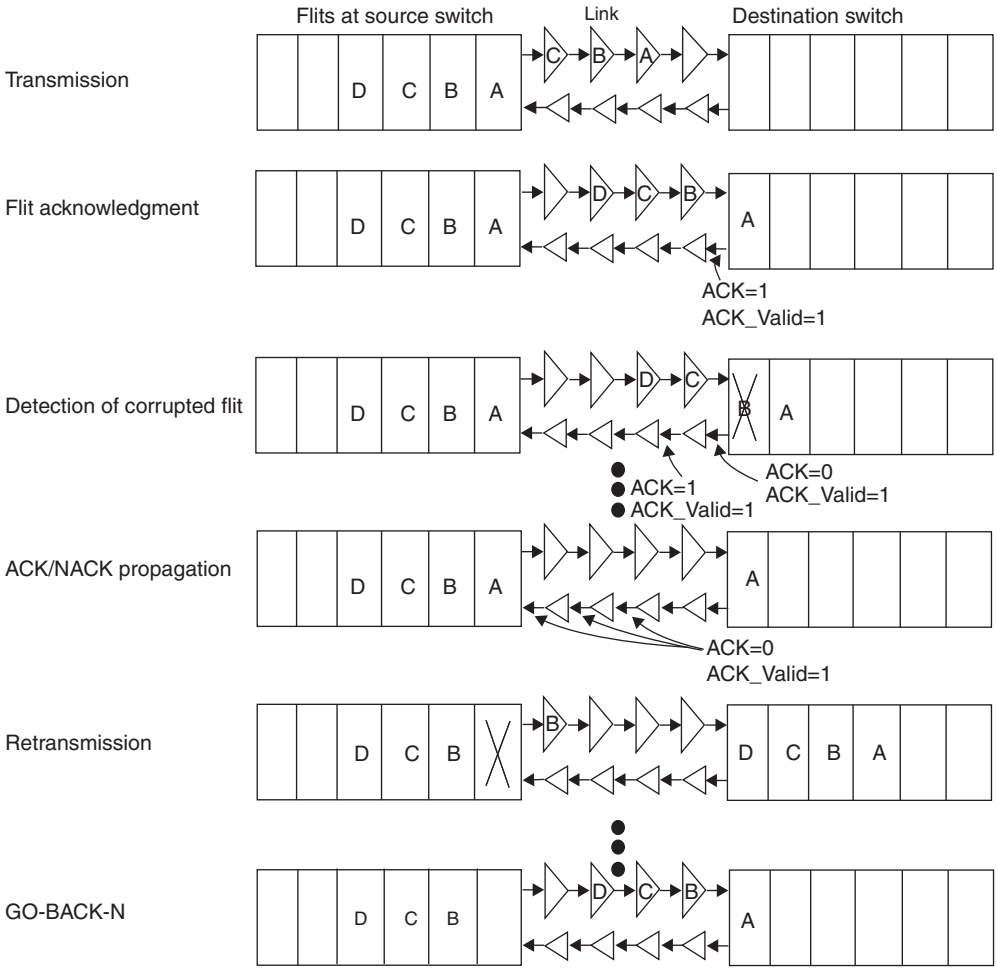

FIGURE 95.2 Pipelined link model and latency-insensitive link-level error control.

© 2005 by CRC Press LLC

switch. On the contrary, a corrupted flit is NACKed and will be retransmitted in due time. The implemented retransmission policy is GO-BACK-N, to keep the switch complexity as low as possible.

Switch

The task of the switch is to carry packets injected into the network to their final destination, following a statically defined or dynamically determined routing path. The switch transfers packets from one of its input ports to one or more of its output ports.

Switch design is usually characterized by a power-performance trade-off: power-hungry switch memory resources can be required by the need to support high-performance on-chip communication. A specific design of a switch may include both input and output buffers or only one type of buffers. Input queuing uses fewer buffers, but suffers from head-of-line blocking. Virtual output queuing has a higher performance, but at the cost of more buffers.

Network flow control (or routing mode) specifically addresses the limited amount of buffering resources in switches. Three policies are feasible in this context [5].

In *store-and-forward routing*, an entire packet is received and entirely stored before being forwarded to the next switch. This is the most demanding approach in terms of memory requirements and switch latency. Also, *virtual cut-through routing* requires buffer space for an entire packet, but allows lower latency communication, in that a packet is forwarded as soon as the next switch guarantees that the complete packet will be accepted. If this is not the case, the current router must be able to store the whole packet.

Finally, a *wormhole routing* scheme can be used to reduce switch memory requirements and to permit low latency communication. The first flit of a packet contains routing information, and header flit decoding enables the switches to establish the path and subsequent flits simply follow this path in a pipelined manner by means of switch output port reservation. A flit is passed to the next switch as soon as enough space is available to store it, even though there is not enough space to store the whole packet. If a certain flit faces a busy channel, subsequent flits have to wait at their current locations and are therefore spread over multiple switches, thus blocking the intermediate links. This scheme avoids buffering the full packet at one switch and keeps end-to-end latency low, although it is more sensitive to deadlock and may result in low link utilization.

Guaranteeing quality of service in switch operation is another important design issue, which needs to be addressed when time-constrained (hard or soft real time) traffic is to be supported. Throughput guarantees or latency bounds are examples of time-related guarantees.

Contention-related delays are responsible for large fluctuations of performance metrics, and a fully predictable system can be obtained only by means of contention-free routing schemes. With *circuit switching*, a connection is set up over which all subsequent data are transported. Therefore, contention resolution takes place at setup at the granularity of connections, and time-related guarantees during data transport can be given. In *time division circuit switching* (see [25] for an example), bandwidth is shared by time division multiplexing connections over circuits.

In packet switching, contention is unavoidable since packet arrival cannot be predicted. Therefore, arbitration mechanisms and buffering resources must be implemented at each switch, thus delaying data in an unpredictable manner and making it difficult to provide guarantees. Best-effort NoC architectures can mainly rely on network overdimensioning to bound fluctuations of performance metrics.

The *Aethereal* NoC architecture makes use of a router that tries to combine GT and BE services [34]. The GT router subsystem is based on a time-division multiplexed circuit switching approach. A router uses a *slot table* to (i) avoid contention on a link, (ii) divide up bandwidth per link between connections, and (iii) switch data to the correct output. Every slot table T has S time slots (rows), and N router outputs (columns). There is a logical notion of synchronicity: all routers in the network are in the same fixed-duration slot. In a slot s, at most one *block* of data can be read/written per input/output port. In the next slot, the read blocks are written to their appropriate output ports. Blocks thus propagate in a store and forward manner. The latency a block incurs per router is equal to the duration of a slot and bandwidth is guaranteed in multiples

© 2005 by CRC Press LLC

of block size per S slots. The BE router uses packet switching, and it has been showed that both input queuing with wormhole routing or virtual cut-through routing and virtual output queuing with wormhole routing are feasible in terms of buffering cost. The BE and GT router subsystems are combined in the *Aethereal* router architecture of Figure 95.3. The GT router offers a fixed end-to-end latency for its traffic, which is given the highest priority by the arbiter. The BE router uses all the bandwidth (slots) that has not been reserved or used by GT traffic. GT router slot tables are programmed by means of BE packets (see the arrow "program" in Figure 95.3). Negotiations, resulting in slot allocation, can be done at compile time, and be configured deterministically at runtime. Alternatively, negotiations can be done at runtime.

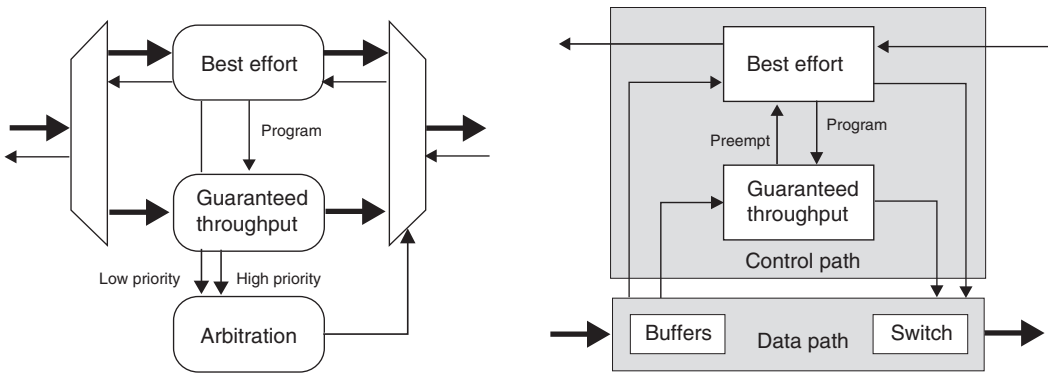
A different perspective has been taken in the design of the switch for the best-effort *Xpipes* NoC. Figure 95.4 shows an example configuration with four inputs, four outputs and two virtual channels multiplexed across the same physical output link. A physical link is assigned to different virtual channels on a flit-by-flit basis, thereby improving network throughput. Switch operation is latency insensitive, in that correct operation is guaranteed for arbitrary link pipeline depth. In fact, as explained above, network links in *Xpipes* interconnect are pipelined with a flexible number of stages, thereby decoupling link data introduction rate from its physical length.

For a latency-insensitive operation, the switch has virtual channel registers to store $2N + M$ flits, where N is the link length (expressed as the number of basic repeater stages) and M is a switch architecture-related contribution (12 cycles in this design). The reason is that each transmitted flit has to be acknowledged before being discarded from the buffer. Before an ACK is received, the flit has to travel across the link (N cycles), an ACK/NACK decision has to be taken at the destination switch (a portion of M cycles), and the ACK/NACK signal has to be propagated back (N cycles) and recognized by the source switch (remaining portion of M cycles). During this time, other $2N + M$ flits are transmitted but not yet ACKed.

Output buffering was chosen for *Xpipes* switches, and the resulting architecture is reported in Figure 95.5. It consists of a replication of the same output module, accepting all input ports as its own inputs. Flow control signals generated by each output block are directed to a centralized module, which takes care of generating proper ACKs or NACKs for the incoming flits from the different input ports.

Each output module is deeply pipelined (seven pipeline stages) to maximize the operating clock frequency of the switch. Architectural details on the pipelined output module are illustrated in Figure 95.6. Forward flow control is used and a flit is transmitted to the next switch only when adequate storage is available. The CRC decoders for error detection work in parallel with the switch operation, thereby concealing their impact on switch latency.

The first pipeline stage checks the header of incoming packets on different input ports to determine whether those packets have to be routed through the output port under consideration. Only matching packets are forwarded to the second stage, which resolves contention based on a round-robin policy. Arbitration is carried out against receipt of the tail flits of preceding packets, so that all other flits of a



(a) Conceptual view

(b) Hardware view

FIGURE 95.3 A combined GT–BE router.

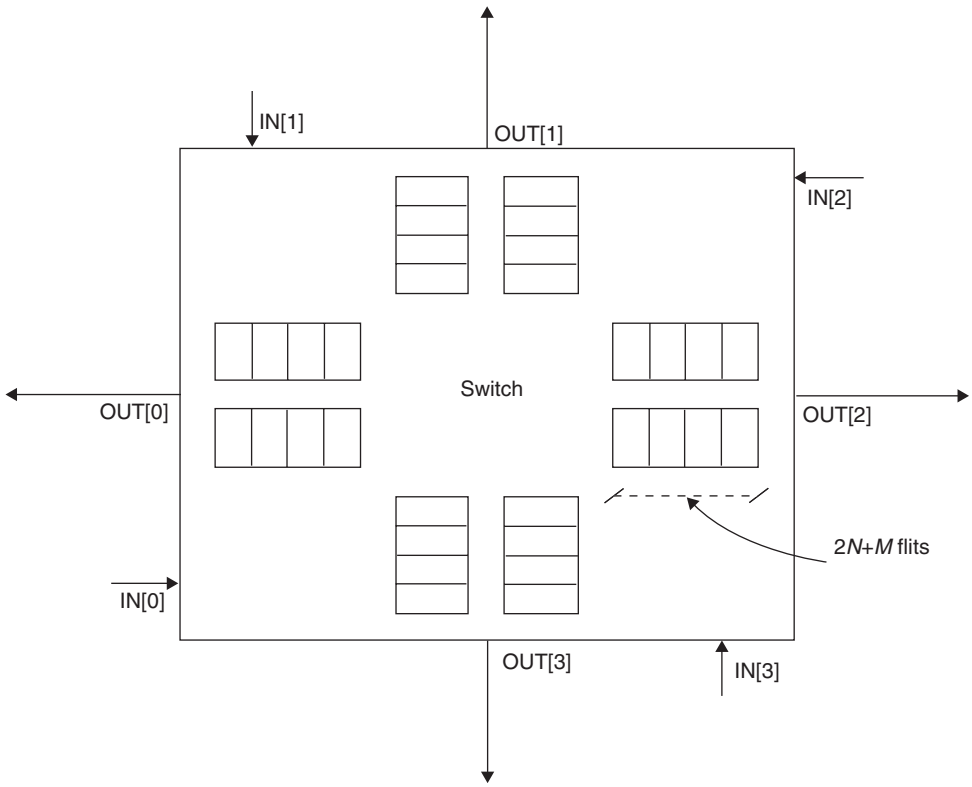

FIGURE 95.4 Example of switch configuration with two virtual channels.

packet can be propagated without contention resolution at this stage. A NACK for flits of nonselected packets is generated. The third stage is just a multiplexer, which selects the prioritized input port. The following arbitration stage retains the status of virtual channel registers and decides whether the flits can be stored in the registers or not. A header flit is sent to the register with more free locations, followed by successive flits of the same packet. The fifth stage is the actual buffering stage, and the ACK/NACK message at this stage indicates whether a flit has been successfully stored or not. The following stage takes care of forward flow control and finally a last arbitration stage multiplexes the virtual channels on the physical output link.

Finally, the switch is highly parameterizable. Design parameters are: number of I/O ports, flit width, number of virtual channels, length of switch-to-switch links, and size of output registers.

Network Interface

The most relevant tasks of the *network interface* (NI) are: (i) concealing the details about the network communication protocol to the cores, so that they can be developed independent of the communication infrastructure, (ii) communication protocol conversion (from end-to-end to network protocol), and (iii) data packetization (packet assembly, delivery, and disassembly).

The former objective can be achieved by means of standard interfaces. For instance, the VSIA vision [23] is to specify open standards and specifications that facilitate the integration of software and hardware virtual components from multiple sources. Different complexity interfaces are described in the standard, from Peripheral *Virtual Complexity Interfaces* (VCI) to Basic VCI and Advanced VCI.

Another example of standard socket to interface cores to networks is represented by *Open Core Protocol* (OCP) [24]. Its main characteristics are a high degree of configurability to adapt to the core's

© 2005 by CRC Press LLC

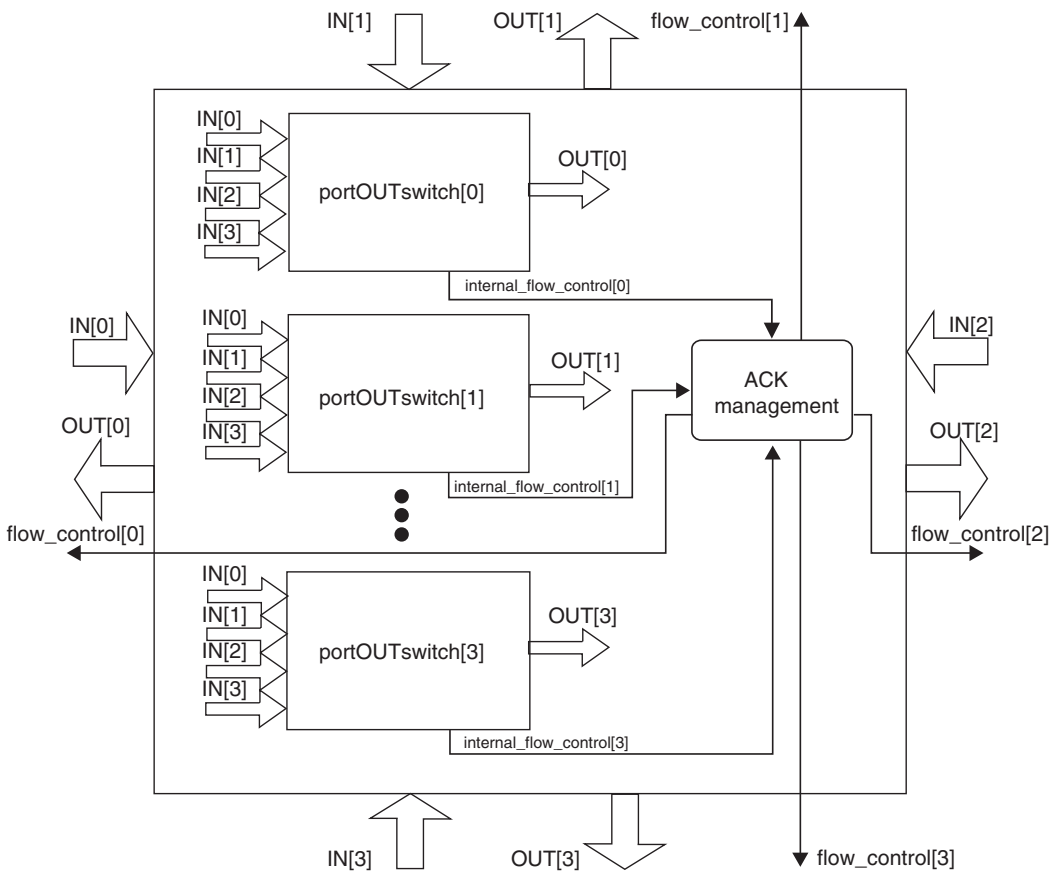

FIGURE 95.5 Architecture of output-buffered *Xpipes* switch.

functionality and the independence of request and response phases, thus supporting multiple outstanding requests and pipelining of transfers.

Data packetization is a critical task for the network interface, and has an impact on the communication latency, besides the latency of the communication channel. The packet preparation process consists of building packet header, payload, and packet tail. The header contains the necessary routing and network control information (e.g., source and destination address). When source routing is used, the destination address is ignored and replaced with a route field that specifies the route to the destination. This overhead in terms of packet header is counterbalanced by the simpler routing logic at the network switches: they simply have to look at the route field and route the packet over the specified switch output port. The packet tail indicates the end of a packet and usually contains parity bits for error-detecting or error-correcting codes.

An insight into the *Xpipes* network interface implementation will provide an example of these concepts. It provides a standardized OCP-based interface to network nodes. The NI for cores that initiate communication (initiators) needs to turn OCP-compliant transactions into packets to be transmitted across the network. It represents the slave side of an OCP end-to-end connection, and it is therefore referred to as *network interface slave* (NIS). Its architecture is shown in Figure 95.7.

The NIS has to build the packet header, which has to be spread over a variable number of flits depending on the length of the path to the destination node. In fact, *Xpipes* relies on a static routing algorithm called *street sign routing*. Routes are derived by the network interface by accessing a lookup table based on the destination address. Such information consists of direction bits read by each switch and indicating the output port of the switch that flits belonging to a certain packet have to be directed to.

© 2005 by CRC Press LLC

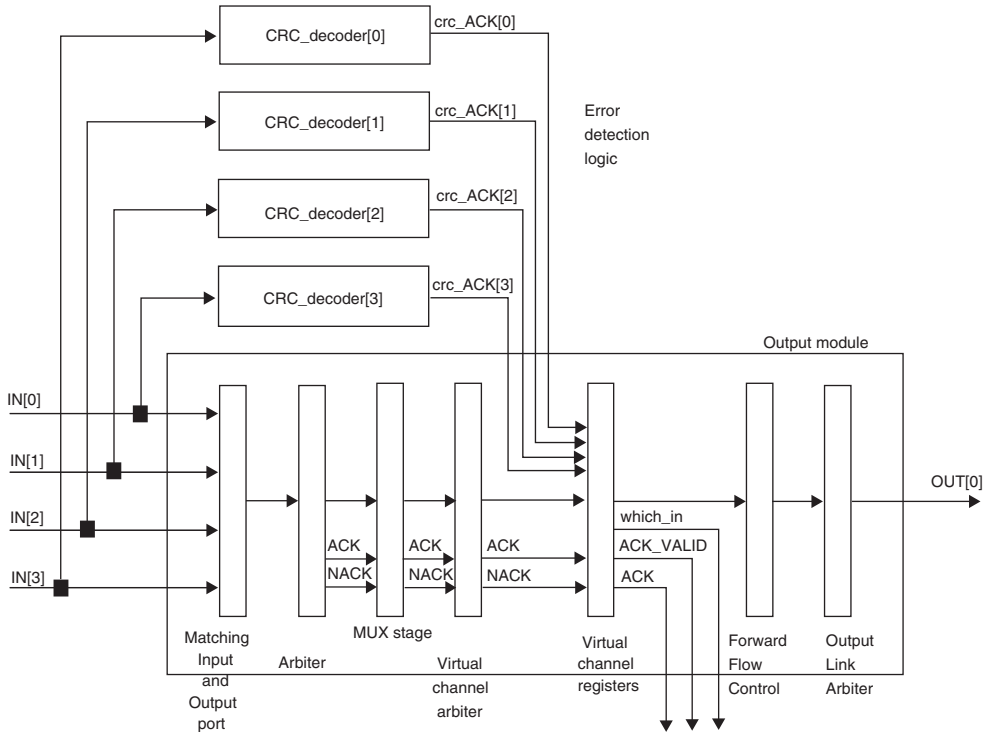

FIGURE 95.6 Architecture of an *Xpipes* switch output module.

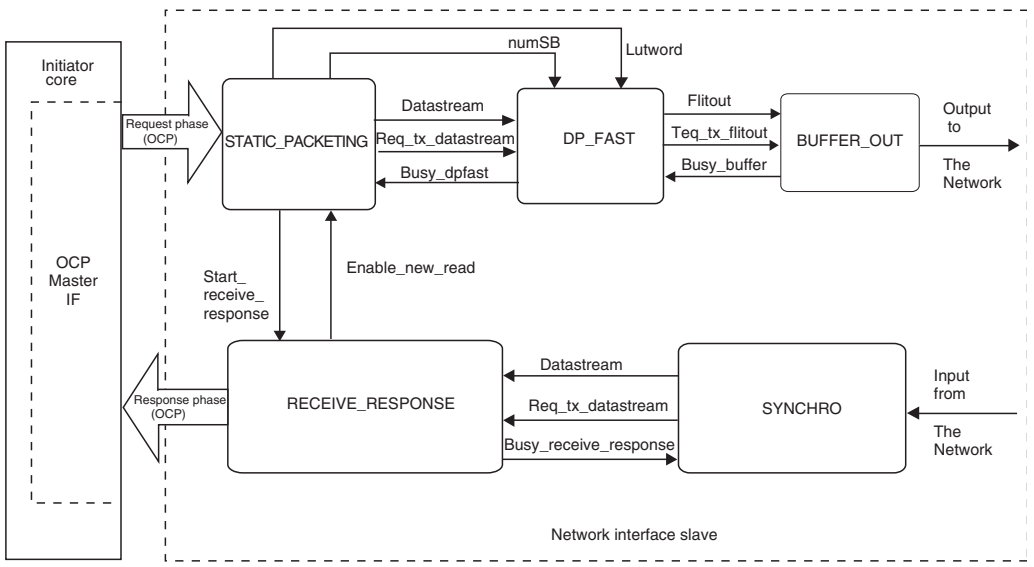

FIGURE 95.7 Architecture of the *Xpipes* network interface slave.

The lookup table is accessed by the *STATIC_PACKETING* block, a finite state machine that forwards the routing information *numSB* (number of hops to destination) and *lutword* (word read from the lookup table) as well as the request-related information *datastream* from the initiator core to the *DP_FAST* block, provided the enable signal *busy_dpfast* is not asserted.

© 2005 by CRC Press LLC

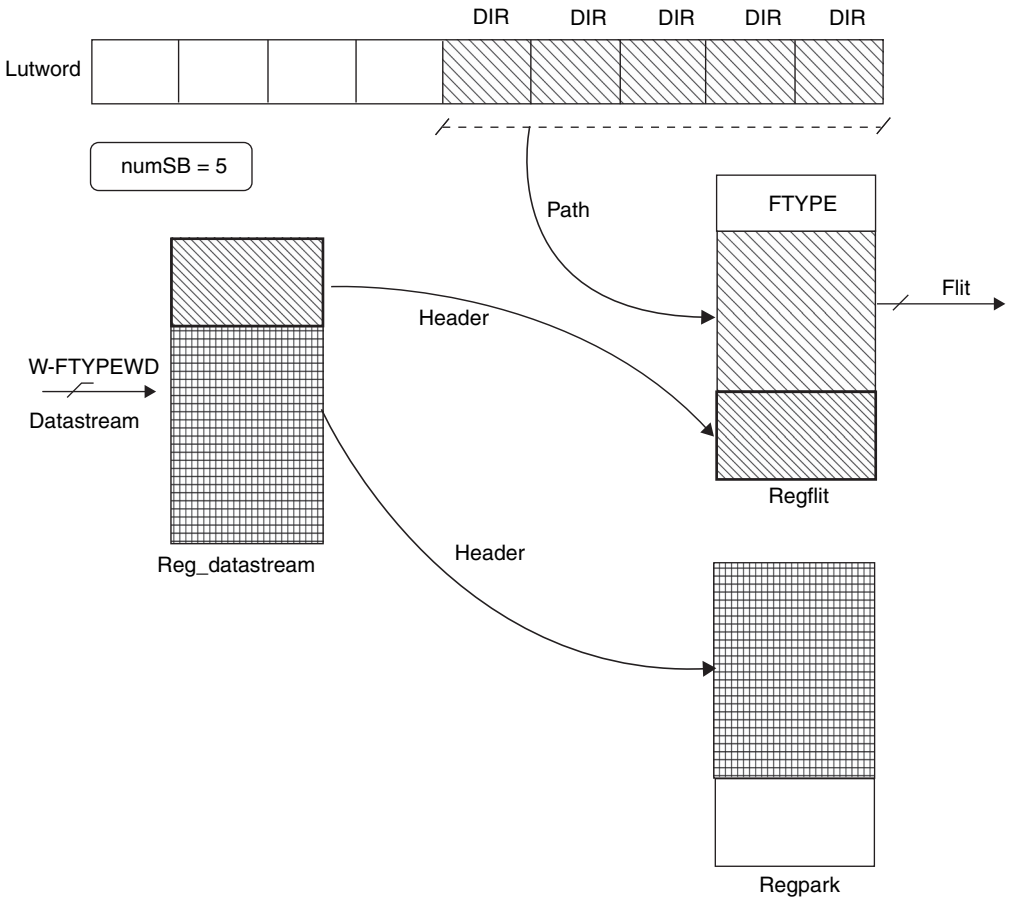

FIGURE 95.8 Mechanism for building header flits.

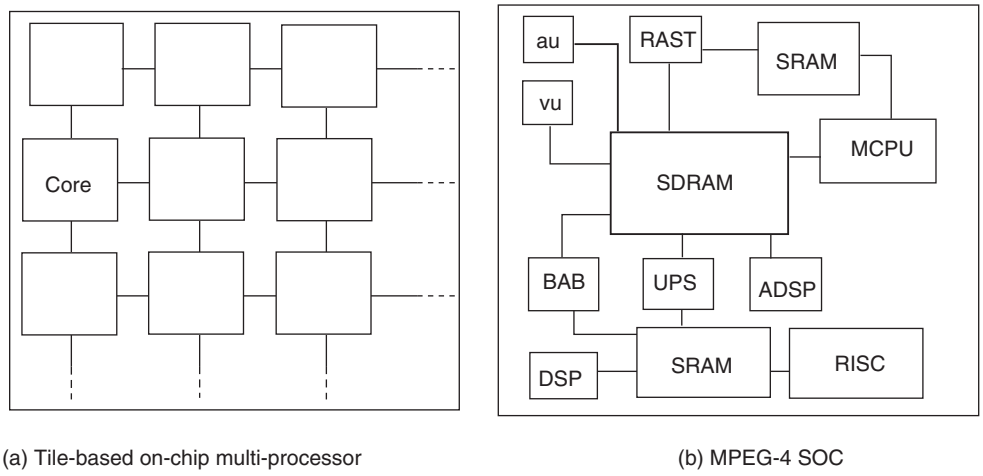
Based on the input data, module *DP_FAST* has the task of building the flits to be transmitted via the output buffer *BUFFER_OUT*, according to the mechanism illustrated in Figure 95.8. Let us assume that a packet requires *numSB = 5* hops to get to the destination, and that the direction to be taken at each switch is expressed by *DIR*. Module *DP_FAST* builds the first flit by concatenating the flit-type field with path information. If there is some space left in the flit, it is filled with header information derived from the input *datastream*. The unused part of the *datastream* is stored in a *regpark* register, so that a new datastream can be read from the *STATIC_PACKETING* block. The following header and/or payload flits will be formed by combining data stored in *regpark* and *reg_datastream*. No partially filled flits are transmitted to make transmission more efficient.

Finally, module *BUFFER_OUT* stores flits to be sent across the network, and allows the NIS to keep preparing successive flits when the network is congested. The size of this buffer is a design parameter.

The response phase is carried out by means of two modules. *SYNCHRO* receives incoming flits and reads out only useful information (e.g., it discards route fields). At the same time, it contains buffering resources to synchronize the network's requests to transmit remaining packet flits with the core consuming rate. The *RECEIVE_RESPONSE* module translates useful header and payload information into OCP-compliant response fields.

When a read transaction is initiated by the master core, the *STATIC_PACKETING* block asserts a *start_receive_response* signal that triggers the waiting phase of the *RECEIVE_RESPONSE* module for the requested data. As a consequence, the NIS supports only one outstanding read operation to keep interface

© 2005 by CRC Press LLC



(a) Tile-based on-chip multi-processor (b) MPEG-4 SOC

FIGURE 95.9 Homogeneous versus heterogeneous architectural template.

complexity low. Although no read after read transactions can be initiated unless the previous one has been completed, an indefinite number of write transactions can be carried out after an outstanding read has been initiated.

The architecture of a network interface master is similar to the one just described, and is not reported here due to lack of space. At instantiation time, the main network interface-related parameters to be set are: total number of core blocks, flit width, and maximum number of hops across the network.

95.5 Network-on-Chip Topology

The individual components of SoCs are inherently heterogeneous with widely varying functionality and communication requirements. The communication infrastructure should optimally match communication patterns among these components accounting for the individual component needs.

As an example, consider the implementation of an MPEG4 decoder [40], depicted in Figure 95.9 (b), where blocks are drawn roughly to scale and links represent interblock communication. First, the embedded memory (SDRAM) is much larger than all other cores and it is a critical communication bottleneck. Block sizes are highly nonuniform and the floorplan does not match the regular, tile-based floorplan shown in Figure 95.9 (a). Second, the total communication bandwidth to/from the embedded SDRAM is much larger than that required for communication among the other cores. Third, many neighboring blocks do not need to communicate. Even though it may be possible to implement MPEG4 onto a homogeneous fabric, there is a significant risk of either underutilizing many tiles and links, or, at the opposite extreme, of achieving poor performance because of localized congestion. These factors motivate the use of an application-specific on-chip network [27].

With an application-specific network, the designer is faced with the additional task of designing network components (e.g., switches) with different configurations (e.g., different I/Os, virtual channels, buffers) and interconnecting them with links of uneven length. These steps require significant design time and the need to verify network components and their communications for every design.

The library-based nature of network building blocks seems the more appropriate solution to support domain-specific custom NoCs. Two relevant examples have been reported in the open literature: *Proteo* and *Xpipes Interconnects. Proteo* consists of a fully reusable and scalable component library where the components can be used to implement networks from very simple bus emulation structures to complex packet networks. It uses a standardized VCI interface between the functional cores and the communication network. *Proteo* is described using synthesizable VHDL and relies on an interconnect node architecture that

© 2005 by CRC Press LLC

targets flexible on-chip communication. It is used as a testing platform when the efficiency of network topologies and routing schemes are investigated for on-chip environments. The node is constructed from a collection of parameterized and reusable hardware blocks, including components such as FIFO buffers, routing controllers, and standardized interface wrappers. A node can be tuned to fulfill the desired characteristics of communication by properly selecting the internal architecture of the node itself.

Xpipes NoC adopts a similar approach. As described throughout this chapter, its network building blocks have been designed as highly configurable and design-time composable soft macros described in SystemC at the cycle-accurate level.

An optimal system solution will also require an efficient mapping of high-level abstractions onto the underlying platform. This mapping procedure involves optimizations and trade-offs between many complex constraints, including the quality of service, real-time response, power consumption, area, etc. Tools are urgently needed to explore this mapping process, and assist and automate optimization where possible.

The first challenge for these tools is to bridge the gap in building custom NoCs that optimally match the communication requirements of the system. The network components they build should be highly optimized for that particular NoC design, providing large savings in area, power, and latency with respect to standard NoCs based on regular structures.

In the following section, an example of design methodology for heterogeneous SoCs is briefly illustrated. It is relative to Xpipes interconnect and relies on a tool that automatically instantiates an application-specific NoC for heterogeneous on-chip multi-processors (called *XpipesCompiler* [41]).

Domain Specific Network-on-Chip Synthesis Flow

The complete *XpipesCompiler*-based NoC design flow is depicted in Figure 95.10. From the specification of an application, the designer (or a high-level analysis and exploration tool) creates a high-level view of the SoC floorplan, including nodes (with their network interfaces), links and switches. Based on clock speed target and link routing, the number of pipeline stages for each link is also specified. The information on the network architecture is specified in an input file for the *XpipesCompiler*. Routing tables for the network interfaces are also specified. The tool takes as additional input the SystemC library of soft network components. The output is a SystemC hierarchical description, which includes all switches, links,

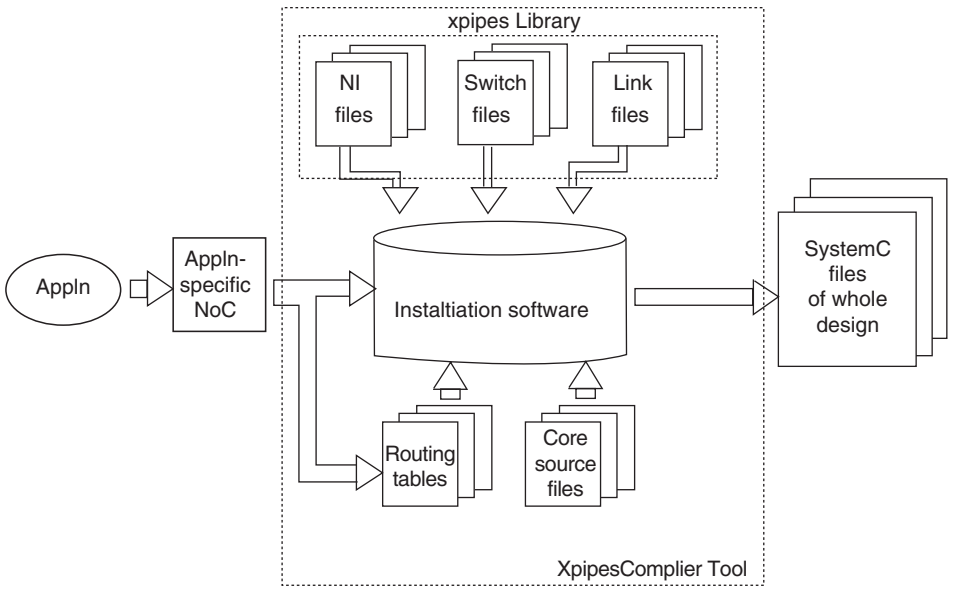


FIGURE.95.10 NoC synthesis flow with *XpipesCompiler*.

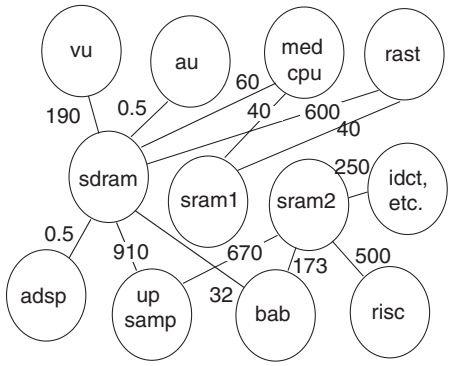

FIGURE 95.11 Core graph representation of an MPEG4 design with annotated average communication requirements.

TABLE 95.1 Area and power estimates for the MPEG4-related NoC configurations

NoC Configuration	Area (mm^2)	Ratio mesh/cust	Power (mW)	Ratio mesh/cust
Mesh	1.31		114.36	
Custom 1	0.86	1.52	110.66	1.03
Custom 2	0.71	1.85	93.66	1.22

network nodes and interfaces, and specifies their topological connectivity. The final description can then be compiled and simulated at the cycle-accurate and signal-accurate level. At this point, the description can be fed to back-end RTL synthesis tools for silicon implementation.

In a nutshell, the *XpipesCompiler* generates a set of network component instances that are custom-tailored to the specification contained in its input network description file. This tool allows a very instructive comparison of the effects (in terms of area, power, and performance) of mapping applications on customized domain-specific NoCs and regular mesh NoCs.

Let us focus on the MPEG4 decoder already introduced in this chapter. Its core graph representation together with its communication requirements are reported in Figure 95.11. The edges are annotated with the average bandwidth requirements of the cores in MB/s. Customized application-specific NoCs that closely match the application's communication characteristics have been manually developed and compared to a regular mesh topology. The different NoC configurations are reported in Figure 95.12. In the MPEG4 design considered, many of the cores communicate with each other through the shared SDRAM. Thus, a large switch is used for connecting the SDRAM with other cores (Figure 95.12 (b)), while smaller switches are connected to less communication-intensive cores. An alternate custom NoC is also considered (Figure 95.12 (c)): it is an optimized mesh network, with superfluous switches and switch I/Os removed.

Area (in 0.1 μm technology) and power estimates for the different NoC configurations are reported in Table 95.1. Since all cores communicate with many other cores, many switches are needed and therefore area savings are not extremely significant for custom NoCs.

Based on the average traffic through each network component, the power dissipation for each NoC design has been calculated. Power savings for the custom solutions are not very significant, as most of the traffic traverses the larger switches connected to the memories. As power dissipation on a switch increases nonlinearly with an increase in switch size, there is more power dissipation in the switches of custom NoC1 (that has an 8×8 switch) than the mesh NoC. However, most of the traffic traverses short links in this custom NoC, thereby giving marginal power savings for the whole design.

Figure 95.13 reports the variation of average packet latency (for 64B packets, 32-bit flits) with link bandwidth. Custom NoCs, as synthesized by *XpipesCompiler*, have lower packet latencies as the average number of switches and link traversals is lower. At the minimum plotted bandwidth value, almost 10% latency saving is achieved. Moreover, the latency increases more rapidly with the mesh NoC as the link

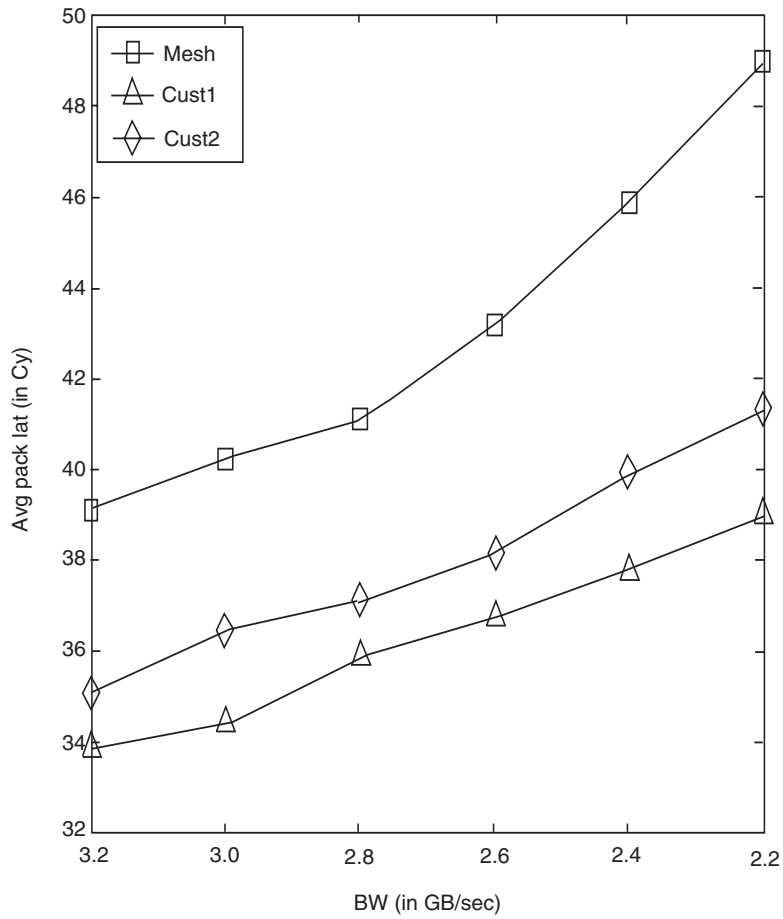

FIGURE 95.13 Average packet latency as a function of the link bandwidth.

© 2005 by CRC Press LLC

bandwidth decreases. Also, custom NoCs have better link utilization: around 1.5 times the link utilization of a mesh topology.

Area, power, and performance optimizations by means of custom NoCs turn out to be more difficult for MPEG4 than other applications such as Video Object Plane Decoders and Multi-Window Displayer [41].

95.6 Conclusions

This chapter describes the motivation for packet-switched networks as communication paradigm for deep submicron SoCs. After an overview of NoC proposals from the open literature, this chapter goes into the details of NoC architectural components (switch, network interface and point-to-point links), introducing the *Xpipes* library of composable soft macros as a case study. Finally, the challenging issue of heterogeneous NoC design is addressed, showing an example NoC synthesis flow and detailing area, power, and performance metrics of customized application-specific NoC architectures with respect to regular mesh topologies. The chapter aims at highlighting the main guiding principles and open issues for NoC design on gigascale multi-processor SoCs.

96.1 Introduction

Rapid advances in microelectronic technology coupled with integration of microelectronic radios on the same board or even on the same chip has been a powerful driver of growth and revolutionary advances in the telecommunications industry over the last decade. Recently, a new breed of *Networked Embedded Systems* (NES) has emerged, which are multiple distributed computing devices with wireline and/or wireless communication interfaces embedded in myriad products such as automobiles, medical components, sensor networks, consumer products, and personal mobile devices. These systems have been variously referred to as Embedded Network Systems (EmNets), Networked Embedded System Technology (NEST), and NES [1–3].

NES are often distributed embedded systems that must interact not only with the environment and the user but also with each other to coordinate computing and communication. And yet, these devices must often operate in very constrained environments related to their size, energy availability, network connectivity, etc. The challenges posed by the design and deployment of NES have captured the imagination of a large number of researchers and galvanized whole new communities into action. The design of NES requires multi-disciplinary, multi-level cooperation and development to address the diverse hardware (processor cores, radios, security cores) and software (applications, middleware, operating systems, networking protocols) needs. In this paper, we briefly highlight some of the design concerns and challenges in deploying NES.

© 2005 by CRC Press LLC

Some examples of NES are wireless data acquisition systems such as habitat [4–7], agriculture and weather monitoring [8], disaster management and civil monitoring, Cooperative Engagement Capability (CEC) [9] for military use [10], and fabric e-textile [11, 12]. Common to all these systems/applications is their ability to provide an interaction between the environment and humans through a medium of devices such as sensors for data collection, computation processors to perform data computation, and remote storage devices to preserve and collate the information.

A good exposition of the characteristics, parameters, examples, and design challenges of networked embedded systems is presented in [1]. We draw heavily on this book for material and examples. Similar surveys and expositions of challenges in the applications and design and implementation of sensor networks are given in [13–17].

96.2 Characteristics of NES

The realm of possibilities where NES applications can be implemented makes characterizing these systems an inherently difficult task. However, we make an attempt at characterizing the basic functionality and constraints, distributed nature and usability, dependability, and availability of such systems. Then, we describe NES through some examples.

Functionality and Constraints

Networked embedded systems are typically designed to interact with and react to the environment and people that are around them. Thus, often, NES have sensors that measure temperature, moisture, movement, light, and so on. By definition, NES have a communication mechanism — either a wireline connection or a wireless radio. Also, they typically have computation engines that can do at least a minimal amount of computing on the data they acquire.

The environment and user needs place constraints on NES such as small size, low weight, harsh working conditions, safety and reliability concerns, low cost, and poor resource availability in terms of low computational ability and low energy availability (limited battery) [18]. NES devices have to be small in size so that their deployment does not interfere with the environment; that is, they must function almost invisibly to the environment. For example, animals must not be aware of the habitat-monitoring sensors that are embedded on them or around them. This example also demonstrates the need for these systems to be low weight and be able to work under harsh working conditions, that is, be tolerant of temperature changes, physical abuse, vibration, shock, and corrosion. Since NES are frequently deployed in the field with little or no access to renewable energy sources, they have to live off a limited energy source or battery. Due to real-time and mission-critical requirements, NES have to frequently meet safety and reliability constraints. For example, the cruise control, antilock braking, and airbag systems in automobiles have to respond within given real-time constraints to meet safety requirements. The small form factor and wide distribution of NES also place a constraint on cost; price fluctuations of even a few cents on each device have a large impact as the volume of devices deployed increases.

Figure 96.1 shows the Berkeley NES device that consists of a MICA processor and a radio board [19]. As technology advances, these devices are becoming smaller. In fact, the latest Berkeley "mote" is as small as a coin. This has led to the notion of *smart dust* or a massively distributed sensor network that is self-contained, networked, and provides multiple sensor and coordinated computational capabilities [20, 21, 7, 22].

Distributed Nature

The application spectrum of NES often means that these systems are physically distributed. In fact, the distributed nature of NES extends to distributed functionality and communication as well. *Distributed in function* refers to NES components that perform specific roles and work together with other NES components to complete the system. Automotive electronics is a good example where many different function-specific components work in unison, such as the power control modules, the engine, airbag

© 2005 by CRC Press LLC

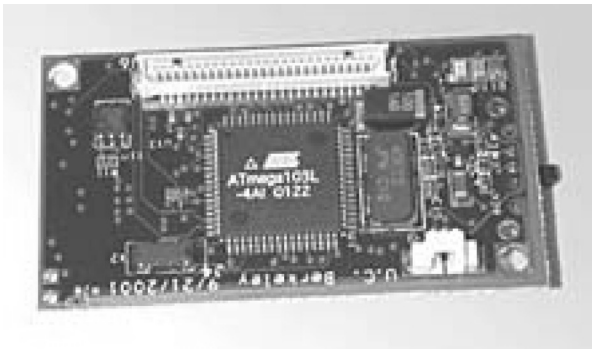

FIGURE 96.1 U. C. Berkeley NES device — the MICA processor and radio board [19].

deployment, cruise control, suspension, etc. Figure 96.2 shows the components from Kyocera that are widely used in automotive electronics. Similarly, *distributed communication* refers to local and global communication between the embedded systems distributed throughout the system. For example, automotive systems have local wires from actuators/sensors to Electronic Control Units (ECUs) and global wires/buses between ECUs [23].

Usability, Dependability, and Availability

NES are becoming an increasingly dominant part of a number of devices and systems in all aspects of our daily lives from entertainment, transportation, personal communications to biomedical devices.

The pervasiveness of these systems, however, raises concerns about dependability and availability. *Availability* generally means access to the system. In scenarios where some of the components of the NES fail, there must be a mechanism through which the users can interface and interact with the components to investigate and rectify the problems. Mediums of access can be through Personal Digital Assistants (PDAs), wired serial access points, infra-red technology, etc. Another dimension of availability is the *long life* expected from NES components. Often, NES do not have access to a renewable energy source and sometimes it is not possible to change the battery source either. For example, sensors deployed to measure traffic on roads or sensor tags placed on animals are inaccessible or difficult to reach after deployment.

Dependability or *reliability* is also a major concern that goes hand in hand with the availability requirement. The system must guarantee a certain level of service that the user can depend on. For example, temperature sensors and smoke detectors are critical to the fire safety requirements of any building.

Availability and dependability characteristics are especially crucial to safety-critical systems such as avionics and biomedical applications. The sensors used in an airplane to monitor cabin pressure, oxygen levels, elevation, relative speed, etc, are all important to maintain safety. For example, the release of oxygen into the oxygen masks in airplanes is controlled via sensors that monitor the cabin oxygen levels. For biomedical applications such as electronic heart pacemakers, the need for dependability is obvious since malfunctioning components can be life threatening. Military personnel monitoring is another example for biomedical applications with NES where devices are used to transmit the location and vital statistics of the personnel.

Since NES consist of diverse hardware and software components that interact with each other, component *interoperability* becomes another important concern [1]. Today, cars have tens or sometimes even a hundred embedded computing systems that are designed and manufactured by different contractors. Such complex distributed, interacting embedded systems raise difficult challenges in system integration, component interoperability, and system testing and validation.

These networked embedded systems characteristics present new challenges and constraints for systems engineers, which have not been fully addressed in the design of past networking and distributed systems. Software and hardware tools and techniques are required to satisfy the need for low cost, low power, QoS guarantees, and fast time-to-market. Formalization of methodologies to ensure functional correctness of

design and efficiency of design is paramount in meeting the time-to-market requirements by reducing the iterations in the design process.

In the following sections, we discuss some of the interesting applications of NES and then describe NES tools and methodologies such as programming languages, simulation environments, and performance measurement tools designed specifically to address the design challenges posed by NES.

96.3 Examples of NES

To demonstrate the characteristics, constraints, and design challenges of NES, we present several examples from current and future NES. These examples are representative of the diverse application domains where NES can be found. We start with three examples from [1].

Automobile: Safety-Critical Vs. Telematics

Cars today typically have tens to a hundred microprocessors controlling all aspects of the automobile from entertainment systems to the emergency airbag release mechanisms. Figure 96.3 shows some of the telematic components in a Mitsubishi car [25]. The microprocessors in charge of the functionality frequently communicate and interact with other processors. For example, the stereo volume is automatically reduced when the driver receives (or answers) a call on his or her cell phone.

Thus, a range of devices that perform different tasks are beginning to be organized in sophisticated networks as distributed systems. Broadly speaking, there are two such distributed systems: *safety-critical processing systems* and *telematics* systems. Clearly, the safety-critical aspects cannot be sacrificed or compromised in any way. These two systems are an integral part of the design and construction of the automobile and dictate several design parameters. Since automobiles have times-to-market that can span up to five years from concept to final product, frequently the technology used for the telematics and safety-critical components in the automobile is already outdated. This is a rising concern, especially for the safety-critical components, because upgrading or switching out components is generally not performed or usually not even feasible. Note that systems that cannot be upgraded or altered after final production are considered to be *closed systems*.

Conversely, open systems allow plugging in newer components with more capabilities and features similar to a plug-and-play environment. Thus, to make automobiles open systems, we have to develop technologies that enable automobile designers to construct the safety-critical and telematics systems in an abstracted manner such that components with a standardized communication protocol and interface

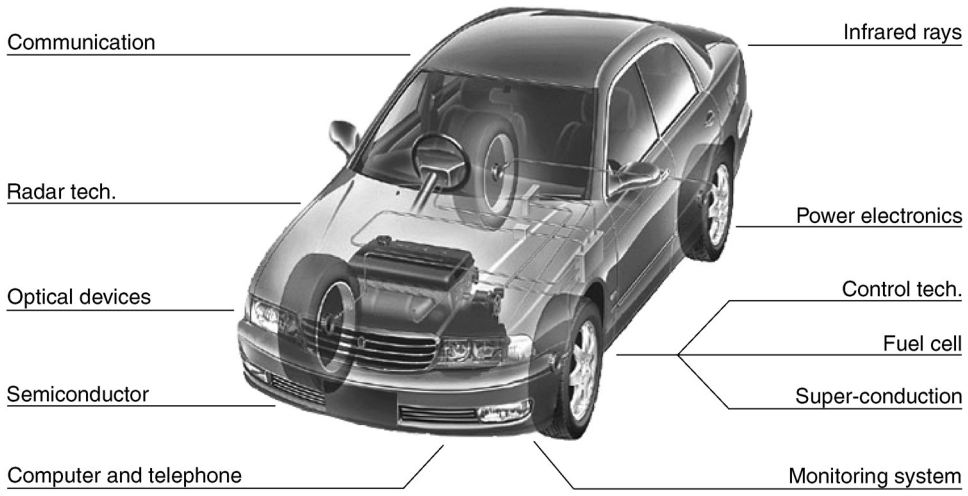

FIGURE 96.3 Telematics components in an automobile [25].

© 2005 by CRC Press LLC

can simply be plugged into the final product. This resolves the disparity between the long design cycles for automobiles and the rapid advances in NES components used in them.

The increasing popularity of wireless technology has spawned interesting applications for automobiles. For example, the OnStar system from General Motors can monitor the location of a car and customer service staff can remotely unlock the car, detect when airbags have been deployed, and so on. Wireless communication opens up infinite possibilities such as automobile service requests and data collection for automobile users, dealers, and manufacturers.

Data Acquisition: Precision Agriculture and Habitat Monitoring

The use of sensor nodes for data acquisition is becoming a useful tool for agricultural and habitat monitoring. In [7], the authors present a study in which they used wireless sensor networks in a real-world habitat monitoring project. The small footprint and weight of modern sensor nodes make them attractive for habitat and agricultural monitoring since they cause minimal disturbance to the animals, plant

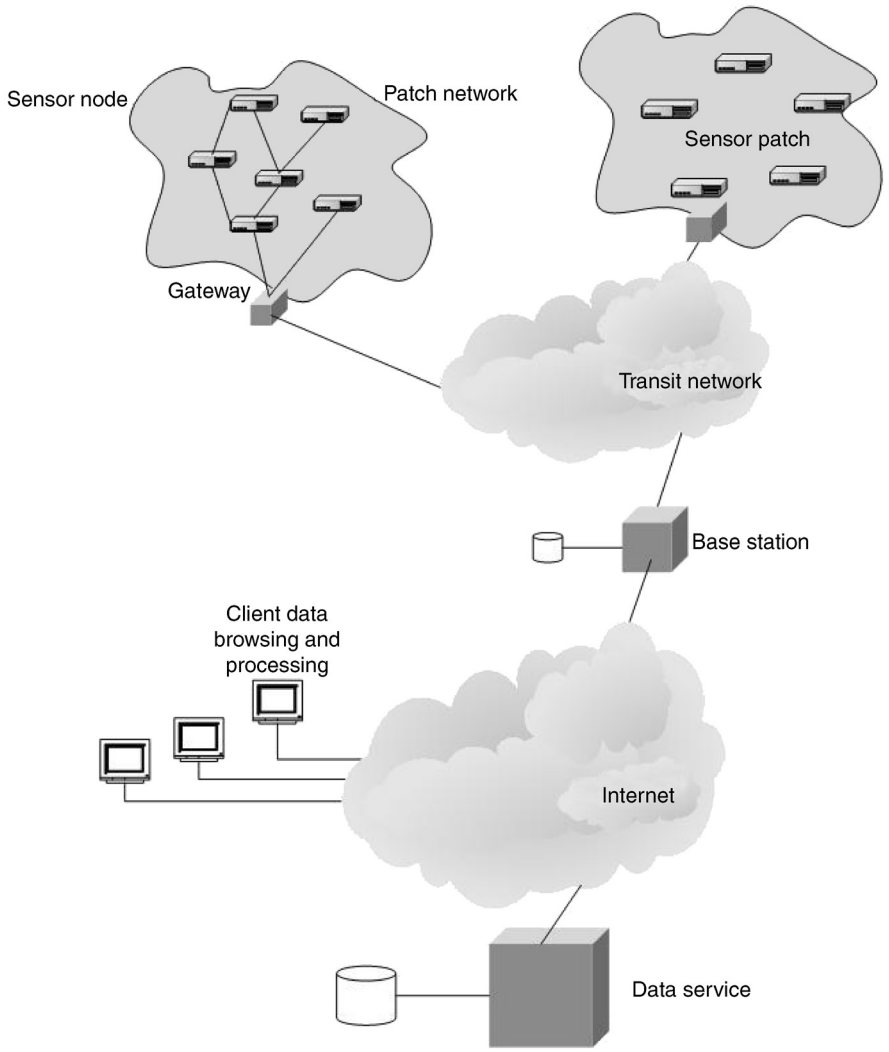

FIGURE 96.4 System Architecture of NES for common data acquisition scenarios [7].

© 2005 by CRC Press LLC

population, and other natural elements of the habitats being monitored. This solution to monitoring automates some of menial tasks such as data collection for researchers (Figure 96.4).

Precision agriculture is an important area of research, where NES technology is likely to have a large impact [1, 26, 27]. Precision agriculture envisages sensor deployment to monitor and manage crop productivity, quality, and growth. Besides increasing productivity, better crop quality and crop management are also key aspects of using NES in precision agriculture.

Crop management provides monitoring and adjusting the level of fertilizer, pesticides, water for particular areas, resulting in better yields at less pollution, emissions, and definitely lower costs. The automation of these functions requires an adaptive behavior to the changing surroundings such as water levels if it rains, or pesticides for a particular season when bug problems are more common. This adaptation is an integral aspect of precision agriculture. While there exist models that dictate the necessary amount of fertilizer, water, nutrient combinations, these models are not always accurate for the specific locale. Thus, NES can also perform on-the-side data acquisition functions for purposes of reconstructing appropriate models and recalibrating or reconfiguring the sensor metrics accordingly to better suit the specific climate and locale.

Feedback into such systems is crucial to develop the notion of true automated precision agriculture. Fine-grained tuning to crop management can be done automatically based on these regularly updated models that can also be monitored by researchers. However, manual adjustments of some kind would require appropriate interfaces between the deployed NES and the end-user attempting to make the change. Once again, wireless interfaces can be used for such manual fine-tunes. Configuration and management of the network can be handled remotely via hand-held devices or even desktops. A practical example of such a deployment is shown in [27] and wireless sensor networks for precision agriculture in [26]. A similar two-tiered network that couples wireless and wired networks together has been proposed for structural monitoring of civil structures that can be affected by natural disasters such as earthquakes [28]. The small size and wireless nature of NES sensor nodes enable field researchers to deploy these sensors in small and sensitive locations.

Defense Applications: Battle-Space Surveillance

NES are projected to become crucial for future defense applications, particularly in battle-space surveillance and condition and location monitoring of vehicles, equipment, and personnel. A military application called CEC, developed by Raytheon Systems [9, 29], acts as a force multiplier for naval air and missile defense systems by distributing sensor and weapons data to multiple CEC ships and airborne units. Data from each unit are distributed to other CEC units, after which the data are filtered and combined via an identical algorithm in each unit to construct a common radar-like aerial picture for missile engagements.

DARPA has funded research in several areas of defense systems under the aegis of their future combat systems program [30]. Manipulating battle environments and critical threat-identification are projected uses of NES in such systems. Manipulating battle environments refers to controlling opposition by detecting their presence and either altering their route or constraining their advance. Threat-identification involves identifying a threat early for force protection. A force-protection scenario involves deployment of sensors around a perimeter that requires protection so that forced entry can be identified and automated responses such as alarms can be triggered based on a certain event.

System deployment used to be of concern in the past because sensors were bulky and large in size and required manual deployment. However, with the advances in technology, entire sensor networks can now be deployed by airdrop, personnel, or even via artillery. The small sizes have enabled NES to be deployed for monitoring vehicles in a manner similar to the automobile example we discussed earlier.

A relatively new technology called *e-textiles* has emerged whereby sensors or other computation devices are integrated into wearable material [11]. Nakad et al. [11] are investigating the communication requirements between sensing nodes of e-textile and the computing elements embedded with them. One key and obvious application of e-textiles is for data acquisition for human monitoring where sensor nodes can be used to track the location and vital statistics of military personnel.

© 2005 by CRC Press LLC

Biomedical Applications

A "civilian" application for e-textiles is for monitoring the health of people — particularly, old people. A sensor node embedded in an e-textile worn by patients with heart problems can automatically alert doctors or emergency services when the patient suffers from heart failure. We have already seen the value of heart pacemakers for helping millions of people around the world maintain a regular heart beat.

Work is in progress to make sensors small enough and body-friendly enough that they can either be surgically inserted or swallowed for temporary monitoring. These devices can be used to monitor, diagnose, and even correct anomalies in the health of a patient. Of course, surgical insertion or ingestion of microelectronic devices raises several concerns about safety, and the ability of the body to adapt to the foreign bodies. These are active areas of research.

Disaster Management

Scenarios that involve disaster management can be seen as data acquisition applications where certain information is gathered, based on which a response is computed and performed. A good example of an implemented scenario is provided in [31], where remote villages are monitored by four sensors measuring the seismic activity and water levels for earthquakes and floods, respectively. Through wireless media, these sensors are connected to the nearest emergency rescue stations signaling emergency events when the thresholds for maximum water levels and seismic activity are crossed. As mentioned earlier, Kottapalli et al. [28] propose a sensor network for structural monitoring of civil structures in case of natural disasters such as earthquakes. Other applications of disaster management systems include severe cold (or heat) monitoring, fire monitoring (smoke detectors, heat sensors), volcano monitoring, etc.

96.4 Design Considerations for NES

The examples presented in the last section given an idea of the breadth of the application domains in which NES can be deployed. By studying these examples, we understand the various requirements, constraints, issues, and concerns involved in developing these kind of systems. Furthermore, as NES proliferate, the true potential of these systems will be realized when they are deployed at a massive scale, in the order of thousands or more components. Such a large-scale deployment, however, raises some problems [17, 13, 15, 16]:

Deployment: Deployment refers to the physical distribution of the nodes in the NES. The first concerns for deployment are safety, durability, and sturdiness; if devices are dropped from the air, they should not do damage to other objects (people, animals, plants, or material) while landing, and should not be damaged themselves either. This is clearly important for defense applications where surveillance sensors may be airdropped in the battle-space.

Several deployment strategies are available that can be classified into either random or strategic deployment. As the name suggests, *random deployment* refers to deploying NES nodes in an arbitrary manner in the field. Random deployment is useful when the region being monitored is not accessible for precise placement of sensors [32]. The problem then becomes of determining region coverage and also the possible redeployment or movement of nodes to improve coverage. *Strategic deployment* refers to placing NES nodes at well-planned points so that the coverage is maximized or to place nodes strategically in a small field of concentration such that these motes are not easily subjected to natural damages (e.g., for habitat monitoring).

The number of NES nodes deployed must be considered in the cost and performance/quality of monitoring tradeoff because some nodes are generally bound to be destroyed by some means so that there should be sufficient reserves or fault tolerance in the network to continue the monitoring.

Environment-interaction: NES components often need to interact with the environment without human interaction. Thus, a requirement of NES is an ability to work on their own and perhaps also have a feedback loop so that nodes can adapt to changes (failure of nodes, movement of objects) in the environment and continue functioning correctly. Systems such as those used in precision agriculture, chemical and hazardous

© 2005 by CRC Press LLC

gas monitoring, and so on are designed to interact and react to changes in the system. For example, in agriculture, the release of water can be tied to the moisture content in the air.

Life-expectancy of nodes: As discussed earlier, an essential requirement for nodes in an NES is a long life expectancy. This is because once deployed, it is very difficult to access and refurbish the batteries in the nodes. Also, these nodes must sustain environmental challenges such as inclement weather and unexpected loss of nodes to animal interaction or due to component failure. Thus, a whole body of work has gone into identifying node failure and subsequent reconfiguration of the network to have some amount of fault tolerance [33].

Communication protocol between devices: A combination of wired and wireless links can be used to establish a NES. Furthermore, the nodes in the network may be stationary or mobile. Mobile nodes bring in a whole range of issues related to dynamic route and neighbor discovery, dynamic routing, etc. The NES should also be able to reconfigure and adjust to tolerate loss of nodes from a communication point of view. That is, if a node that is a relay point fails or dies, then the network should be able to use other nodes for relaying instead.

Reconfigurability: In many scenarios, it is not possible to physically reach nodes. However, NES frequently require nodes to reconfigured after deployment. This may be to add, remove, or change functionality or to adjust parameters of the functionality. For example, hand-held devices or even desktops may be used to reconfigure nodes to fine tune certain aspects of the system. For example, the water level can be increased in precision agriculture when the weather report suggests a sudden heat wave for the following few days [26, 27].

Security: NES — particularly those that use wireless communication — are prone to malicious attack [34]. This is most evident in military equipment where communication has to be secure from enemy eavesdropping. Security in hand-held devices is becoming an increasing concern with their widespread use in office environments for everything from checking email to exchanging sensitive documents and data. Running security protocols is computationally expensive and hence, power hungry, and several researchers are proposing ways to reduce these power requirements for sensor networks and hand-held devices [35–37].

Energy-constrained: The small form factor, low weight, and the deployment of NES nodes in inaccessible and remote regions imply that these nodes have access to a limited nonrenewable energy source. Thus, one major focus of the research community is to develop networking protocols, applications, operating systems, etc (besides devices), that are energy efficient and utilize robust, high throughput but low-power communication schemes [17, 13].

Operating System: There is a need for special or optimized operating systems due to the stringent hardware constraints (small form factor, limited energy source, limited memory space) and strict application requirements (real-time constraints, adaptability). Several real-time operating systems have been proposed for embedded devices such as eCos [38], LynxOS from LynuxWorks [39], QNX RTOS [40], etc.

Adequate design methodologies: Standard design methodologies and design flows have to be modified or new ones have to be created to address the special needs of NES. For example, there is a need for design methodologies for low-power system-on-a-chip implementations to enable integration of the large number of diverse components that form an NES device [41].

96.5 System Engineering and Engineering Tradeoffs in NES

The design considerations presented in the previous section raise opportunities for interesting tradeoffs between the hardware and software components in NES. Whereas area, power, and weight constraints limit the amount of hardware that can be put in an NES node, integration, debugging, and complexity issues are hindering, increased dependence on software.

Hardware

Rapid advances in silicon technology are ushering in an era where we will see the widespread use of smart dust or very small sensor nodes with reasonably complex computational and communication abilities

© 2005 by CRC Press LLC

[20–22]. Besides a small size, these nodes have low power and have a variety of actuators and sensors, along with radio/wireless communication devices, and processors for computation. This enables these nodes to move from beyond being just data acquisition sensors that send their data to a central server. They can now also act as computation points that first collate and process the data before sending it to a server or even coordinate computation among themselves independent of a central server.

The power and area constraints on NES nodes mean that general-purpose microprocessors cannot be used in them. However, low-power application-specific instruction processors (ASIPs) augmented with application-specific integrated circuits (ASICs) will provide the necessary computational ability at a relatively low power. Whereas the ASIPs are easily programmable, the ASICs can be used for executing computationally expensive and/or time-sensitive portions of applications. For example, target identification in defense systems or airbag release mechanisms in cars require ASICs to meet their timing and computational needs.

In fact, Henkel and Li [42] and Brodersen et al. [1] have shown that less power is consumed by custom-made processors than by general-purpose processors. The reason for this is that with custom chips, parallelism can be effectively exploited to gain better power consumption. Also, hardwiring the execution of each function eliminates the need for instruction storage and decoding, thus reducing power as well.

On the other hand, applications such as habitat monitoring and precision agriculture do not have high timing or computational requirements; hence, generic microprocessors or ASIPs can be used. The compromise is speed and computational ability versus programmability. ASICs have a high design and manufacturing cost and are inflexible when compared to programmable processors. A change in applications or protocols leads to a large redesign effort. Programmable processors, on the other hand, can be reused for several generations of an application (provided computational requirements do not increase).

Reconfigurable hardware such as field programmable gate arrays (FPGA) provides a middle path between programmable processors and hardwired ASICs. As the name suggests, FPGAs can be reprogrammed after being deployed in the field and hence provide the flexibility of microprocessors while providing the hardwired speed of ASICs. In fact, FPGAs can be configured at runtime as suggested by Nitsch and Kebschull [43]. They propose storing the functional behavior and structure of applications in an XML format. When a client wishes to execute an application, the XML is analyzed and the appropriate mapping is done to the FPGA. The drawbacks of FPGAs are that they require large chip area and have a low clock frequency.

Software

Small memory storage devices and low computational processors limit the size and complexity of the software that can run on NES nodes. Porting commonly used operating systems and applications to NES is difficult because of the limitations posed by the hardware. Hence, software development for NES nodes is another challenge that embedded systems designers have to overcome.

The Tiny microthreading operating system (TinyOS) [44] has been proposed to address the unique characteristics of NES nodes. TinyOS is a component-based, highly configurable embedded operating system with a small footprint. TinyOS has a highly efficient multithreading engine and maintains a two-level FIFO scheduler. TinyOS consists of a set of interconnected modular components. Each component has tasks, events, and command handlers associated with it. Tasks are the processing units of components. Components can signal event, issue commands, and execute other tasks. They are allocated a static area of memory to hold the state information of the thread associated with the component. TinyOS does not provide the functionality of dynamic memory allocation due to the restrictions imposed by the hardware. The component-based structure allows TinyOS to be a highly application-specific operating system that can be configured by altering configuration files (.comp and .desc files) (Figure 96.5).

Volgyesi and Ledeczi [2] provide a model-based approach to the development of applications based on TinyOS. They presented a graphical environment, called *GRATIS*, through which the application and operating system components are automatically glued together to produce an application. GRATIS provides automatic code generation capability and a graphical user interface to construct the .comp and .desc

© 2005 by CRC Press LLC

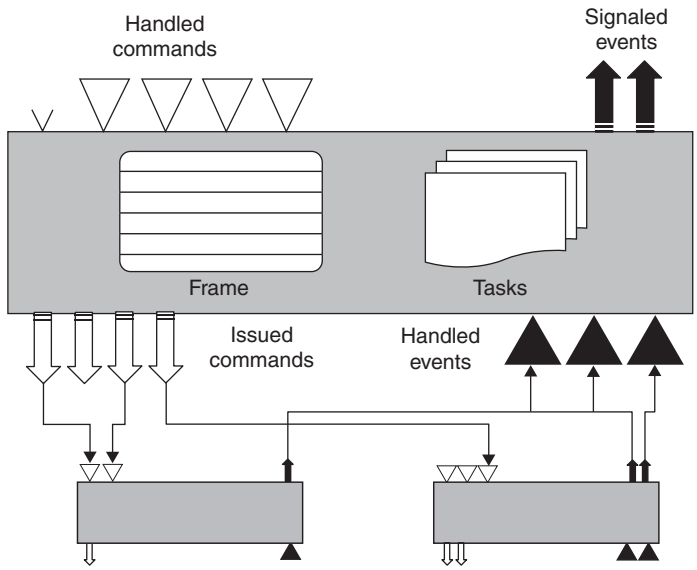

FIGURE 96.5 Events and commands in TinyOS.

files automatically, thus simplifying the task of component description and wiring for building TinyOS-based applications [2]. This increases design productivity and reconfigurability.

Another design effort to provide functionality to program operating system in sensor nodes is the development of a programming language framework called *nesC* [41]. nesC provides a programming paradigm based on an event-driven execution, flexible concurrency, and component-based design. TinyOS is an example where this language has been used to develop a commonly used Linux-based operating system for sensor networks. This programming language manages to successfully integrate concurrency, reactivity to the environment, and communication.

The distributed nature of NES means that these systems are inherently concurrent. For example, data processing and event arrival are two processes that need to be concurrently executed on the NES node. Concurrency management then has to ensure that race conditions do not occur. For example, in the emergency airbag release system, the sensor needs to be able to sense the impact as well as react to it based on processing the collected data. These type of real-time demands along with the small size and low cost of NES nodes make concurrency management a challenging task.

nesC addresses these issues by drawing upon several existing language concepts. Three of the main contributions that nesC provides are: definition of a component model, expressive concurrency model, and program analysis to improve the reliability and reduce code volume. The component model supports sensor node-like event-targeted systems with bidirectional channel interfaces to ease event communication. It also provides flexible hardware and software boundaries and avoids dynamic component instantiation and the use of virtual functions. Expressive concurrency model is tied in with compile time analysis yielding data race detection at compile time to allow for comprehensive concurrent behaviors in NES nodes. Reduction of code size and improvement of reliability are natural goals for any programming language.

TinyOS influenced the design of nesC due to the specific features of the operating system. Firstly, TinyOS provides a collection of reusable system components best suited for component-based architectures. The channel interface connecting components is called the wiring specification, which is independent of the specific implementation of the component. Tasks and events are inherent in TinyOS where tasks are regarded as nonpreemptive computation mechanisms and events are similar to tasks except that they can preempt another task or event. The event-task-based concurrency scheme in TinyOS makes event-driven and expressive concurrency closely related to the implementation of nesC.

© 2005 by CRC Press LLC

Components in nesC are of either modules or configuration types, where the former consists of application code and the latter provides interfaces for communicating between components. Modules are written in C-style code and a top-level configuration is used to wire components together. This resembles the VHDL-like component-architecture scheme where components are defined and the architecture is the top-level model that connects signals between components. The component-based architecture brings flexibility to application implementations and allows users to write highly concurrent programs for a very small-scale platform with limited physical resources. Fortunately, with the aid of nesC and graphics, configuration tools such as GRATIS construction of dedicated operating systems based on TinyOS is gradually becoming easier [2]. These tools allow a designer to build their own operating system with relative ease, but application-specific functionality still requires implementation at a programming level.

Another area of software for NES nodes that has received considerable attention is network protocols [14, 17]. Power and energy constraints in NES nodes necessitate efficient network protocols for transmission of sensed data and intermediary communication. Two broad classifications of sensor networks are proactive and reactive. *Proactive*, as the word suggests, periodically sends the sensed attribute to the data collection location or base station. The period is known a priori, allowing the sensors to migrate to their idle, sleep, or off modes to conserve energy. Applications that require periodic monitoring are best suited for this type of sensor network. A protocol called low-energy adaptive clustering hierarchy (LEACH) [45] is one of the many proposed proactive protocols.

Reactive networks, on the other hand, continuously sense the environment and transmit their data to the base station only upon sensing that the attribute has exceeded a specified threshold. This type of network is useful for time-critical data so that the user or base station receives the sensitive information immediately. One such time-sensitive protocol for reactive systems that has been proposed recently is the threshold-sensitive energy-efficient-sensor network (TEEN) protocol [46].

Hybrid networks constitute a third type of sensor networks that are a combination of proactive and reactive networks and are an attempt to overcome the drawbacks experienced by the other two network systems [47]. In hybrid networks, sensor nodes send sensed data at periodic intervals and also when sensed data exceed the set threshold. The periodic interval is generally longer than the ones found in proactive networks such that the functionality of the two network types can be incorporated within one. Furthermore, hybrid systems can be made to work in only proactive or only reactive modes as well.

96.6 Design Methodologies and Tools

Deploying large-scale distributed networked embedded systems is inherently a complex and error-prone task. Designers of such systems rely on system-level modeling and simulation tools during the initial architectural definition phase for design space exploration, to come up with possible architectures that will satisfy the constraints and requirements and then to verify the functionality of the system.

Design verification at the highest levels of abstraction down to final implementation is an important concern with any complex system. With distributed systems, this need becomes even more acute due to the inability of a system designer to foresee all possible events and sequences of events that may occur.

Several tools have been developed for simulating NES at the highest level of abstraction as communicating network models composed of basic network models. Network Simulator 2 (NS-2), OPNET, SensorSim, and NESLsim are popular network simulation tools widely used in the community [48–51]. SensorSim and NESLsim are simulation frameworks specifically designed for sensor networks.

SensorSim closely ties in sensor networks with their power considerations by constructing a two-pronged approach to creating the models. The first prong involves creating a sensor functional model that represents the software functions of the sensor consisting of the network protocol stack, middleware, user applications, and the sensor protocol stack. The second prong is the power model that simulates the hardware abstracts such as CPU, and radio module to provide the sensor functional model to execute. The architecture of the SensorSim simulator is shown in Figure 96.6.

This two-pronged model implies that the sensor functional model dictates the execution of the tasks to the power model and these two models work in parallel with each other. An added feature is the sensor

© 2005 by CRC Press LLC

channel that allows sensing devices to detect events. In this way, the sensor channel exposes external signals to the sensor modules such as microphones, infra-red detectors, etc. The signals that are transmitted through this channel can be of any available form such as infra-red light and sound waves for microphones. Every type of signal has different characteristics based on the medium through which they travel and this is the primary goal of the sensor channel — to simulate these characteristics accurately and to detect and monitor the events in a sensor network.

The use of a power model in SensorSim follows from the importance placed in designing low-power NES devices [52]. Efficient power control is a basic requirement for the longevity of these devices. The basis behind the power model is that there is a single power supplier, the battery, and all other components or models are energy consumers (as shown in Figure 96.6). The consumers such as the CPU model and radio model drain energy from the battery through events.

An attractive feature of SensorSim is its capability to perform hybrid simulations. This refers to the ability of SensorSim to behave as a network emulator and interact with real external components such as network nodes and user applications. However, network emulation for sensor networks differs from traditional network emulation. The large number and speed of input/output events in sensor networks mandate readjusting the real-time delays for the events and reordering the events, making the implementation of an emulator for such networks a much more difficult task.

SensorSim enables reprogramming the sensor channel to monitor external inputs, thus using real inputs instead of models for these channels. For example, instead of modeling waves traveling through a wired (e.g., coaxial) cable, a microphone can be connected using a sensor channel to send waveforms through a wired link to the simulator.

NESLsim is another modeling framework for sensor networks. It is based on the Parallel Simulation Environment for Complex Systems (PARSEC) simulator [51]. NESLsim abstracts a sensor node into two entities: the *node entity* and the *radio entity*. The node entity is responsible for computation tasks such as scheduling, traffic monitoring, and congestion control, whereas the radio entity undertakes the responsibility to maintain the communication between the sensor nodes in the NES. A third entity that is not part of the sensor node is the *channel entity*. This models the wireless medium through which communication is performed.

NS-2 is a discrete event simulator based on an open-source C++ framework that implements a discrete event simulator developed by Virtual Inter Network Test bed (VINT) collaborative research project at University of Southern California and the University of California, Berkeley. They provide substantial support for simulation of the routing and multicast protocols in the TCP/IP networking stack (IP, TCP, UDP, etc) over both wired and wireless channels. *OPNET* also performs similar tasks but is a proprietary software developed by Opnet Technologies.

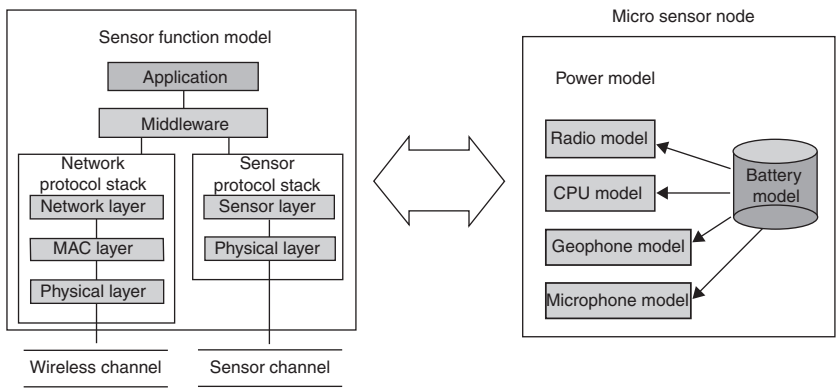

FIGURE 96.6 SensorSim architecture [52].

© 2005 by CRC Press LLC

SystemC [53, 54] is a system-level description language developed to model both the hardware and software of a behavioral specification. Drago et al. [55] developed a methodology to combine the simulation environments of NS-2 and SystemC to simulate and test the functionality of NES. They promote the use of NS-2 for modeling the network topology and communication infrastructure and SystemC for representing and simulating the hardware/software components of the embedded system. Using NS-2 relieves the designer of writing detailed high-level network protocols that already exist and are available for simulation in NS, whereas SystemC allows modeling and simulation of implementations of embedded systems. Together, these simulation frameworks preserve simulation integrity and reduce the modeling effort with an admissible degradation in simulation performance.

Integration of simulators is regarded as a valuable resource for systems designers. However, to be able to perform such a link between simulators, the underlying development platform must be similar. For example, NS-2 and SystemC both have a C++ underlying framework on which these simulators were built. Also, the basic simulation paradigm in NS-2 and SystemC is similar. NS-2 is a discrete event-driven simulator where the scheduler runs by selecting the next event, executing it to completion, and looping back to execute the next event. Similarly, the SystemC simulator also has a discrete-event-based kernel where processes are executed and signals are updated at clocked transitions, working on the evaluate–update paradigm. Drago et al. [55] use a shared memory queue to pass tokens and packets for communication between the NS-2 kernel and SystemC kernel.

System-level design methodologies for embedded systems are based on a hardware–software codesign approach [56–59]. Hardware–software codesign is a methodology where the hardware and software are designed and developed concurrently and in collaboration. This leads to a more efficient and optimized implementation of applications.

Ramanathan et al. [3,60] present a timing-driven design methodology for NES and explore the need for temporal correctness while designing these systems. Determining temporal correctness of system models is difficult because these models are not cycle accurate and usually have no notion of hardware and/or software implementation. Determining the correctness of timing constraints after the hardware has been manufactured naturally leads to costly redesign iterations for both the hardware and software subsystems. Instead, the authors propose a solution whereby they specify, explore, and exploit temporal information in high-level network models and bridge the gap between requirement analysis and system design. At each stage of the design refinement, timing information modeled at the higher-level network models is trickled down to finer and lower level models. The authors used NS-2 as their modeling framework.

This timing-driven design methodology uses high-level network models generated using a rate derivation technique called *RADHA-RATAN* [60, 61]. RADHA-RATAN works on generalized task graphs that have nodes that represent functionality or tasks and edges that are asynchronous, unidirectional communication channels between producers and consumers. RADHA-RATAN is a collation of algorithms that generate timing budgets for the task graph nodes based on their preset execution (firing) and data production and consumption rates.

Along with RADHA-RATAN, network-level models at the highest level are used to represent functionalities such as routing, congestion, and quality of service. The designer can specify distributions, protocols, and such settings to generate the network graph in NS-2. The nodes of the network graph simulate the transfer of packets and tokens among themselves. This enables testing of the functionality of the protocols. However, further refinement by an experienced designer of this high-level network graph results in network subsystems that capture timing requirements. In a process known as *timing-driven task structuring*, the designer can then mutate the task graph until the desired timing behavior is achieved, after which partitioning of hardware and software can be performed. The disconnect between requirement analysis and system design is circumvented by this mutation, allowing the mix of the NS-2 modeling paradigm and formal timing analysis techniques to provide a methodology whereby timing requirements seep from high-level network models to low-level synthesis models.

Simulation and timing analysis is one part of the puzzle in hardware–software codesign. Automated hardware synthesis and software synthesis and compilation techniques are the next step in generating implementations from the system-level models. To this end, Gupta et al. [62] have proposed the *SPARK*

© 2005 by CRC Press LLC

parallelizing high-level synthesis framework that performs automated synthesis of behavioral descriptions specified in C to synthesizable register-transfer level VHDL. This framework can then be used in a system level codesign methodology to implement an application on a core-based platform target [63].

Such hardware–software codesign methodologies are crucial for the design and development of networked embedded systems. Automated or semiautomated methodologies are less error-prone, lead to faster times-to-market, and can help realize hardware–software tradeoffs and design exploration that may not be obvious in large systems.

96.7 Conclusions

The increasing interest in networked embedded systems is quite timely as evident from the several important application areas where such systems can be used. The development process for these applications and systems remains an *ad hoc* process. We need methodologies and tools to provide system designers with the flexibility and capability to quickly construct efficient and optimized system designs. In this paper, we have examined the range of design and verification challenges faced by the NES designers. Among existing solutions, we have presented techniques that promise to increase the efficiency of the design process by raising the level of design abstraction and by enhancing the scope of system models. These include design tools such as GRATIS and nesC for operating system configuration and NS-2, SystemC, NESLsim, and SensorSim for simulation and codesign of embedded systems. There are several open research problems. Reducing device size and power and increasing device speed further remain important objectives. There is a need for distributed applications, along with middleware and operating system support and support for network protocols for distributed coordinated collaboration. Continued progress in these technologies will fulfill the promise of networked embedded systems as ubiquitous computing systems.

97.5 Conclusions and Future Work

97.1 Introduction

For the past decade, the impact of web-based technologies has added "*velocity*" to the design, manufacturing, and aftermarket service of a product. Today's competition in manufacturing industry depends not just on lean manufacturing but also on the ability to provide customers with total solutions and life-cycle costs for sustainable value. Manufacturers are now under tremendous pressure to improve their responsiveness and efficiency in terms of product development, operations, and resource utilization with a transparent visibility of production and quality control. Lead times must be cut short to their extreme extent to meet the changing demands of customers in different regions of the world. Products are required to be made-to-order with no or minimum inventory, requiring (a) an efficient information flow between customers, manufacturing, and product development (i.e., plant floor, suppliers, and designers), (b) a tight control between customers and manufacturing, and (c) near-zero downtime of the plant floor assets. Figure 97.1 summarizes the trends in manufacturing and function of predictive intelligence as an enabling tool to meet the needs [1–4].

With emerging applications of Internet and tether-free communication technologies, the impact of e-intelligence is forcing companies to shift their manufacturing operations from the traditional factory integration philosophy to an e-factory and e-supply chain philosophy. It transforms companies from a local factory automation to a global enterprise and business automation. The technological advances for achieving this highly collaborative design and manufacturing environment are based on multimedia-type information-based engineering tools and a highly reliable communication system for enabling distributed procedures in concurrent engineering design, remote operation of manufacturing processes, and operation of distributed production systems. As shown in Figure 97.2, e-manufacturing fills the gaps existing in the traditional manufacturing systems. The gaps between product development and supply chain consist of lack of life-cycle information and lack of information about supplier capabilities. Hence, designers, unless with years of experience, work in a vacuum, design the product according to the specification given, and wait for the next step. Most of the time, the design made according to specifications is realized to be infeasible for manufacturing with suppliers' machinery. As a result, lead times become longer. Similarly, for instance, because of the lack of information and synchronization between suppliers

© 2005 by CRC Press LLC

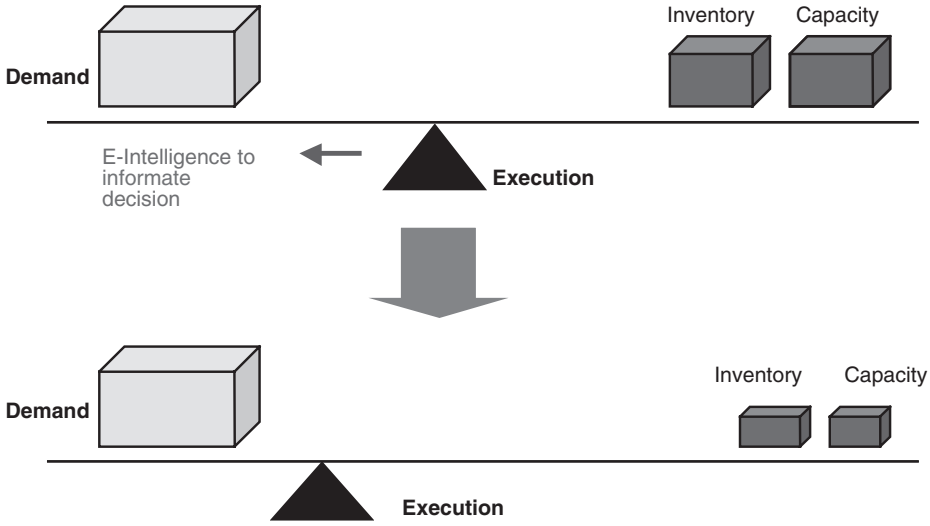

FIGURE 97.1 The transformation of e-Manufacturing for unmet needs.

and assembly plants, just-in-time manufacturing and on-time shipment become possible only with a substantial amount of inventory whereas with e-manufacturing, real-time information regarding reliability and status of supplier's equipment will also be available as a part of the product quality information. With these information and synchronization capabilities, less and less inventory will be necessary contributing to the profitability of the enterprise.

97.2 e-Manufacturing: Rationale and Definitions

e-Manufacturing is a transformation system that enables the manufacturing operations to achieve predictive near-zero-downtime performance as well as to synchronize with the business systems through the use of web-enabled and tether-free (i.e., wireless, web, etc.) infotronics technologies. It integrated information and decision-making among data flow (of machine/process level), information flow (of factory and supply system level), and cash flow (of business system level) [5–7]. e-Manufacturing is a business strategy as well as a core competency for companies to compete in today's e-business environment. It is aimed to complete integration of all the elements of a business *including suppliers, customer service network, manufacturing enterprise, and plant floor assets* with connectivity and intelligence brought by the web-enabled and tether-free technologies and intelligent computing to meet the demands of e-business/e-commerce practices that gained great acceptance and momentum over the last decade. e-Manufacturing is a transformation system that enables e-Business systems to meet the increasing demands through tightly coupled supply chain management (SCM), enterprise resource planning (ERP), and customer relation management (CRM) systems as well as environmental and labor regulations and awareness, (Figure 97.3) [4–7].

e-Manufacturing includes the ability to monitor the plant floor assets, predict the variation of product quality and performance loss of any equipment for dynamic rescheduling of production and maintenance operations, and synchronize with related business services to achieve a seamless integration between manufacturing and higher level enterprise systems. Dynamically updated information and knowledge about the capabilities, limits, and variation of manufacturing assets for various suppliers guarantee the best decisions for outsourcing at the early stages of design. In addition, it enables customer orders autonomously across the supply chain, bringing unprecedented levels of speed, flexibility, and visibility to the production process reducing inventory, excess capacity, and uncertainties.

The intrinsic value of an e-Manufacturing system is to enable real-time decision making among product designers, process capabilities, and suppliers as illustrated in Figure 97.4. It provides tools to access

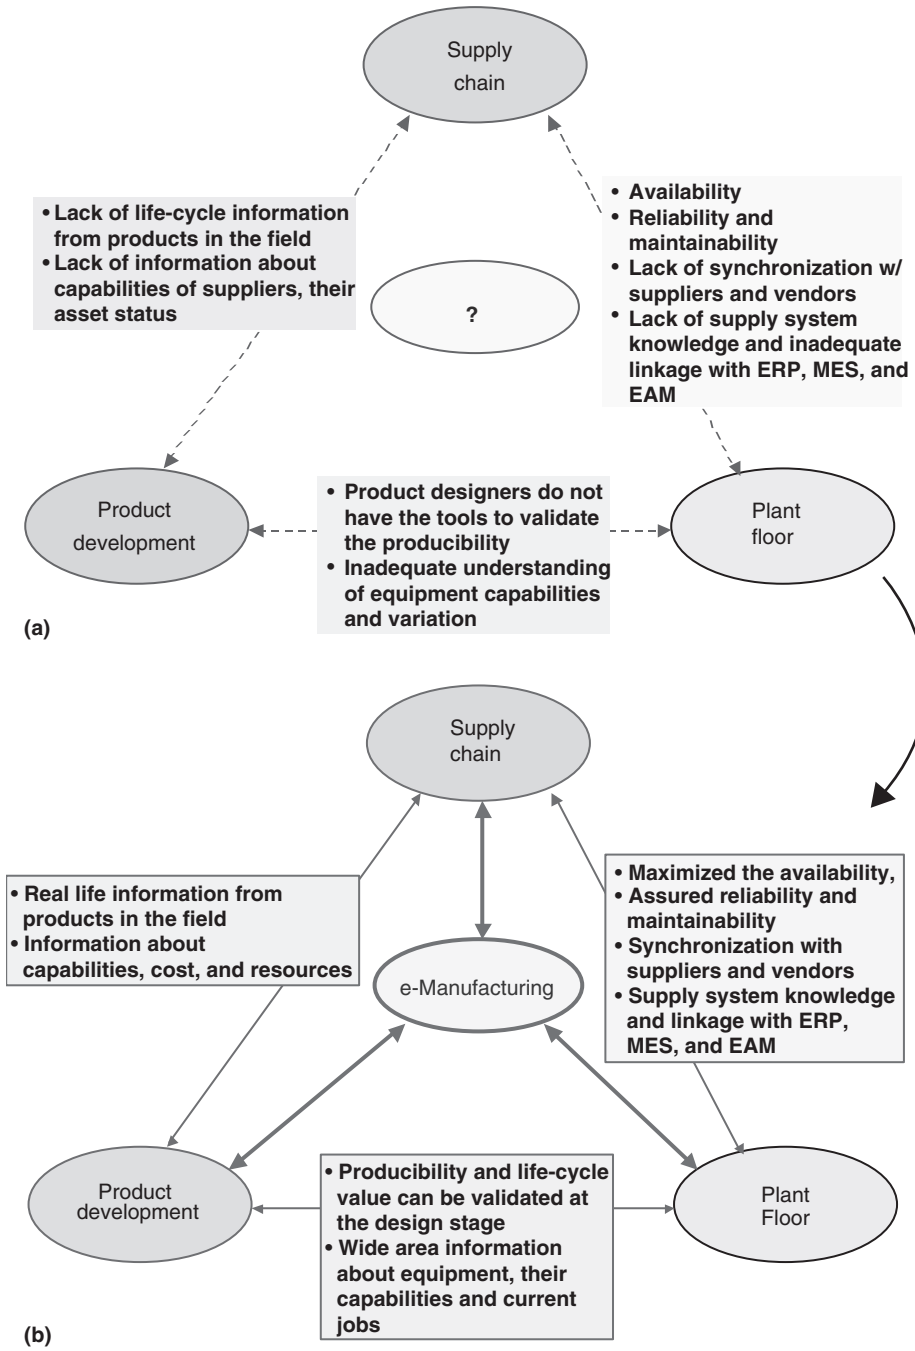

FIGURE 97.2 The transformation of e-Manufacturing for unmet needs.

life-cycle information of a product or equipment for continuous design improvement. Traditionally, product design or changes take weeks or months to be validated with suppliers. With the e-Manufacturing system platform, designers can validate product attributes within hours using the actual process characteristics and machine capabilities. It also provides efficient configurable information exchanges and synchronization with various e-business systems.

97.3 e-Manufacturing: Architecture

Currently, Manufacturing Execution Systems (MES) enable the data flow among design, process, and manufacturing systems. The ERP systems serve as an engine for driving the operations and the supply chain systems. However, the existing structure of the ERP and MES cannot *informate* (i.e., communicate the information in real-time) the decision across the supply chain systems. The major functions and objectives of e-Manufacturing are: (1) enable an only handle information once (OHIO) environment; (2) predict and optimize total asset utilization in the plant floor; (3) synchronize asset information with supply chain network; and (4) automate business and customer service processes. The proposed e-manufacturing architecture in this position paper addresses the above needs.

To address these needs, an e-Manufacturing system should offer comprehensive solutions by addressing the following requirements: (1) development of intelligent agents for continuous, real time, remote, and distributed monitoring of devices, machinery, and systems to predict machine's performance status (health condition) and to enable capabilities of producing quality parts; (2) development of infotronics platform that is scalable and reconfigurable for data transformation, prognostics, performance optimization, and synchronization; and (3) development of virtual design platform for collaborative design and manufacturing among suppliers, design, and process engineers as well as customers for fast validation and decision making. Figure 97.5 illustrates the proposed e-Manufacturing architecture and its elements [5–7].

Data gathering and transformation: This has already been done at various levels. However, massive raw data are not useful unless it is reduced and transformed into useful information format (i.e., XML) for responsive actions. Hence, data reconfiguration and mining tools for data reduction, representation for plant floor data

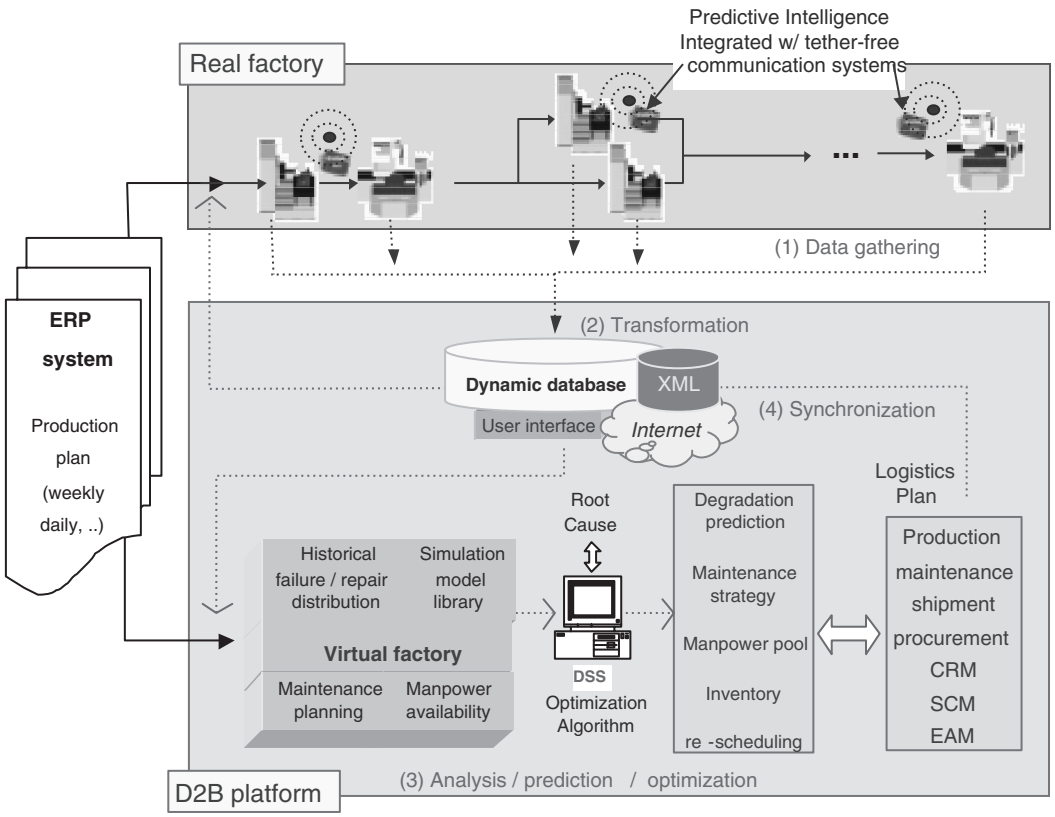

FIGURE 97.5 An e-Manufacturing architecture that comprises (1) and (2) data gathering and transformation, (3) prediction and optimization, and (4) synchronization [5].

© 2005 by CRC Press LLC

need to be developed. An infotronics platform, namely, Device-to-Business (D2B™) has been developed by the Intelligent Maintenance Systems (IMS) Center. To make pervasive impacts to different industrial applications, existing industrial standards should be used (i.e., IEEE 802.xx standard committees, MIMOSA, etc.)

Prediction and optimization: Advanced prediction methods and tools need to be developed in order to measure degradation, performance loss, or implications of failure, etc. For *prediction* of degradation on components/machinery, computational and statistical tools should be developed to measure and predict the degradation using intelligent computational tools.

Synchronization: Tools and agent technologies are needed to enable autonomous business automation among factory floor, suppliers, and business systems. Embedded intelligent machine infotronics agent that links between the devices/machinery and business systems and enables products, machinery, and systems to (1) learn about their status and environment, (2) predict degradation of performance, (3) reconfigure itself to sustain functional performance, and (4) informate business decisions directly from the device itself [1–7].

Under this architecture, many web-enabled applications can be performed. For example, we can perform remote machine calibration and experts from machine tool manufacturers can assist users to analyze machine calibration data and perform prognostics for preventive maintenance. Users from different factories or locations can also share this information through these web tools. This will enable users to exchange high-quality communications since they are all sharing the same set of data formats without any language barriers.

Moreover, by knowing the degradation of machines in the production floor, the operation supervisor can estimate their impacts to the materials flow and volume and synchronize it with the ERP systems. The revised inventory needs and materials delivery can also be synchronized with other business tools such as CRM system. When cutting tools wear out on a machining center, the information can be directly channeled to the tool providers and update the tool needs for tool performance management. In this case, the cutting tool company is no longer selling cutting tools, but instead, selling cutting time. In addition, when the machine degrades, the system can initiate a service call through the service center for prognostics. This will change the practices from MTTR to MTBD (mean time between degradation) [10–13]. Figure 97.6 shows an integrated e-Manufacturing system with its elements.

97.4 Intelligent Maintenance Systems and e-Maintenance Architecture

Predictive maintenance of plant floor assets is a critical component of the e-Manufacturing concept. Predictive maintenance systems, also referred to as e-Maintenance in this document, provides manufacturing, and operating systems with near-zero downtime performance through use and integration of (a) real-time and smart monitoring, (b) performance assessment methods, and (c) tether-free technologies. These systems can compare a product's performance through globally networked monitoring systems to shift to the degradation prediction and prognostics rather than fault detection and diagnostics. To achieve maximum performance from plant floor assets, e-maintenance systems can be used to monitor, analyze, compare, reconfigure, and sustain the system via a web-enabled and infotronics platform. In addition, these intelligent decisions can be harnessed through web-enabled agents and connect them to e-business tools (such as customer relation management systems, ERP systems, and e-commerce systems) to achieve smart and effective service solutions. Remote and real-time assessment of machine's performance requires an integration of many different technologies including sensory devices, reasoning agents, wireless communication, virtual integration, and interface platforms [14–17].

Figure 97.7 shows an intelligent maintenance system with its key elements. The core-enabling element of an intelligent maintenance system is the smart computational agent that can predict the degradation or performance loss (Watchdog Agent™), not the traditional diagnostics of failure or faults. A complete understanding and interpretation of states of degradation is necessary to accurately predict and prevent failure of a component or a machine once it has been identified as a critical element to the overall production system. The degradation is assessed through the performance assessment methods explained in the previous sections.

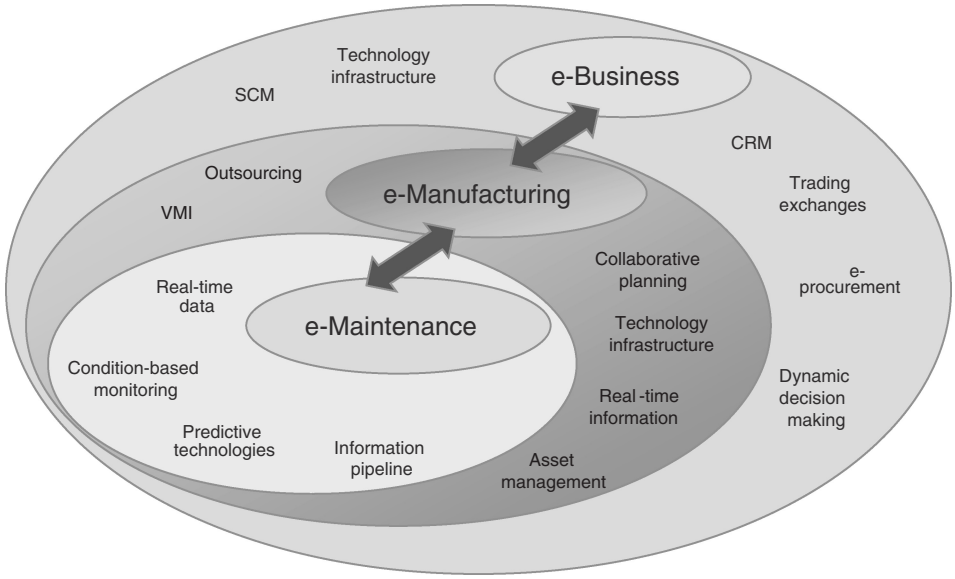

FIGURE 97.8 e-Manufacturing and Its Integrations with e-Maintenance and e-Business.

A product's performance degradation behavior is often associated with multi-symptom-domain information cluster, which consists of degradation behavior of functional components in a chain of actions. The acquisition of specific sensory information may contain multiple behavior information such as nonlinear vibration, thermal or materials surface degradation, and misalignment. All of the information should be correlated for product behavior assessment and prognostics.

97.5 Conclusions and Future Work

This position paper introduced an e-Manufacturing architecture, and outlined its fundamental requirements and elements as well as expected impact to achieve high-velocity and high-impact manufacturing performance. Web-enabled and infotronics technologies play indispensable roles in supporting and enabling the complex practices of design and manufacturing by providing the mechanisms to facilitate and manage the integrated system discipline with the higher system levels such as SCM and ERP. E-Maintenance is a major pillar that supports the success of the integration of e-Manufacturing and e-business. Figure 97.8 shows the integration among e-Maintenance, e-Manufacturing, and e-Business systems. If implemented properly, manufacturers and users will benefit from the increased equipment and process reliability with optimal asset performance and seamless integration with suppliers and customers.

In order to further advance the development and deployment of the e-Manufacturing system, research needs can be summarized as follows:

1. Predictive intelligence (algorithms, software, and agents) with a focus on degradation detection on various machinery and products.
2. Mapping of relationship between product quality variation and machine and process degradation.
3. Data mining, reduction, and data-to-information-to-knowledge conversion tools.
4. Reliable, scalable, and common informatics platform between devices and business, including implementation of wireless, Internet, and Ethernet networks in the manufacturing environment to achieve flexible and low-cost installations and commissioning.
5. Data/information security and vulnerability issues at the machine/product level.
6. Distributed and web-based computing and optimization and synchronization systems for dynamic decision making.

© 2005 by CRC Press LLC

7. Education and training of technicians, engineers, and leaders to make them capable of pacing with the speed of information flow and understanding the overall structure.
8. Develop a new enterprise culture that resonates the spirit of e-manufacturing.

98.2 XML for the Description of Control System Hardware Components
98.3 XML for the Description of Control Programs According to IEC 61131-3
98.4 XML for the Exchange of Plant Engineering Information
98.5 Conclusion

Alexander Fay
ABB Corporate Research Center

98.1 Introduction: The Need for Information Exchange in the Engineering of Automation Systems

The engineering of industrial automation systems, that is, the design and implementation of manufacturing and production plants and the related control and automation systems, comprises a huge number of tasks: in the manufacturing industry, these are mainly the mechanical engineering, electrical engineering, and control engineering, and in the production industry, these are process engineering, plant engineering (including construction), and process automation engineering. Furthermore, usually a variety of companies are involved, which partner in different ways to provide a running plant. For each of these tasks, specialized software tools, for example, CAD and CAE tools, have been designed and implemented and used already for many years. However, the information exchange between the different involved parties has mostly been based on paper, firstly to fulfill the legal documentation requirements, secondly because the software tools have been designed individually and independently and specially for different tasks, without spending much attention to the need for electronic information exchange with tools from different vendors, built for different purposes. With the rising need for electronic information exchange, export and import interfaces have been built to support a variety of data formats, most of them proprietary and tool vendor-specific. This has led to a huge number of data formats and interfaces that have to be maintained and supported, and still considerable information has to be reentered manually, which is tedious and error-prone.

Today, with the need for quick and seamless information exchange to shorten the engineering time, the lacks regarding electronic information exchange become obvious, and urgent activities are needed to overcome today's deficiencies.

© 2005 by CRC Press LLC

The most straightforward solution is to agree among all involved companies in a project on one common project database and related tool suite. However, this approach usually fails for several reasons:

- very few tool suites exist that cover all phases of the engineering life cycle, from process design to commissioning & test and beyond,
- not all the tools in these tool suites are regarded optimal for the individual tasks by all the respective companies involved (which are each responsible for their task and their results),
- instead, each company has a preferred tool that they are familiar with and, for which they have solution libraries, and using a different tool would increase training and engineering effort for them,
- at the beginning of an automation project, not all companies are known which will become partners in the project (e.g., the providers of electrical and control system equipment will be chosen later in the project based on requirements and tendering).

Therefore, the approach must be to exchange information electronically via a commonly accepted data format with commonly agreed syntax and semantics.

Extended markup language (XML) [1] has gained considerable momentum during the last few years as a meta-language for the file-based exchange of information. During the first hype, the impression was widely common that XML would overcome all the problems of data exchange of the past. Realistically seen, XML is a very valuable means because it defines (in device type documents (DTD) or extensible schema description (XSD)) how information can be ordered in a file in a hierarchical tree, with the possibility to define tags that describe the information items in between them. XML has the advantage that it especially defines the syntax of the files, and the elements of the metalanguage allow to impose some restrictions regarding the "well-formedness" of XML files, for example, which file entries are mandatory and which are not, and the number of elements of a certain kind allowed. Thus, XML provides a means to bridge the syntactical gaps for information exchange.

However, XML does not overcome the intrinsic problem of communication: the partners involved do not only have to agree on the syntax of information exchange but also on the semantics.

To give an example: Company A might use

< SetPoint>0.8</SetPoint>

as a means to internally store the set point for a control loop in their control system. However, another Company B might have defined

<controller_setpoint_value>0.8</controller_setpoint_value>

in their XML schema, and the XML parser of their controller configuration tool will — unlike humans — not understand the tags used by Company A. Further complications might arise in the interpretation of the value itself — is it in engineering units, on a scale between 0 and 1, or on a different standard scale like 4–20 mA?

The simple example given above already illustrates the continuing need to agree upon the semantics of the information to be exchanged. Once the semantics and the structuring of the information have been agreed upon, either as a company standard, or as an agreement between project partners, or even beyond as a national or international standard, one can straightforwardly create an XML schema to define the XML files for information exchange based on this standard, and commercially available XML parsers can be used to read such an XML file and to transfer it into a tool-internal object model.

Recently, various attempts to use XML as an information exchange vehicle have emerged. In the following, three examples will be described to provide an idea of the possibilities, the difficulties, and the chances of XML for the exchange of industrial automation project information.

98.2 XML for the Description of Control System Hardware Components

An automation system for a manufacturing or production plant is usually composed of several controllers being connected by a communication network, each of the controllers comprising several units with ports for (a) receiving data from the sensors and/or (b) sending data to the actuators. According to the digital or

© 2005 by CRC Press LLC

analog nature of the signals, the ports are called digital input (DI), analog input (AI), digital output (DO), and analog output (AO). Usually, the units combine 4 or 8 or 16 or 32 ports of the same type, thus being named DI boards, AI boards, DO boards, and AO boards, respectively. The boards further differ in the type of physical signal level (0–10V, 4–20mA, etc.) and additional features like signal quality checking etc. Therefore, usually a control system vendor offers dozens of types of input/output boards.

In a large automation project, for example, a power plant or a large chemical plant or rolling mill, thousands of input and output signals have to be connected to suitable input and output ports, and therefore hundreds of input/output boards have to be installed in the plant. The engineers have to select the input/output boards from product catalogs, matching them with the requirements and at the same time keeping the actual number of boards and the costs of the control system low.

To support the engineer, a tool has been designed [2] that, based on a specification of the required input/output signals, selects the needed input/output boards from a product catalog, while optimizing the selection and configuration according to predefined optimization criteria, such as costs, redundancy, ease of extension, rack and cubicle space, etc. Figure 98.1 shows the basic concept.

XML plays a twofold crucial role in this concept:

(a) XML is used to describe the requirements on the input/output signals, and
(b) XML is used to describe the technical features of the available products in the product database.

Thus, the selection and optimization algorithm can operate on a common format, easily matching requirements with available products. The special advantages of XML, which have been the reasons for choosing XML for this particular project, are that XML allows for a description that is independent of the control system, the application domain, the operating system, and even the vendor of the automation system components. The format of the XML files for requirements and for product descriptions have been defined jointly and specified in a DTD. During application, the XML parser reads the requirements specification document and compares against the DTD to automatically detect inconsistencies with the required format. This reduces the need for manually programming consistency check functions.

The approach described above has been specific for one control system vendor. However, other vendors follow similar approaches, and the effort to join the approaches (provided there is a will) is rather low, thanks to extensible stylesheet language translation (XSLT), which is a language for transforming XML documents into other XML documents [3].

98.3 XML for the Description of Control Programs According to IEC 61131-3

With the general tendency toward *open* industrial automation systems, which allow to combine components (field devices, remote I/O, fieldbus connectors, etc.) from various vendors, there are also increasing

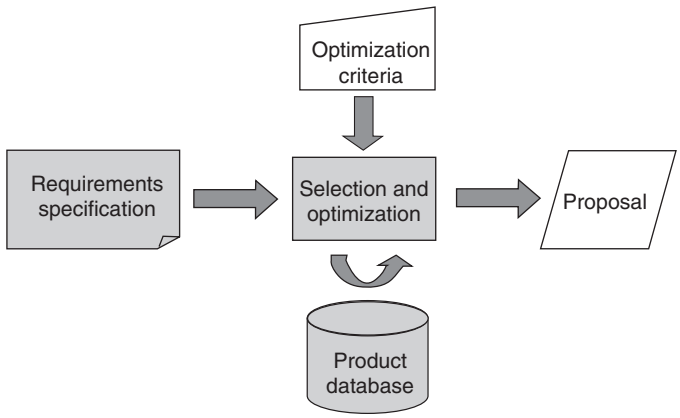

FIGURE 98.1 Basic concept of the automation system configuration optimizer.

© 2005 by CRC Press LLC

user demands regarding the interoperability and interchangeability of the control units of the automation systems, that is, the components that execute the programs that control the process. In the past, these programs have been programmed and debugged with engineering tools provided by the vendor of the respective control unit. The introduction of the international standard IEC 61131-3, which defines syntax and semantics of five industrial control programming languages (Function Block Diagram, Sequential Function Chart, Structured Text, Instruction List and Ladder Diagram), has led to some standardization among the vendors of industrial control systems. However, there are still many proprietary features among the programming languages used and the implementation of the standard.

The users, that is, those who implement and operate industrial automation systems, especially long for a possibility to exchange the source code of control programs between control systems of different vendors. One use case, as an example, is a globally active company with highly automated plants on several continents. Due to local preferences, automation systems from different vendors are installed at the different production sites. This company would like to create and maintain the source code for their automation solutions only once in a central lab and then distribute it to the production sites and compile and download it into the different control systems.

Therefore, there is an increasing need for a generic, vendor-independent description of control programs written in the above-mentioned languages.

Figure 98.2 shows an example of a (very much simplified) control program written as a Function Block Diagram, with one instance "FB1" of the Function Block "MyType" and two "AND" Functions.

A standardized description of such Function Block Diagram should not only cover the logics of the signal flow and control functions (such as connections of variables with functions and *vice versa*) but also the graphical information, that is, the positioning and size of the elements (e.g., Function Blocks, Functions, and connections).

The organization "PLCopen" [4] is a vendor- and product-independent worldwide association supporting the standard IEC 61131-3, for the benefit of all the users of industrial automation systems. PLCopen has recently started to seize this issue [5]. XML has been chosen as a basis for an exchange format for graphical and textual languages of IEC 61131-3, due to its high profile and the wide range of available tools (viewers, parsers, etc.). The goal of PLCopen is to provide in XML format the logic information with optional explicit graphics for the languages Function Block Diagram, Sequential Function Chart, and Instruction List and Ladder Diagram. Proposals have been provided already by Schneider Automation, Rockwell Automation, and ABB. Further companies participating in this joint approach are, among others, Siemens, Matsushita, and Triconex. An example of a proposed XML description of the Function Block Diagram shown in Figure 98.2 is shown partially below in Figure 98.3. The *x* and *y* coordinates refer to a predefined grid. The object positions given for connections denote the positions of corners of the connecting line:

The expectation is that a first draft of a commonly agreed XML description format will be elaborated and presented in 2003, with subsequent refinements and possible standardization in the following years.

98.4 XML for the Exchange of Plant Engineering Information

At a certain point in the engineering workflow of a process plant (like a power, chemical, or pharmaceutical plant), the process engineer hands over to the control engineer. At this time, the process engineer has designed the so-called "Pipe & Instrumentation Diagrams" (P&IDs), which document most of the process engineer's work (Figure 98.4). This P&ID is supplemented by tables ("Instrument Lists") which specify for each control item the setpoint, the measurement range, etc. On this basis, the control engineer designs and implements the continuous control loops, the interlocks, and the sequence control.

In the past, the handover of these documents has always been via printouts, and the control engineer had to manually reenter a huge amount of data, which is time-consuming and error-prone. The main reasons, among others, are that process engineering and control engineering are usually carried out by different companies, and that the paper format was prescribed for documentation purposes. The latter can be accomplished with similar effect by electronic document management systems today, and the former is no more accepted as an excuse for inefficient work processes. Therefore, the electronic transfer of process engineering information to the control engineer is required today. With respect to the Instrument Lists, this can be achieved with little effort, since the table headlines are few and easy to agree upon. With respect to the P&IDs, however, there is little progress in electronic exchange, due to the reasons described in Section 98.1.

To bridge the gap between process engineering and control engineering, a new attempt has been made recently by automation and engineering tool manufacturers and an institute of the RWTH Aachen (Aachen University) to define a meta model that allows to exchange information about a plant (especially about the process and its control system) in a format independent of a proprietary engineering or control tool. This information can be exchanged based on XML.

© 2005 by CRC Press LLC

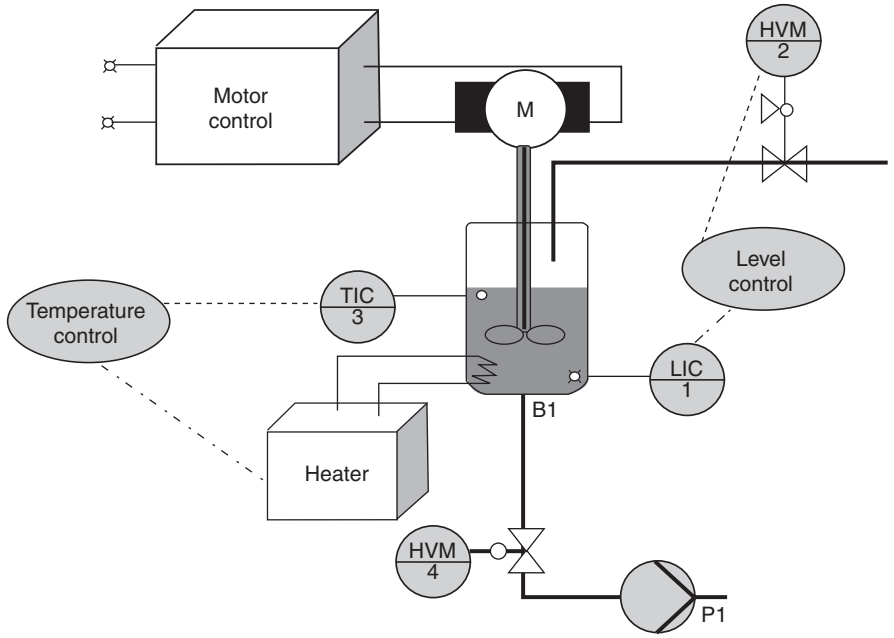

FIGURE 98.4 Pipe & Instrumentation Diagram example of a Technical Unit.

The requirements for this attempt have been: The proposed neutral XML description should

1. be able to store each state of the plant design workflow (to document defined steps and progress),
2. be prepared to support several workflow types (e.g., subcontracting of various tasks, bottom-up versus top-down, draft & refine iterations),
3. offer object-oriented concepts (which become more and more state of the art in engineering)
4. support hierarchical design of plants (e.g., plants consisting of components),
5. include not only the process and control objects but also the links in between (process material flow and information flow),
6. support user libraries and vendor libraries (which are always required in addition to agreed basic standards),
7. support several methods of reusing (e.g., reuse by "cut&paste" of objects from former projects).

Instead of presenting the complete XML schema, the following discussion concentrates on the key requirements and how they can be implemented with XML in general. Further information about the XML schema and its use can be found in [6].

To ensure consistency of the information given in one XML file, it is not sufficient to provide only the data about the object instances in the file — furthermore, the definition of the object type where this instance is derived from has to be provided as well. To support any type of libraries, both well-known public standards and proprietary project libraries, the information about the object type can be provided

- by a link to an entry in a public library or
- by attaching a library to the XML file or
- by directly including parts of a library.

In case the object type is inherited from other object types, these also have to be referenced or included.

To allow for different types of workflow and to also store intermediate planning results in a consistent manner, the concept allows to create instances from generic object types first (such as "pump") and to assign a more detailed specification as a refinement later ("pump for corrosive liquids, capacity 10 m^3/hour," "Vendor x, purchase order no. 341-45467").

FIGURE 98.5 XML representation of a Technical Unit (draft).

Figure 98.5 shows the XML representation of the Technical Unit of Figure 98.4 within a simplified plant hierarchy. Note the references to libraries in the header of the file, as well as that most PlantObjectInstances refer to a reference ElementClass (which is a generic object type) except for the two valves V1 and V2 to which already a specified reference SystemUnitClass is assigned.

© 2005 by CRC Press LLC

This approach can serve the automation engineer to gain consistent information about the plant that should be automated. Since the XML definition allows to mix different levels of detail in the specification of components, the information exchange can already take place early during the workflow, which gives the automation engineer the possibility for iterative and concurrent engineering and the chance to deliver optimal results with respect to the quality of the automation solution.

98.5 Conclusion

Information technologies do not only have an impact on the automation system itself but also on the methods and tools used to engineer the automation system. The wealth of special tools for dedicated tasks, together with the need for efficient work, requires quick and seamless information exchange. Many description means and exchange formats for engineering information have been developed in the past, and few have gained widespread use. The key to success is to find a good compromise between simplicity (imagine to interpret comma-separated-value files like "2, 300, 1, 10.0, ..." without explanation) and expressiveness (where the definition of all mandatory information items might already be outdated when published). XML does not guarantee a solution, but has the capability to, if used carefully, form the basis for a valuable information exchange, as shown for example, by the examples given above.

99.1 Introduction

The integration of enterprise-level business systems with manufacturing systems is increasingly an important factor driving productivity increases and making businesses more responsive to supply chain demands. As a result, more and more businesses are making integration a priority and are searching for standards and tools to make integration projects easier. The World Batch Forum's (WBF) Business To Manufacturing Markup Language (B2MML) is an Extensible Markup Language (XML) vocabulary based upon the ANSI-ISA 95 (ISA-95) standards and the international equivalent IEC/ISO 62264-1 standard.

99.2 Integration Challenges

While there are many software tools that provide varying levels of assistance for integrating systems, integration projects typically require extensive labor in order to overcome differences between terminology, data formats, interfaces, and communications options in the systems to be integrated.

A significant difference in the software tools commonly used within the enterprise and manufacturing domains exists. For example, many enterprises use middleware products that provide robust communications between systems from the same and different vendors. This type of middleware is not commonly seen in manufacturing systems, primarily due to the cost of the software and the technical expertise required by the middleware. Higher level manufacturing systems, such as Plant Information

© 2005 by CRC Press LLC

Management Systems that collect and aggregate data from manufacturing systems, are sometimes used with enterprise middleware systems, although often the interfaces with enterprise systems are a custom-developed or single vendor solution.

At this point in time, manufacturing systems are predominantly based upon Microsoft Windows. This is in large part a result of the constant drive to reduce manufacturing costs, the mature nature of the manufacturing system marketplace, and the reluctance to replace manufacturing systems with newer versions or operating systems. These factors often preclude the use of enterprise middleware solutions and has fostered a *de facto* industry standard for communication called OPC.

OPC is a set of communication protocols developed by the OPC Foundation for the exchange of manufacturing data using Microsoft's Distributed Common Object Model (DCOM) technology. The OPC Foundation is a nonprofit organization, primarily funded by manufacturing system vendors, that develops and maintains the OPC protocols. While limited to Microsoft platforms, the OPC Foundation is starting to develop web service implementations of their protocols to enable cross-platform connectivity. While OPC is a common tool for interoperability in the manufacturing domain, it is infrequently seen in the enterprise domain and is not a match for high-end middleware products.

The use of the World Wide Consortium's (W3C) XML is a common trait in many recent integration projects. As a mainstream technology, XML offers universal support by software vendors, a large number of tools for developing and using it, and the promise of a common language that will work with disparate systems. However, while XML provides interoperability on the protocol level, there remains an application-level integration issue of what structure the XML being exchanged should have, the elements/attributes to use, and the organization of the data.

When integration projects settle on communication formats and protocols, there is still the need to identify the data to be exchanged followed by a data mapping exercise. When cross-functional project teams assemble, there is usually a learning curve as team members from different parts of the organization learn the type of data available and needed in other parts of the organization.

99.3 Solutions

While the communication issues involving the physical and transport layers should be resolved as appropriate for each project, taking into account corporate and local requirements and infrastructure it is assumed that the resulting architecture will utilize XML for the protocol layer. XML provides the following benefits as the protocol for integration projects:

- It is a mainstream technology supported by all major operating system and application software vendors.
- Numerous tools are available for manipulating XML making the task of data mapping/conversion simpler.
- As a mainstream technology, it has a better chance of providing a longer lived technology than proprietary and older technologies. This is an important consideration in determining the total cost of ownership of a solution.

With XML as the common protocol for an integration project, the issue of standardizing the XML vocabulary for the project becomes critical. B2MML provides a solution to this issue. Also, since B2MML is based on the ISA-95 and IEC/ISO 62264-1 standards. Coupled together, B2MML and ISA-95 permit designers to define the data mapping using a standardized, common terminology and models that can be carried over to the B2MML XML vocabulary.

If custom interface development is required to integrate a computer system, there is a long-term benefit to using ISA-95 and B2MML. By interfacing individual systems to B2MML, a single format is used for all data received by a system, the number of interfaces is reduced, programmers may more easily move between interfaces, and the same terminology used for designing the data mapping is used in the interfaces. These factors will reduce software maintenance costs, make the integrated system easier to upgrade, and integrate new systems. Figure 99.1 shows a comparison of the number of interfaces required when

© 2005 by CRC Press LLC

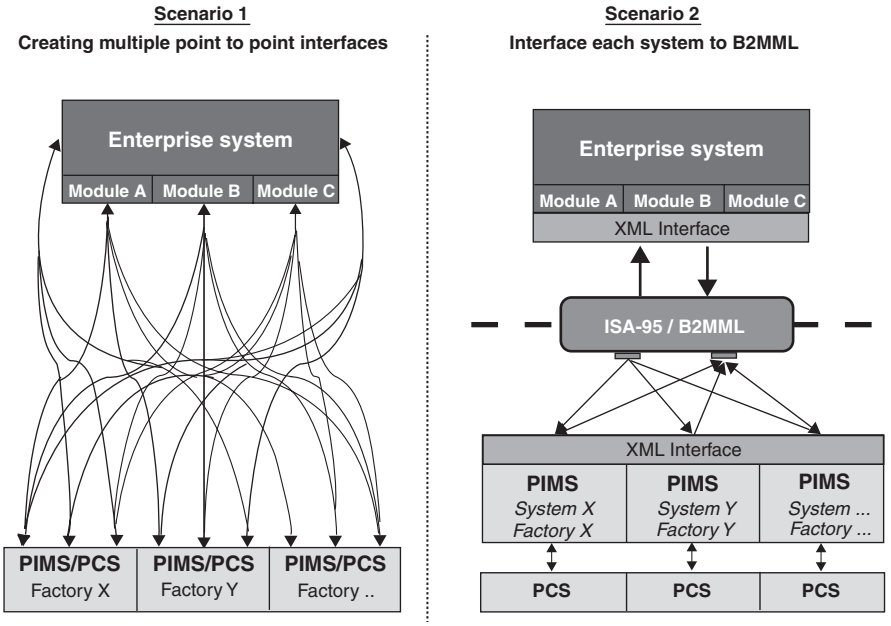

FIGURE 99.1 Point to point vs. common interfaces.

point-to-point interfaces are used as in scenario 1 vs. fewer interfaces required when a common format such as B2MML is used as in scenario 2.

99.4 B2MML

The B2MML is a set of XML schemas that are based on the ISA-95 Enterprise-Control System Integration Standards. The XML schemas comply with the W3C's XML schema format and define a vocabulary using the terminology and models in the ISA-95 standard. XML documents based on B2MML may be used to exchange data between the business/enterprise and manufacturing systems.

B2MML was developed by a group of volunteers working for the World Batch Forum (WBF), a non-profit educational professional organization. While the WBF is the owner of B2MML, the licensing terms make the schemas available royalty free for any use. B2MML was created with the intention of fostering the use of the ISA-95 standards by providing XML schemas that could be used, and modified as necessary, for integration projects.

The existence of a core set of ISA-95 XML schemas is critical since without it each company, or even work group, would have to develop their own definitions of XML elements and types based on the ISA-95 standards. This would inevitably lead to numerous variations with enough structural and nomenclature differences to make the exchange of data using XML more difficult than expected. The creation of B2MML will not make XML-based data exchange easy, but it should make it easier. Even when the B2MML schemas are used to derive proprietary schemas that extend and constrain the originals if the B2MML element names and type definitions are used, there will be a common footing that can be used to establish a data mapping between applications.

B2MML has advantages over proprietary interfaces in that it is independent of any one vendor, based on an international standard and that representatives from the manufacturing domain, both vendors and end users, have been very active in its development.

As a vendor-independent and standards-based XML vocabulary B2MML can be used to implement ISA-95-based designs using most XML enabled middleware and application interfaces. This provides the ability for project teams to use a vendor-independent framework during analysis and design and the ability to carry it directly to the implementation phase.

© 2005 by CRC Press LLC

While other organizations, such as the Open Applications Group (OAG), provide standard interfaces for enterprise applications, they do not provide the level of detail and completeness required for full functioned interfaces with manufacturing systems that B2MML provide. Where OAG's OAGIS XML schemas provide interfaces primarily for within the enterprise domain, B2MML's interfaces are totally focused on the exchange of data between the enterprise and manufacturing domains.

99.5 ISA-95 Standard

In order to understand B2MML, one must have a basic understanding of the ISA-95 standards. A complete explanation of the ISA-95 standards is beyond the scope of this paper; however, a brief overview of the standards is provided.

ISA is a nonprofit educational organization that serves instrumentation, systems, and automation professionals in manufacturing industries. ISA is an accredited standards body under agreement with the American National Standards Institute (ANSI). ISA develops standards relating to the manufacturing industry, primarily, process manufacturing. The ISA-95 standards that B2MML is based upon are:

ANSI/ISA-95.00.01-2000 — Enterprise-Control System Integration Part 1: Models and Terminology and
ANSI/ISA-95.00.02-2001 — Enterprise-Control System Integration Part 2: Object Model Attributes.

The Part 2 standard provides attributes for the object models defined in Part 1. Since B2MML uses the models and terminology defined in Part 1 and the attributes defined in Part 2, it is said to be based upon the ISA-95 standards.

After ISA-95 was accepted as a U.S. standard by ANSI, it was submitted to the IEC and ISO for acceptance as international standards. While slight modifications were made to the standards, the international versions are substantially the same as the ISA version. IEC and ISO agree to release the international standard as a dual logo standard; therefore, it is available from either organization. The international version of Part 1 is called IEC/ISO 62264-1. At the time of writing, the Part 2 version of the international standard was progressing through the joint IEC/ISO working group; hence, it is not yet a released international standard.

ISA-95 builds upon existing work, its models are based upon "The Purdue Reference Model for CIM" developed in the 1990s by a group of chemical company representatives under the leadership of Dr. Theodore Williams at Purdue University (Purdue Model); the MESA International Functional Model as defined in "MES Functionality and MRP to MES Data Flow Possibilities — White Paper Number 2 (1994); and IEC 61512-1 batch control — Part 1: models and terminology (ANSI/ISA-88)." The value of ISA-95 is in providing a more comprehensive and detailed definition of the data exchange between the enterprise and manufacturing domains than the previous works.

The terms enterprise and manufacturing domains are defined in ISA-95 in order to put terms to the reality of the different business issues, needs, and drivers at the different levels of a business. ISA-95 uses the levels defined in the Purdue Model as shown in Figure 99.2.

Levels 0–2 represent process control and supervisory functions and are not addressed in the standard. Level 3, manufacturing operations and control, is considered the manufacturing domain and represents the highest level of manufacturing functions. Level 4, business planning and logistics, encompasses all enterprise- or business-level functions that interact with manufacturing and is referred to as the enterprise domain. The focus of the standards is on the interfaces between levels 3 and 4.

Is it important to note that the ISA-95 enterprise and manufacturing domains refer to functions, not organizations, individuals, or computer systems. Any one organization, person, or computer system may perform functions in both domains.

In practice, there is no single boundary between domains that applies to all industries, companies, divisions, and manufacturing plants. The standards draw an arbitrary line based upon commonly accepted practices. In recognition of the flexible boundaries between domains, the ISA is currently working on further parts of the standards that will define the functions an data flows inside level 3 so that when different boundaries exist, the standard may be used to identify the data flows that cross the specific level 3–4 boundary in use.

© 2005 by CRC Press LLC

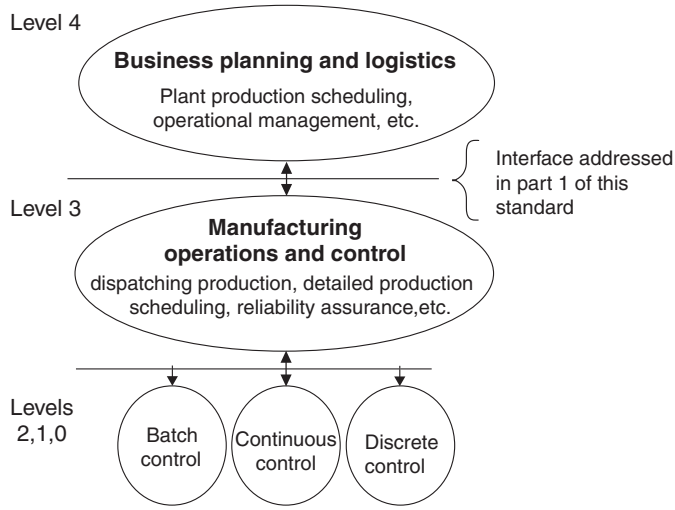

FIGURE 99.2 Levels in a manufacturing enterprise.

Figure 99.3 illustrates the concept of the flexible boundary between the enterprise and manufacturing domains. When boundary #1 between the enterprise and manufacturing domains is used, functions 1 and 3 in the enterprise domain must interface with functions 4 and 5 in the manufacturing domain. Functions 2 and 6 do not interface with functions in the other domains and therefore would not be the focus of an integration project. However, when boundary #2 is used, all the functions except for 1 and 2 would be the focus of an integration project since they interface with functions in the other domain.

Drawing heavily upon the Purdue Model, ISA-95 defines data flows that may cross between the enterprise and manufacturing domains. These data flows are grouped into categories of information, which are the foundations of the ISA-95 models and the B2MML schemas. The key information categories are listed in Figure 99.4.

Figure 99.5 illustrates the overlap of information in the enterprise and manufacturing domains and how the three key information categories provide a conduit for the flow of information between domains.

In addition to the three categories of information, three types of resources used by each category are identified in the standard as:

Each category of information may include information about some or all of the resource types and may include information about multiple instances of each resource type (Figure 99.6).

99.6 ISA-95 Models

ISA-95 defines nine object models defining the structure of the categories of information and resources. Each object model defines the data associated with the category of information or resource. The models are listed in Figure 99.7.

Communicating actual production results from the manufacturing domain to the enterprise domain is one of the most common and important goals of integration projects. The production performance model, shown in Figure 99.8, addresses this function.

This model is typical of the category of information models in that it defines a hierarchy built upon resources.

The hierarchy starts with the production performance object, which is made up of one or more production responses. This permits manufacturing requests from the enterprise domain to be split into multiple elements, for example, if the request was for more than to be manufactured at one time. In this case, each production response would report the results of an element of the manufacturing request, with the sum of all the production responses making up the production performance associated with the manufacturing request.

© 2005 by CRC Press LLC

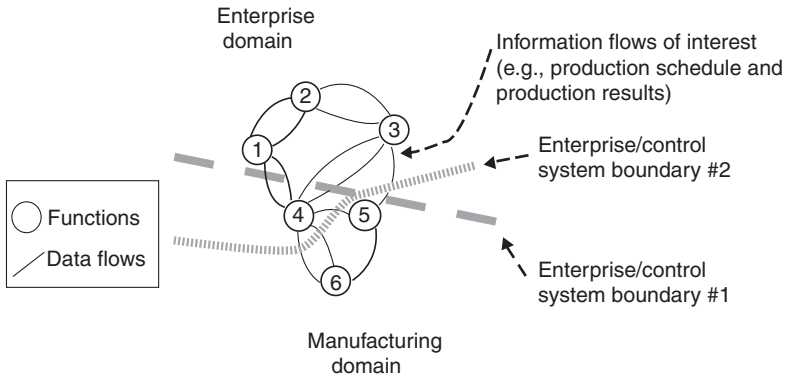

FIGURE 99.3 Flexible domain boundary.

Production capability	Information describing the manufacturing capability for a period of time. Total capability is the sum of committed, available and unattainable capabilities. This information is used to inform enterprise systems of a manufacturing area's ability to produce which is required to develop accurate plans and schedules.
Product definition	Information describing how a product is produced. When product definitions are maintained at the enterprise level this information must be sent to the manufacturing domain when product modifications are made or new products introduced.
Production information	Information instructing the manufacturing domain what to make and when in the form of a schedule and the report by the manufacturing domain up to the enterprise domain of actual production accomplishments including material usage, units of labor and equipment used for a product.

FIGURE 99.4 Key information categories between the enterprise and manufacturing domains.

Moving down the hierarchy each production response is made up of one or more segment responses. A segment response is the "production response for a specific segment of production." The production capability and process segment models are used to define segments for each application and would map into production performance at this level. The objects that each segment response consists of are listed in Figure 99.9.

Taken together, the production performance object defines the actual performance of the process that is reported by the manufacturing domain to the enterprise domain, most likely in response to a production request.

Each of the category of information models is constructed in a similar manner. The resource models for personnel, equipment, and material are themselves similar. The material model, shown in Figure 99.10, is a good example of this.

Reading the material model from left to right shows a hierarchy of material information.

Material classes (e.g., oils) define a grouping of material definitions (e.g., peanut oil) that are used to define material lots that may be made up of material sublots. Sublots may themselves by made up of multiple sublots. Material classes, definitions, and lots are further defined by lists of properties. Sublots do not have properties since each sublot must have the same properties of the parent lot. The QA objects provide a means to document test specifications and results for each property.

When used with the category of information models, any of the four levels of material may be referenced as appropriate. For example, production performance typically references specific lots and sublots used in production, production schedule may reference a material definition, or for tracking purposes a material lot or sublot. Production capability and product definition would probably reference material classes and definitions since they deal with more abstract information.

© 2005 by CRC Press LLC

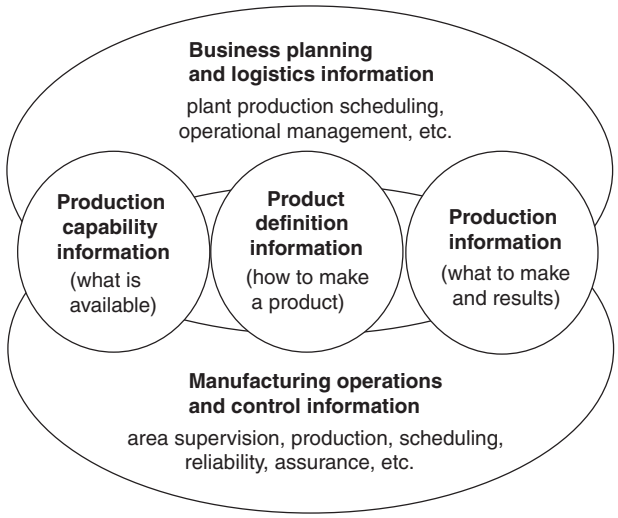

FIGURE 99.5 Categories of information.

Personnel	Individuals, or classes of people, with certain qualifications may be identified as a capability, required as part of a product definition, scheduled or reported as units of labor for production performance.
Equipment	Pieces of equipment, or classes of equipment, with certain characteristics may be identified as a capability, required as part of a product definition, scheduled or reported as utilized as part of production performance.
Material	Material sublots, lots, material definitions or material classes with certain properties may be identified as a capability, required as part of a product definition, scheduled or reported as consumed or produced as part of production performance. Note: The standards considers energy to be a material.

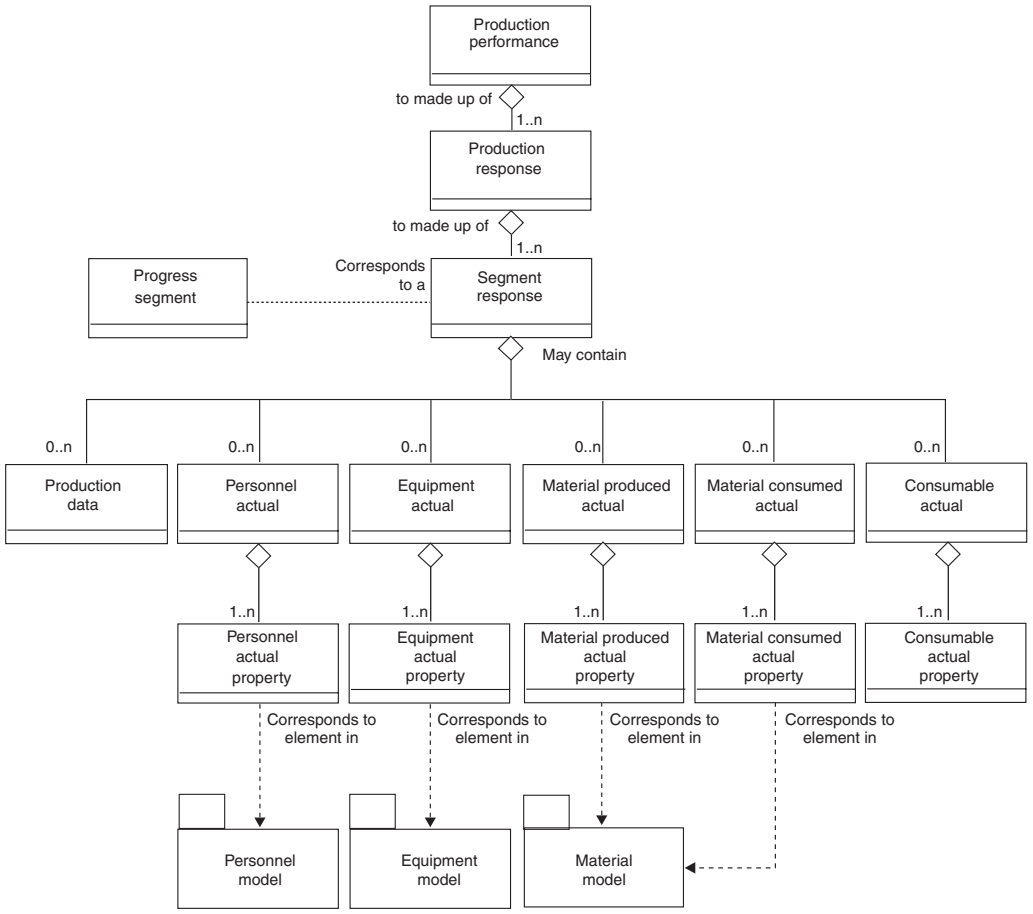

FIGURE 99.8 ISA-95 production performance model.

ment model have been combined under Process Capability. In the standard, these two models were shown separately in order to make them clearer but they both define the capabilities of the manufacturing process.

99.7 B2MML Architecture

B2MML is a collection of XML schemas organized to align with the ISA-95 standard's object models. The basis for each of the schemas, including the mapping to the standard's data models, is listed in Figure 99.12.

There is a separate schema for each model, with the exception of the equipment model, which has two schemas, one for the equipment objects, the other for the maintenance objects. This was done to provide the flexibility of using equipment and maintenance objects separately.

The separate schemas permit applications to only reference the schemas required thereby eliminating unused elements from populating application namespaces.

The common schema, B2MML-V02-Common.xsd, does not directly relate to an ISA-95 model, rather it is used to contain type definitions, which are referenced by more than 1 schema.

The internal structure of the model-related schemas follows the ISA-95 standard's object model structures. The root element in a schema is named after each data model's root element and each object in an object model is generally represented as an XML element.

© 2005 by CRC Press LLC

Production data	Data associated with the products being produced, the process segment or waste material but not directly identified as a resource.
Personnel actual	Units of labor for the personnel classes or persons related with the process segment.
Equipment actual	Equipment or classes of equipment used by the segment.
Material produced actual	Material produced by the segment. This may include one or multiple products or intermediate materials as well as byproducts and waste products. Material may be identified by sublot, lot, material definition or material class.
Material consumed actual	Material consumed by the segment. Material may be identified by sublot, lot, material definition or material class.
Consumable actual	Material not tracked by lots, not included in bills of material, or not individually tracked that have been consumed by the segment.

FIGURE 99.9 Objects that make up the segment response object.

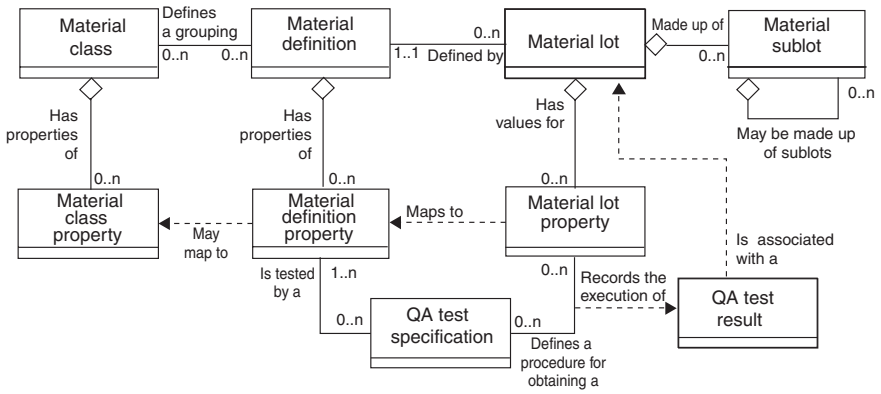

FIGURE 99.10 ISA-95 material model.

The standard's technique of using application-specific properties is implemented in the schemas using property types, which may be used to list any number of application-specific properties in an XML document.

All elements in the schemas are declared using simple and complex types. The common schema is included by each of the other schemas that use the types as needed. Any type that is used in only one schema is defined in that schema.

In B2MML, only a few elements are declared globally, meaning they may be used in other schemas or XML documents. Generally, the objects in the ISA-95 standard that represent data to be exchanged between systems are implemented as global elements with the addition of a few container elements for the equipment, personnel, and material models. The other objects, which are generally part of the exchanged objects, are defined as local elements. The global elements are listed in Figure 99.13.

Most of the elements in the schemas are optional. This enables XML documents based upon them to only contain the elements applicable to the application, resulting in more concise XML documents.

The B2MML schemas permit most XML types to be expanded with additional elements. This is accomplished by placing an element called "Any" as the last element in a type's definition. The "Any" type is defined using the "AnyType," which is based upon the XML schema wildcard component ##any. The XML schema wildcard component permits any element to be included inside the "Any" element that is at the end of the type's list of elements.

© 2005 by CRC Press LLC

The use of this wildcard is a compromise between maintaining the ability to rigorously validate XML documents against the schema and the pragmatic recognition that diverse integration projects have unique requirements that can best be served by permitting application-specific elements to be used to extend B2MML types.

While the application-specific addition of elements can hurt interoperability, this can be limited by having XML processors expect to find either nothing or some unknown (from the B2MML viewpoint) element after the last standard B2MML element in each type. This technique will make XML processors more robust and ensure that the standard B2MML data can be processed.

99.8 Using the B2MML Schemas in XML Documents

The root element in a B2MML XML document must be a globally defined element. For example, a production performance document may use either the ProductionPerformance or ProductionResponse element while a material document may use one of the MaterialClass, MaterialDefinition, Material Information, MaterialLot, or MaterialSubLot elements.

Individual XML documents may reference one or more of the model-based, resource, or common schemas as required. This is done by placing namespace references attributes in the root element as shown in Figure 99.14.

In Figure 99.14, the xmlns attribute declares the namespace for the document. While the string http://www.wbf.org/xml/b2mml-v02 has the form of a URL, it is merely a unique string used to identify the version of B2MML used by the document.

A simple B2MML document is shown in Figure 99.15.

This document uses MaterialInformation as the root element, references the B2MML namespace and schema location, as well as the standard XML W3C namespace. The data contents of the file provide information about the material lot with an ID of M-1215. Note that many optional elements in MaterialLot are not in this file; this is an example of how unneeded optional elements can be omitted.

Many elements are based upon types whose content has been restricted to be an enumerated list. This means that the value of the element must be one of the values listed in the schema. For example, EquipmentElementLevel is based upon EquipmentElementLevelType, which in turn is based upon EquipmentElementLevel1Type. These two types are shown in Figure 99.16.

Whenever there is an enumerated list in B2MML, a simple type's content is restricted to the values in the enumerated list and a companion complex type is declared, which extends the simple type by adding an attribute named OtherValue. This is required in order to provide XML document authors the ability to extend the list. The enumerated list may be extended by an XML document author by giving the EquipmentElementLevel element a content of "Other" and an attribute of "OtherValue" whose content is

FIGURE 99.17 Example of extending an enumerated list in an XML document.

in this case has the value of `Work Center` and then uses the attributes value as the value of the element. This technique may be used on any of the enumerated lists.

The B2MML schemas have been designed to permit most XML types to be expanded with additional elements. The element "Any" that appears as the last element in most complex types serves as a container for any other elements the XML document author wants to insert into an element. The Any element is based upon the AnyType complex type that is defined in the B2MML common schema. The Any element and AnyType ComplexType declarations are shown in Figure 99.18.

The string "##any" seen in Figure 99.18 is a W3C XML schema wildcard component that permits any other element to be added to the end of the type's list of elements. The use of this wildcard is a compromise between maintaining the ability to rigorously validate XML documents against the schema and the pragmatic recognition that diverse integration projects have unique requirements that can best be served by permitting application-specific elements to be used to extend B2MML types.

When elements are added to an existing B2MML element, they must be added within the Any element; otherwise, the XML documents will not be valid. While it is good practice for all added elements to use a prefix that identifies the XML schema, they are defined in this reference as optional and not required by B2MML.

While the application-specific addition of elements can hurt interoperability, this has been limited by having XML processors expect to find either nothing or some unknown (from the B2MML viewpoint) element after the last standard B2MML element in each type. This technique will make XML processors more robust and ensure that the standard B2MML data can be processed.

Figure 99.19 contains an example of adding elements not in B2MML to a B2MML element.

In this case, three elements not defined in B2MML are included as part of the MaterialLot element by placing them inside the Any element. The extended elements have a prefix of "ext:" which is defined in the namespace declarations at the top of the document. There the "ext:" prefix is defined to point to the ExtensionExample.xsd XML schema. The figure contains this schema, which has been used to declare the

Any element declaration:

```
<xsd:element name="Any" type="AnyType"
                        minOccurs="0"
                        maxOccurs="unbounded" />
```

Any type complex type declaration:

```
<xsd:complexType name="AnyType" >
    <xsd:sequence>
        <xsd:any namespace="##any" processContents="skip"
                                   minOccurs = "0"
                                   maxOccurs="unbounded"/>
    </xsd:sequence>
</xsd:complexType>
```

FIGURE 99.18 Any element and AnyType complextype declarations.

simple types used in the XML document. Of note is the fact that while XML processors will check for well-formed XML, they will not validate the content within the Any element since the AnyType has been defined with the attribute processContents= "skip."

99.9 Usage Scenario

The following scenario provides an example of using B2MML's Production Performance schema to report production results from a manufacturing system to an enterprise system. Figure 99.20 lists the manufacturing data to be reported.

Figure 99.21 contains a production performance XML document containing these results. The document has been broken into parts for clarity and for reference in the description below. If the XML in the each box were concatenated, it would create one production performance document.

Header: The header information in figure 21 includes an XML declaration, the start of the document's root element, ProductionPerformance, and attributes declaring XML namespaces, identification of the XML schema the document is based upon, and a suggestion as to the schema's location. To further understand the XML syntax, refer to the W3C's XML and XML schema recommendations.

Production performance and response information: The production performance and production response elements provide information to the receiving system regarding where this information fits into the overall production performance data. There may be one or many production performance XML documents per lot of product. Therefore, sufficient information must be included in the document to permit the receiving system to know where to store or send each piece of data.

In this case, the overall production performance ID of MT593 is a batch ID and the production response, MT593-1, is a subdivision of the batch operating on one unit.

Segment response information: The segment response information identifies the product or process segment within the production response. In this case, the segment maps to a product segment since that element is used and the process segment element is not. The actual start and end times provide potentially important information that can be used by the enterprise system for costing or utilization purposes.

Production data: This section contains four production data elements from the Production Data table above. Each measurement has been placed in its own ProductionData element with a unique ID and containing its value, data type, and units of measure.

Production data:

Date	Time	Event	Temperature 1 (Deg C)	Temperature 2 (Deg C)
2003-08-05	14:34:03	Start Charging Milk	25.0	26.4
2003-08-05	14:39:29	End Charging Milk	19.6	21.3

Material used

Date	Time	Material	Target (Kg)	Actual Quantity (Kg)
2003-08-05	14:34:03	Milk	400	402.4
2003-08-05	14:59:43	Flour	750	750.3

FIGURE 99.20 Production data to be reported to an enterprise system.

Material consumed — milk: The material consumed — milk section is used to transmit the amount of milk actually added to the process, the target (i.e., amount of milk that was supposed to be added), and the time the milk was added.

The MaterialConsumedActual element contains identifying information about the material, the location the material was added from, the amount added, and properties of the material consumed. The properties have been used to convey the time the milk was consumed and the target amount. In any integration project, the sending and receiving systems must be programmed to use the same property IDs as part of the data-mapping exercise.

This is an example of how an element's properties can be used to provide extended information without using the Any element. This type of extension should be easier for receiving systems since properties will be expected.

Material consumed — flour: This section is similar to the milk material consumed section; only, it refers to the addition of flour. This is an example of how each material consumed may be documented.

End of elements: These three lines indicate the end of each of the elements opened in the earlier sections. </ProductionPerformance> indicates the end of the XML document.

Many optional elements have been omitted from this example, as will often be the case in actual implementations. When empty elements are shown above, it is because they are required by the B2MML schemas.

While elements such as MaterialProducedActual, PersonnelActual, and EquipmentActual have not been shown, their usage closely follows the above example.

99.10 Schema Customization

While the ISA-95 standards provide a firm basis for many integration projects, they cannot satisfy every requirement. If the addition of elements using the "Any" type is insufficient, the schemas may be used to derive custom corporate or application-specific schemas. While the derivation of new schemas may seem contradictory to the use of a standard, it is a pragmatic recognition that companies have requirements beyond the core functionality of the standards and B2MML.

B2MML types and elements may be referenced or included in other schemas. This may be done to build new types that are extensions or restrictions of B2MML types or to include B2MML elements inside corporate or project-specific schemas.

Since the B2MML schemas are freely distributed with no restrictions placed on their use, each user is free to change their contents or include them in other work. It is strongly recommended that if modifications are

FIGURE 99.21 (continued)

made to the B2MML types, they be done as part of another schema using a different namespace and filename. If a B2MML schema file has its contents changed without the namespace and filename being changed, there is an increased risk of errors in the future from incompatible versions of the same file being mixed up.

99.11 Conclusion

B2MML, the Business To Manufacturing Markup Language, is an XML-based implementation of the ISA-95 standard. This industry markup language will enable the use of mainstream information technology with a standards-based approach to integrating enterprise and manufacturing systems.

100.1 Introduction

Integrated automation systems are gaining more and more momentum in the automation industry. They address not only the vertical integration that covers layers from devices via manufacturing execution systems to business applications but also the horizontal integration ranging from design, engineering, and operation to maintenance and support. The emerging Web Services technology with growing acceptance in industry are a good way to create an open, flexible, and platform-neutral integrated system. In this chapter, we attempt to analyze and describe the main challenges in using Web Services for integrated automation systems. We believe that performance, client compatibility, client addressability, object designation, and ability to deal with multiple structures are important and essential issues for deploying Web Services in automation systems. We present some solution concepts including architecture, mechanisms and methods such as the structure cursor, Web Services bundling, the event service, the object designator, and so forth. Finally, we discuss the future of using Web Services, where Ontology will play an important role for efficient system engineering and assembling.

100.2 Background

Integration is a strong trend in the current development of the automation technology. Integrated control systems, integrated factories, or integrated manufacturing are some examples. A large integrated automation system covers not only the whole production life cycle including purchase, design, engineering, operation, and maintenance but it also involves the different control levels ranging from the field device layer to Enterprise Resource Planning (ERP) layer [1–3]. The creation of such systems thus poses the challenge of addressing various requirements from different areas at the same time, of assembling heterogeneous applications, integrating data models, and binding the applications to the data models. Typically, the diverse applications developed for handling issues of different business areas such as purchase, design, and engineering are distributed via network and unstructured. It is difficult for an engineer to find a suitable application for his specific purpose. There is no common and structured way of organizing or describing the applications in the automation area. Another challenge for large integrated automation system is the heterogeneity of platforms on which applications are developed. On the one hand, Microsoft's COM technology is widely used to create applications for traditional automation systems such as human–machine interface (HMI) or Supervisory Control And Data Acquisition (SCADA). OLE for Process Control (OPC), originally based on the COM technology, provides a standard specification for data access. It greatly facilitates interoperability for access to control instruments and devices. On the other hand, many applications in other areas such as ERP or Supply Chain Management (SCM) are based on CORBA or EJB. Interoperability between heterogeneous platforms is always a headache for integration — a uniform base would extremely reduce development costs. Appropriate data models are another challenge when building large integrated automation system. A unified description method, easy transformation and mapping, and efficient navigation mechanisms are natural requirements on data modeling. Last but not the least, the binding of applications to data models of a large automation system is crucial. The engineering costs for finding appropriate applications for specific data is quite high. An efficient way to reduce costs will greatly influence the development direction of automation technology. Web Services will play an ever-more important role in addressing the challenges in integrated automation systems due to their open, flexible, standard,- and service-oriented architecture.

100.3 ABB Industrial IT Platform

To address the integration challenges in automation systems, ABB has created an integration platform for integrated automation systems called Aspect Integrator Platform (AIP), which follows the paradigm of decoupling the data model from its computational model. It is subjected to IEC 61346 [13]. The basic elements in the model are Aspect Object, Aspect, and Structure. An *Aspect Object* in AIP is a container that holds different parts of an object in an automation system. Such an object might be, for example, a reactor, a pump, or a node (computer). The Aspect Object covers data modeling, including data type, relationship among data, and its structure. The *Aspect* represents operations that are associated with an object. It can contain its own data. Examples of aspects are signal flow diagram, CAD drawing, analysis program, simulation, trend display, and so on. The Aspect focuses on the operational aspect. Figure 100.1 shows an AIP example.

To create an automation system based on the AIP platform, a data model should usually be built at first. Then, the engineer chooses suitable applications in the form of aspects and binds them to the data model. For an integrated automation system, which covers the whole production life cycle and all control levels, a large number of Aspects and Aspect Objects result. Thus, binding suitable Aspects to a certain Aspect Object requires significant engineering effort. Web Services could help to simplify this process. By creating an additional layer to cover Aspects of AIP, they could be searched and accessed in a unified way, using the standard Web Service discovery and description mechanisms. Besides, it should be noted that an Aspect itself can also be a Web Service.

A *Structure* — another element defined in AIP architecture and conforming to IEC 61346 — represents the semantic relationship of a data model. In IEC 61346 it is separated from the objects and expressed through an additional aspect such that an object can be organized in different structures at the same time. IEC 61346 presents three examples of information structures that are important for design, engineering,

© 2005 by CRC Press LLC

operation, and maintenance: function-oriented, location-oriented, and product-oriented structures. A structure is determined through a defined hierarchy, which describes the semantic relationships between Aspect Objects from a certain point of view. For example, the function-oriented structure organizes objects based on their purpose or function in the system, while the location-oriented structure results from the spatial constitution relationship, for example, ground area, building, floor, room, and so on. IEC 61346 provides the structure concept to address the semantics of a data model, but it does not define mechanisms to describe the semantics in different structures. Figure 100.2 shows three structures regarding function, location, and maintenance. The maintenance structure presented in the figure is useful for a maintenance engineer.

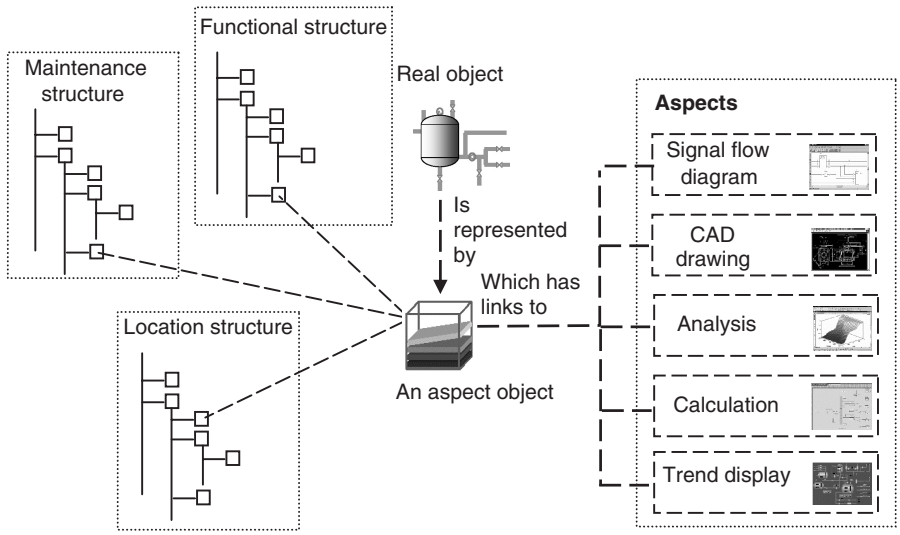

FIGURE 100.1 An example showing AIP architecture concept.

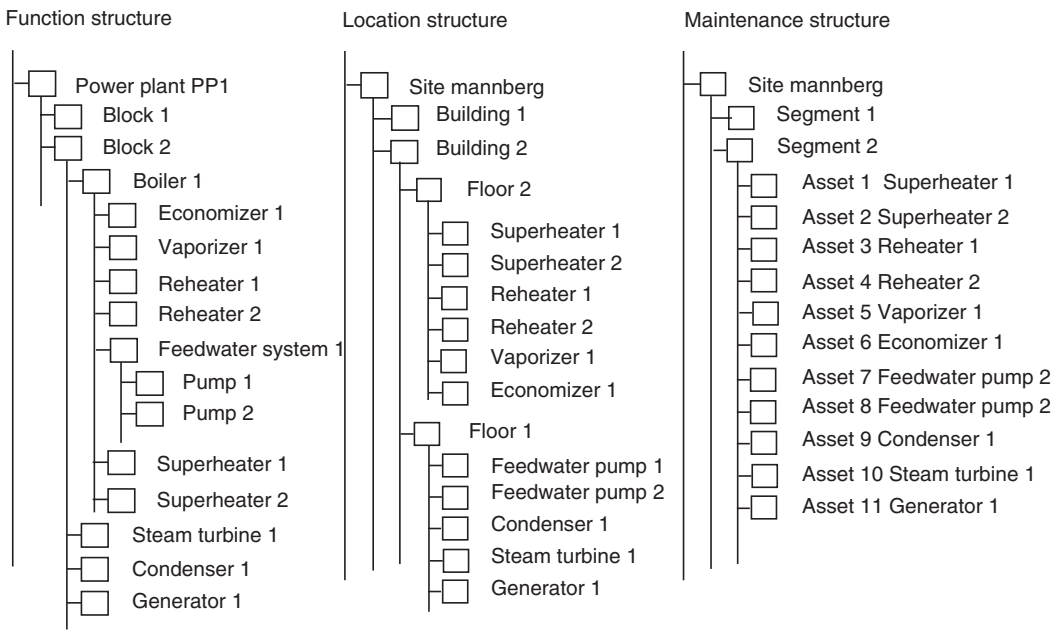

FIGURE 100.2 Example for functional, location, and maintenance structure.

100.4 Web Services

Definition

Web Services can be defined in different ways [5]. From a business point of view, Web Services present a common service-oriented architecture for companies and organizations to provide their key businesses in the form of services. From an application point of view, Web Services create a platform-independent and programming language-neutral middleware for interoperable interaction among applications. In this chapter, we concentrate on the technical aspect of Web Services and use the definition from the W3C [4]. "A Web service is a software system identified by a URI [RFC 2396], whose public interfaces and bindings are defined and described using XML. Its definition can be discovered by other software systems. These systems may then interact with the Web Service in a manner prescribed by its definition, using XML based messages conveyed by Internet protocols." Web Services have the following key features:

They can be described according to their nonoperational service information and operational information. The nonoperational information includes service category, service description, and expiration date, as well as business information about the service provider (e.g., company name, address, and contact information). The typical description language used for the nonoperational information is Universal Description, Discovery, and Integration (UDDI). The operational information describes the behaviors of Web Services. It covers dynamical aspects such as service interface, implementation binding, interaction protocol, and the invoking endpoint (URL). Web Service Description Language (WSDL) is usually used to describe the operational information.

Web Services have repositories for storing the nonoperational and operational information of Web Services. By means of the repositories, Web Services can be published, located, or discovered anywhere and anytime. They can also be invoked over a network such as the World Wide Web. SOAP is used to describe messages for Web Services. HTTP, TCP/IP, etc., can be used as communication protocols.

Web Services are standard-based, platform, and programming language-independent. They use standards for the description of services.

In comparison with the traditional middleware and component-based technologies, the differentiating features of Web Services are description and discovery mechanisms based on standards that enable the platform- and programming language-neutrality. Web Services provide a way for integrating applications developed on different platforms; it is thus a natural choice to use them within integrated automation systems.

Architecture

Basic Components

The Web Service architecture consists of a set of building blocks, which represent different roles. The key components are Service Provider, Service Requester, and Service Broker. Their relationship is illustrated in Figure 100.3.

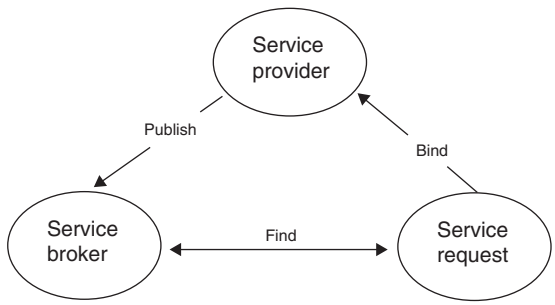

FIGURE 100.3 Basic components of Web Services.

© 2005 by CRC Press LLC

The Service Provider deploys and publishes services by registering them with the Server Broker. It provides an environment for running Web Services so that consumers can use them. The Service Broker has a repository to register and manage the service description including nonoperational and operational information. It can also provide some mechanism for efficiently organizing and structuring Web Services. The Service Requester finds required services using the Service Broker, binds them to the Service Provider, and then uses them.

Technology Stacks

The Web Service concept comprises different aspects such as description, discovery, composition, management, interaction, and communication. These are addressed through different layered and interrelated technologies. Figure 100.4 gives an overview of their relationship.

The figure shows how Web Services include the basic technology stacks and communications. The security and management of Web Services are also important for the development of a Web Service system. The process stack in the basic technology stacks is responsible for the discovery, aggregation, and choreography of Web Services, while the description stack defines how to describe a Web Service. The messages stack is related to the method of exchanging information between Web Services.

Web Service Style

There are two Web Service styles: remote-procedure-call (RPC)-style and message-style.

RPC-style: A remote procedure call (RPC)-style Web Service is like a remote object for a client application. When the client application invokes a Web Service, it sends parameter values to the Web Service, which executes the required methods and then sends back the return values. Because of this back and forth conversation between the client and the Web Service, RPC-style Web Services are tightly coupled and resemble traditional distributed object paradigms, such as RMI or DCOM. RPC-style Web Services are synchronous, meaning that when a client sends a request, it waits for a response before doing anything else.

Message-style: Message-style Web Services are loosely coupled and document-driven rather than being associated with a service-specific interface. When a client invokes a message-style Web Service, the client typically sends an entire document, for example, a purchase order, rather than a discrete set of parameters. The Web Service accepts the entire document, processes it, and may or may not return a result message. Because there is no tightly coupled request–response between the client and the Web Service, message-style Web Services provide a looser coupling between the client and the server. Message-style Web Services are usually asynchronous, meaning that a client that invokes a Web Service does not wait for a response before it does something else. The response from the Web Service, if any, can appear hours

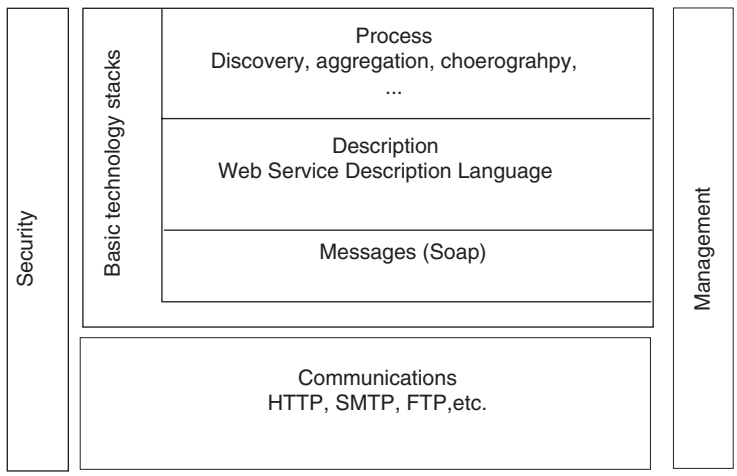

FIGURE 100.4 Technology stacks.

or days later, making interactions more efficient. Asynchronous Web Services may be a requirement for enterprise-class Web Services.

100.5 Challenges of Using Web Services for Integrated Automation Systems

Web Services provide many attractive features for integrated automation systems, but there are also several challenges.

Multiple Structures

For automation systems, it is crucial to have close integration of the information, which is carefully selected for specific purposes. Multiple structures of industrial information systems characterize the current trend in information modeling in the automation industry. They vertically cover different business layers from the process, sensor/actuator, field bus, HMI to manufacturing execution system (MES), and ERP. Horizontally, they adress different life-cycle phases ranging from ordering, design, engineering, to operation, optimization, and maintenance.

The information required for each business layer or life-cycle phase is different. It has to be structured accordingly, taking into account the specific properties of the layers and phases, and it has to be provided in a consistent way for the integrated solution. In this context, a multiple structural representation is inevitable. Even for the same business layer or the same life-cycle phase, multi-structure or multiple views of information are sometimes desired to provide an insight into the system from different points of view. The challenges in handling multiple structures can be characterized as follows:

- Information structures and hierarchies are closely related and interactive, that is, they are subject to the global goal of the information system.
- Connection points are clearly defined. The connection points determine how the multiple structures are associated and interrelated. For example, for a plant-centric automation architecture, the connection points are plant objects such as valves, pumps, etc.
- It is possible to navigate between structures.
- Each structure has a clearly defined semantic and serves one purpose. For example, for the engineering process, the product information structure is used to organize the product information.
- Designation is required to uniquely identify an information entity or an object of an information system.
- A multiple hierarchies-based information model should enable the integration of the computation model that provides the operation model for information manipulation and utilization. Additionally, it supports the integration of external computation applications that can use or process the information.

Web Services cover the dynamic aspect of an application, namely functions in the form of interfaces described by WSDL. They promote the separation of operations from the data model. For data presented in the form of multiple structures, it is necessary to provide the corresponding services for navigation, identification of data entities, and moving from one structure to another.

Client Compatibility

One benefit of Web Services is that they allow to integrate heterogeneous applications and to "webalize" legacy applications. A legacy automation system usually has client–server and peer-to-peer architecture using a defined protocol for the communication such as a socket or COM/DCOM. Web Services do not destroy this client–server architecture style. They only change the way of message and interface description and make it independent of the platform and the programming language. One possible scenario is the migration of a legacy automation system to Web service-based architecture. Web Services are usually

© 2005 by CRC Press LLC

used to provide mediator-like interfaces to the clients of the legacy automation system. One requirement could be that the clients who are using the legacy systems should not be required to do any adaptation, at least in the earlier phase of the migration. For example, process graphics displaying process data from the process server machines should not be changed if the data server of an automation system is just wrapped in a web service. This client compatibility guarantees low development cost and incremental evolution of an automation system. Interfaces between clients and servers do not have to be changed, including data types, data models, and invocation methods. For example, if a COM-based application provides an automation model to its clients, the client compatibility requires that the clients can use Web Services in the same way as if nothing has been changed.

Performance

An automation system is a real-time system with a large amount of process data, which changes over time. Thus, data transfer capacity and speed are two essential quality attributes.

Selective Data Access and Presentation

Web Services usually use Simple Object Access Protocol (SOAP) to describe messages exchanged between service requestors and service providers. Different communication protocols (Figure 100.4) can be used. When Web Services are invoked via the Internet or Intranet, the time for communication may be considerably longer than the time for data access, processing, and presentation. For monitoring and controlling an automation system, for example, a SCADA system, data access and presentation are typical functions. Here, it is not necessary to constantly obtain all data from the data server that is connected to instrumentation and devices. Efficient data access and presentation are required. However, in the Web Service environment due to SOAP, much data overhead is introduced. Time-costly roundtrips may occur frequently if no optimization is applied.

Additionally, Web Services communicate with the external world by sending XML messages, which have the advantage of being a platform-independent textual representation of information. Consequently, for the communication between the service provider and the service requestor, it is necessary to package the message, to transfer it to the service provider, and to unpack or parse it. Again, this might take a considerable amount of time and is opposed to the high-performance requirements of a real-time automation system.

An intelligent caching mechanism can help to tackle these problems by creating efficient data access and presentation, and by reducing the data overhead and round-trip time.

"Chatty" Interfaces

Multiple sequential calls between an interface and a business logic layer are acceptable in a stand-alone application for an automation system, but they cause a large performance loss when it comes to Web Services. In an automation system such as SCADA or an HMI system, the amount of process data exchanged between clients and servers is large. Transferring these data via Internet or Intranet through sequential calls will lead to large performance loss. This is a challenge for Web Services applications. Avoiding repetitive data transmission and reducing the number of interactions between the service requestor and the service provider are important issues to be solved.

Object Designation

Web Services are usually stateless, meaning that after the invocation of a Web Service, all state-related data created during the Web Service call are deleted and thus not available anymore. One way to address this problem is to use session management. Each Web Service requestor is allocated with a session on the server side that manages all client-specific state-related data such as intermediate variables, global variables for the client, and so on. But creation of a sessions on the server side for a client is always a burden for the server, impairs the scalability of the system, and thus should be avoided whenever possible. An integrated automation system usually has a structured data repository containing asset- and process-related data,

© 2005 by CRC Press LLC

which are organized in different structures for satisfying a variety of requirements. The ABB Industrial IT platform is such an example. The repository is a kind of data pool that is connected to processes over OPC or other communication channels. Careful design of methods for designating a data entity on the server is essential for efficient data browsing, navigation, and access. Uniqueness and multiple-structure characteristics of data should be taken into account. Well-designed designation methods are a condition for the use of stateless Web Services.

Client Addressability

In a client–server application, the client usually initiates the communication. It sends requests to the server, and the server responds and gives the requested data back to the client. In an automation system, sometimes it is required that the server triggers the interaction between the client and the server. An alarm and event server is such an example, which informs a client that a process parameter such as pressure or temperature has exceeded an upper or lower limit value. For this purpose, it supplies condition-related events.

There are also simple and tracking-related events. For example, a message about the failure of a unit can be represented by a simple event. The information about intervention in a process (corrective action on site) can be represented by a tracking-related event.

Events are organized in the event space. There are a variety of methods by which the client can influence the behavior of the server. Condition-related events, for example, can be enabled, disabled, and acknowledged. Web Services uses SOAP for description of messages and usually HTTP as a communication protocol. But HTTP is not good at delivering event notifications to clients or supporting long-lived message exchanges.

Security

Security is a very important aspect, especially in automation systems. Exposing a Web Service entails that the location and execution mechanism of the code changes, and this change requires a revision of the security policies mechanism. All data sent and received by a Web Service are formatted using SOAP on top of an XML specification. SOAP messages are easily readable; thus, it is necessary to encrypt certain data such as passwords. In this chapter, security is not the focus and thus is not discussed in detail.

100.6 Solution Concepts

We have listed some challenges for using Web Services with integrated automation systems. In this section, we are proposing concepts and solutions to address these challenges.

Overall Architecture of Web Services for an Automation System

Web Services are usually implemented based on the client-server architecture. They require client-side proxies and server-side implementations of the Web Service interfaces. For an integrated automation system, some special Web Services such as the structure navigation service, the service request unpacking service, the event service, and so on are needed on the service provider side. For each Web Service, there exists a service proxy on the service requestor side. Figure 100.5 illustrates the overall architecture of such a system.

Figure 100.5 also contains typical components in a traditional automation system, HMI client, communication channels over control bus (FDT, Profibus) and OPC, and devices. Usually in a client–server architecture, the connection between the HMI client and the automation system server is established through certain programming interfaces, as shown in Figure 100.5. For an automation system with Web Service support, the connections between the client and the server can be realized through Web Services. The façade pattern [8] on the service provider side controls the communication and request handling to simplify the implementation. The client- and server-side caches improve the performance of Web Services. The adapter pattern on the service requestor side solves the problem of client compatibility.

© 2005 by CRC Press LLC

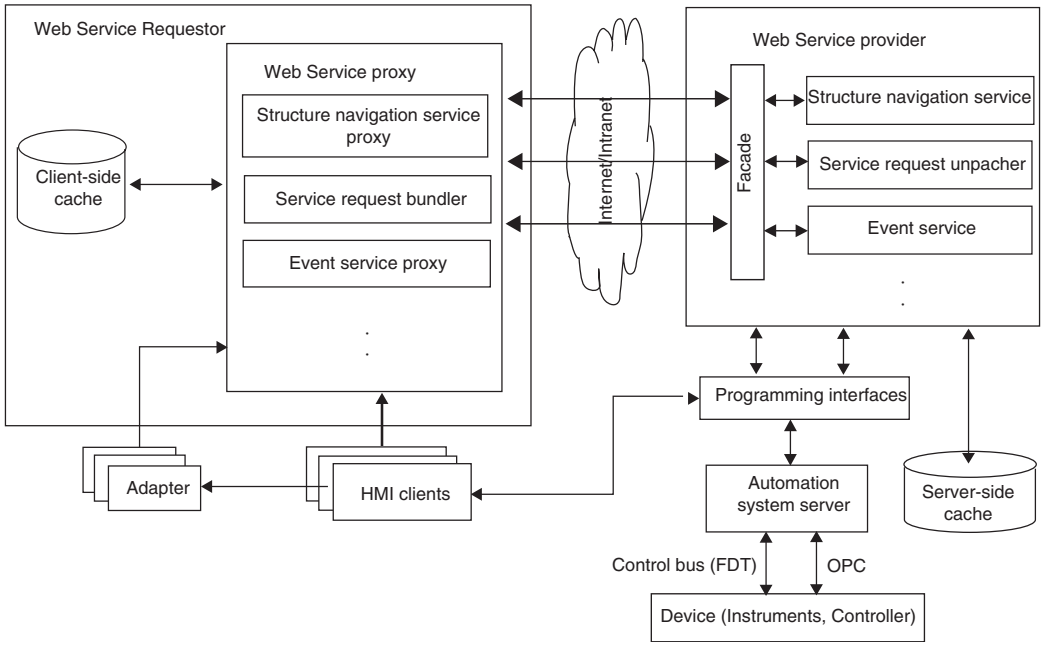

FIGURE 100.5 The overall architecture of an automation system with Web Service Implementation.

The main purpose of this architecture is to migrate an integrated automation system to the Web Service platform to improve interoperability of systems. The service broker (one of the basic components of Web Services) and the process stack including service discovery (one of basic technology stacks of Web Services) are not exploited here. Both must not necessarily be deployed for interoperability improvement.

Structure Cursor

The structure cursor is a concept for implementing the structure navigation service. As mentioned before, multiple structures are a characteristic of an integrated automation system. The structure cursor is used to navigate in a certain structure or to move from one structure to another. It enables access to all information in multiple structures such as product information, real-time information, asset information, location information, and so on. The structure cursor has two parts: the structure navigation service on the service provider side and the structure navigation service proxy on the service requestor side, as illustrated in Figure 99.5. There could be different structure cursors for different purposes [9] so that the structure-specific semantics can be taken into account in navigation.

Client Compatibility

An adapter [8] is an effective way to address client compatibility. Figure 100.5. shows the role of adapters. Their original purpose is to "convert the interface of a class into another interface clients expect." An adapter lets classes work together that otherwise could not because of incompatible interfaces. For the migration of legacy automation systems to the Web Service platform, the implementation usually begins with the server side of automation systems, which provides the processing functionalities. To avoid the forced change on the client-side, the adapter pattern can be used. It addresses incompatibility in interface, type, access logic, and processing logic. For example, if an automation system provides a COM automation object model for accessing information in the automation system, the adapter pattern can be used to solve incompatibility problems when the COM interfaces are converted to the Web Service interfaces. The same also applies for type. The adapter pattern does not add any new functionality; it just plays a role of conversion or transformation.

© 2005 by CRC Press LLC

Another kind of incompatibility in exposing an automation system to its clients by means of Web Services is the possibly different access logic. We could consider COM automation object model as an example again. A COM automation object model is a way to expose the functionalities of an application to its environment so that clients can exploit the functionalities or that the application can be controlled from outside. A COM automation object model usually contains a set of classes, which implement a set of COM interfaces. It is object-oriented, that is, it can be used to navigate the whole object tree to access the information of a concrete object. Identification of objects is accomplished by object names. In contrast, Web Services use URLs to identify themselves, and do not automatically provide mechanisms for identifying an object. Therefore, two kinds of potential incompatibility may occur: identification of objects and navigation in the object tree. One way to work around the potential problems is to use one-to-one mapping and introduce an object designator for each function defined in Web Services. The one-to-one mapping means that each interface implemented in the automation object model is exposed as a Web Service identified through a URL.

Design for Performance

To address the performance challenge when using Web Services for an automation system, it is essential to design a proper mechanism for handling roundtrips and the amount of data transferred between the service requestor and the service provider. The following recommendations should be considered when designing a Web Service.

Caching

Caching is an effective mechanism for increasing performance. Web Services performance in an integrated automation system can be maximized by carefully studying the data characteristics and correctly using data caching. There are three major choices to use caches: near the service client or consumer (client-oriented), near the service provider (provider-oriented), or at strategic points in the network [7]. In this chapter, only client- and server-oriented caches are considered (Figure 100.5).

A client-oriented cache intercepts the requests from a client, and if it finds the requested objects in the cache it returns them to the client. The content to be cached fully depends on the client's needs. Data requested by the client can also be prefetched and stored in the cache if necessary. Typical client-oriented caching is the proxy caching, transparent caching, and so forth [7].

The provider-oriented cache is located on the server side. It is content-dependent, meaning that if many clients require the same data (or the same data are required repeatedly), these data can be put into the cache for sharing. Examples for the provider-oriented cache are the reverse proxy cache and the push cache [7]. The provider-oriented cache is useful if it is very time-consuming to make data available on the provider-side for transfer to the client. An example of such a case is large simulation programs, which require intensive computation and thus a long processing time. In this case, the provider-oriented cache can avoid unnecessary redundant computations and thus reduce the waiting time.

To properly cache data, it is necessary to take the following issues into account:

What kind of data can be cached? You should consider using caching in a Web Service when the service's requested information is primarily read only. An integrated automation system contains not only the real-time process data such as temperature, pressure, and flow rate but also other static data that includes information of equipment or components (name, size, location, etc.), data on the producer of the equipment, data on the features of the equipment, price information, and so on. For a client, it is not necessary to update the static data constantly. Such a kind of data can be cached on the client side. For the provider-oriented cache, it is necessary to identify which data can be shared by many clients, or which are required repeatedly. The key criterion is how long it will take to make data available for the client.

Data marking: Data marking is a mechanism for identifying data entities to be cached. Therefore, object designation plays an important role. This task becomes difficult if the data are organized in multiple structures. Caching can be used for a single property of a data entity, for the whole data entity, or for a structure, such as the functional structure, location structure, or maintenance structure, which contains a group of data entities for a certain purpose.

© 2005 by CRC Press LLC

Time window: It should be possible to define a time window for caching. The time window defines a range in which data should not be obtained from the Web Services server. Only after the defined time window the system refreshes the data. The time window is similar to an aging mechanism. It is necessary to have an update or cleanup mechanism to force the refreshing of the cache. The time window should also allow to differently deal with slowly changing and quickly changing data, as typically both types coexist in automation systems. For example, the temperature of a boiler changes at a comparably slower rate than the pressure in response to the disturbance. Process data changing at a slower rate can have a relatively longer time window.

Data model for cache: As mentioned above, Web Services are usually stateless. Web Services represent a set of functions that can be invoked by the service requestor. Caches only deal with data. To associate functions represented by Web Services and the data to be accessed, the object identification is needed, meaning that each function should contain object identification to specify which objects are treated in the function. Different data models for caching can be used, for example, hierarchical data structures (trees) or hash tables. Today, many libraries are available for the implementation of such data models.

Granularity of data: To avoid unnecessary roundtrips in the client–server communication, it is important to find an optimal granularity of the data handled by the Web Services and transferred between the service requestor and the service provider. While fine-grained data entities lead to smaller sets of data, coarse-grained entities create relatively large data chunks. For Web Services using SOAP as a protocol, each invocation of a Web service needs to parse the XML document request and construct the XML response. Fine grained granularity may cause more roundtrips and more efforts for parsing and constructing the XML data. A tradeoff between the fine- and coarse-grained strategy will help to increase performance. For the coarse-grained strategy, the service provider may provide more information than the client needs for a particular request. However, if the client issues similar requests, caching the data may improve response time. This is especially true for clients making synchronous requests, since they must consider the time to construct the response in addition to the time to transfer the data.

For an automation system, the proper granularity can be found based on an analysis of data, regarding which data are logically related and typically used together. These data entities can be put together and transferred as a chunk. For example, if for monitoring and controlling some process variables such as temperature and pressure shall be displayed together, they can be grouped into a data chunk. For manufacturing execution systems, all information on the work order can build in a single data set.

Bundling Web Services

Another way to improve performance and to reduce the number of roundtrips is to bundle Web Service calls. As already mentioned, each web service invocation requires dealing with XML data, including constructing the XML request and response as well as XML document parsing. This may become critical if a great number of sequential Web Service calls are involved to fulfill a task. A potential solution to improve performance is to bundle the sequential Web service calls to create one single call. The Service Request Bundler on the client side and the Service Request Unpacker on the server side (Figure 100.5) can be used to implement this mechanism.

Serialization

Complex objects and data structures must be serialized to be transmitted, causing an overhead for serialization and deserialization and the volume of serialized data. There are two kinds of serialization:

XML Serialization: This is the default serialization model. When a Web Service returns a complex data structure, it is serialized to XML, producing a significant overhead in the size of the data being transmitted. XML, or SOAP serialization, is platform-independent. This kind of serialization can be used for static data such as asset information, plant structure, and so on.

Binary serialization: Objects are serialized into a sequence of bytes, and transmitted inside a SOAP envelope. This reduces the overhead introduced by XML serialization, but platform independence is lost. Also, it is necessary to introduce some code to manage the serialization and deserialization processes. This kind of serialization is especially suited for real-time data.

© 2005 by CRC Press LLC

Object Designator

The object designator [9] identifies objects and their properties, which need to be processed by Web Services, both on the service requestor and the service provider side. As mentioned earlier, all functions in a Web service should have an object designator as one of their parameters. There are two methods to identify an object in an information system: direct and indirect.

The direct identification method uses a globally unique ID (GUID) to reference an object. The prerequisite is that all information objects or entities are assigned such GUID when they are created. The information system also has to provide the structure to access objects by using GUIDs. Direct identification methods are a very easy way to identify objects, because a client can obtain an object by just supplying a GUID without any complex or complicated navigation. Another advantage is that the server running the information system can be switched to a backup system without affecting the current clients if the same GUIDs are used in both systems. A drawback, however, is the consumption of additional memory and hard disk capacity to manage the potentially large number of GUIDs.

The indirect identification method uses relationships such as aggregation, composition, etc. among objects to identify an object. The indirect identification method usually needs less memory and hard disk capacity, but the reference may be much more complicated.

The object designator can also be used to identify the position of an object in the structures. Obviously, the designator depends on the structure it is addressing, that is, it is structure-specific.

Client Addressability

In an automation system, client addressability regards

- how the service provider finds the suitable service requestors and
- how the service provider informs its service requestors of what has happened on the server side.

An alarm and event server is an example where client addressability is important. Two basic mechanisms are necessary to have client addressability in an automation system with Web Service support. The first mechanism allows for subscribing and unsubscribing events so that the service requestor can be notified about messages coming from the service provider. The second one regards cyclically querying (polling) the service provider to check if any events or messages have occurred. The basic components are the event service proxy on the client-side and the event service on the server-side (Figure 100.5). The event service proxy on the client-side deals with registering, polling, and managing event handlers for the service requestor. The event service on the provider-side is responsible for event queue management and functionalities like registering and managing event handlers. The Event Service Proxy and the Event Service in Figure 100.6 are the basis for the implementation of event-handling mechanisms.

100.7 Future

We have discussed various challenges and solution concepts to address interoperability — a key issue in integrated automation systems. Platform and programming language neutrality is the important feature of Web Services to improve interoperability among various applications for automation tasks such as simulation, data processing, presentation, and management. With increasing complexity and size of integrated automation systems, especially when more and more applications from business management, MES, and different phases of product lifecycle are involved, efficient system engineering and assembling may emerge as a new challenge. Data modeling, computation modeling, association of the computation elements (software applications, components, process modules) to data models [10], efficient composition of systems with existing applications and modules that are implemented in the form of Web Services are just a few examples for the new challenges.

The further development of Web Services technology — automatic Web Service discovery, automatic Web Service execution, and automatic Web Service composition and interoperation [11] — will help to address these issues.

© 2005 by CRC Press LLC

Ontology as an explicit specification of conceptualization [12] will likely play a more important role in the development of Web Service and integration technology. The traditional software (applications, modules, components), especially component-based software, uses the interface description language (IDL) to describe functionalities. It provides a way to describe the semantics of applications or components on a very low level. The description is platform- and programming language-dependent and can only be used for certain platforms such as COM or CORBA. Web Services use WSDL that is based on XML and thus independent from platform and programming language. From that point of view, it is better than IDL, but it still cannot address the description of semantics on a high level such as relationships among Web Services, domain knowledge, concepts, and so forth. Web Ontology [13] is a natural next step of technology development to address this problem. It uses controlled vocabularies or terms to encode classes and subclasses of concepts and relations. It can be used as an additional semantic layer that may sit on top of the data model and computation model including software applications, modules, or components, as illustrated in Figure 100.7. In this way, data model and computation model may share the same ontologies, or the ontologies used for data and computation model can be mapped or transformed in a simple way. The essential issue for successful use of ontologies is efficient ontology engineering. It includes creation of unified and standards-based ontologies, ontology management, ontology mapping and transformation, ontology matching, and so forth. Obviously, ontology engineering, which is aimed at creation of unified and widely accepted ontologies, is not an easy work. It is a long-term process and needs cooperation from different related stakeholders. Creation of ontologies based

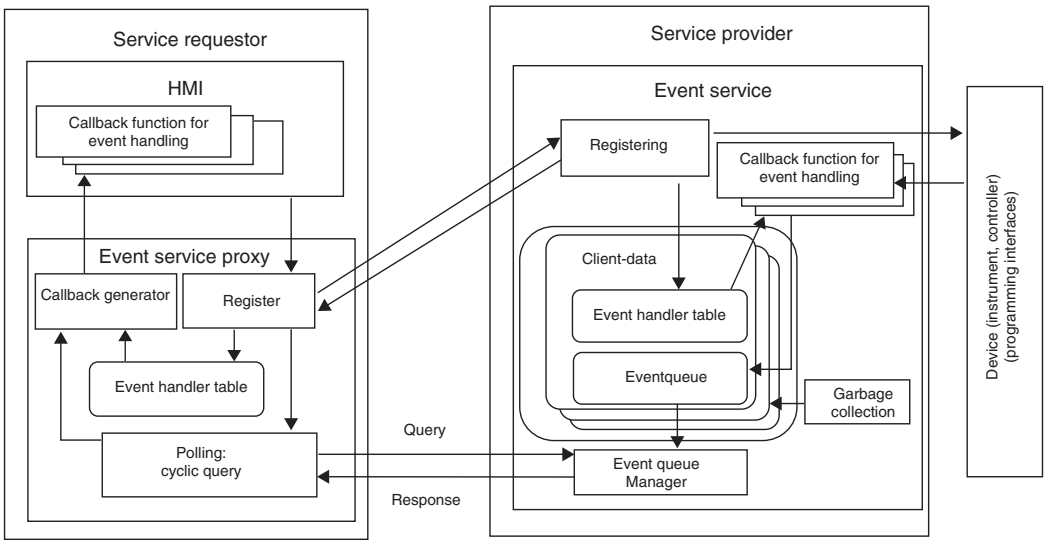

FIGURE 100.6 Event Service architecture.

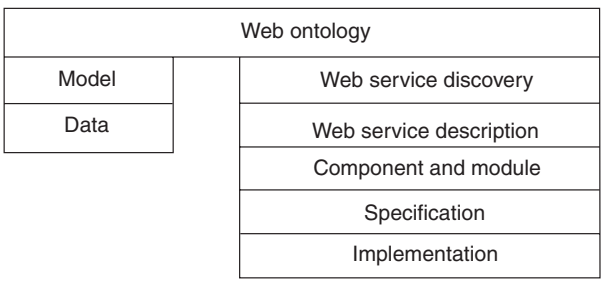

FIGURE 100.7 Data and computation model with ontology layer.

© 2005 by CRC Press LLC

on existing standards could be an effective way. For the integration in automation systems, different ontologies such as domain ontologies and computation ontologies are needed.

For engineering, the full use of other Web Services' features, namely the service broker and service discovery, aggregation, and choreography will facilitate searching for suitable components and aggregating applications to build an integrated automation system.

100.8 Conclusion

In this chapter, we have discussed the use of Web Services for implementing integrated automation systems. We believe that performance, client compatibility, client addressability, object designation, structure navigation, and security are very important for integrated automation systems and pose major challenges. The solution concepts based on Web Services have been presented, such as the structure cursor, the client- and server-oriented cache, Web Services bundling, the object designator, and the event service. More efficient system engineering and assembling will definitely benefit from the further development of Web Services technology such as automatic discovery, execution, composition, and interoperation.

101.1 Introduction

More efficient use of production equipment, best possible scheduling, and optimized production processes are the challenges in today's process and manufacturing industries. These trends become apparent for a wide range of industries such as electric utilities [1] and production facilities in batch and chemical operations [2,3].

With numerous software systems already in place in most production facilities, the challenges ahead lie in seamless integration of the IT landscape, with one of the focus points in manufacturing and process industries being the connectivity between plant floor execution and business systems. Effective and accurate exchange of information is the means to meet those challenges. Existing IT integration projects focused on delivering data from one system to the other, but usually the integration methodology has not concentrated on reusable solutions.

The goal is to shift efforts from point-to-point solutions, which come with a high coding effort when connecting single data sets toward reusable components, which form building blocks of an enterprise — plant floor integration architecture. The challenge is to leverage existing mainstream technologies such as

© 2005 by CRC Press LLC

enterprise application integration (EAI) [4], web services [5] or XML [6], and emerging industry standards (e.g., ISA 95 [7] or CIM [8]) and apply them in the context of the usage scenarios found in today's production environments.

This chapter presents the concepts of an integration study between production and business systems. A software architecture combines a set of functional components for implementing interfaces between manufacturing execution systems and business systems, containing all the elements necessary to develop, execute, and operate the integration in all likely scenarios, including real-time data exchange from shop floor to board room, near-real-time message and event oriented, and periodic data exchange that extracts and imports data in bulk.

The benefits of the integration concept include:

- Reduced overall effort by developing a single architecture for all connectivity scenarios.
- Faster time-to-market for new functionality, since the focus lies on developing this add-on components instead of developing "infrastructure."
- Reduced interface development effort by utilizing tools and templates to jumpstart development.
- Reduced maintenance costs since each interface is implemented using the same technology concepts.

The study presents thoughts on features to be considered in the architecture and technologies that should be used to implement the functional building blocks. The concepts presented are based upon the experiences of the authors and research of recently available technologies. Key elements of the concept are confirmed in proof-of-concept and prototyping activities.

Objectives and Scope

The objectives of the document are to provide the reader with an understanding of the following:

- Initial functional and technical requirements driving the development of the architecture.
- Technology guiding principles used as the basis for making decisions on the selected technology.
- Available integration technologies and approaches.
- High-level design for the integration components.

This chapter is technical in nature and is intended to be read by (technical) project managers and software architects. It assumes basic knowledge regarding functionality performed by the key applications in the integration context — Manufacturing Execution Systems (MES) and Enterprise Resource Planning (ERP).

Document Organization

The chapter is organized as follows: Section 101.2 presents example functional scenarios that provide fundamental requirements for the overall software architecture. Section 101.3 presents integration types, features, and the technology guiding principles that are required to fulfill the base requirements outlined. Integration types define the different technical integration scenarios (view, functional, and data). Required features address the characteristics of architectures common to each integration type. The guiding principles provide high-level criteria that are used in selecting between the various technologies available in constructing the architectures. Additionally, the main components of the presented prototypes — an ABB production system based on the Industrial^{IT} framework and SAP's R/3 system — are outlined with a focus on its main interfacing points and structuring concepts relevant for integration. Sections 101.4–101.6 outline the available technologies being considered for the integration architectures. Each of them addresses an exemplary use case, the architectural concept, and the prototype design of a specific integration type as defined in Section 101.3.

© 2005 by CRC Press LLC

101.2 Integration Scenarios in a Production Environment

Functional Interaction

In a production environment, three generic scenarios (Figure 101.1) can be distinguished:

- *Make* (*intraenterprise integration*): This scenario includes data exchange between business and execution systems within one plant (or company) in order to automate data synchronization, and to optimize production and maintenance schedules.
- *Make/buy* (*business-to-business*): Information from the supplier side is included for optimization reasons, as, for example, scheduling the production triggers placement of orders to a supplier, or production scheduling depending on the availability of raw material from a supplier.
- *Make/sell* (*business-to-consumer*): Production information is available toward customers, for example, availability or production capacity information. Production can be optimized toward certain customers (urgency), or customers can track the production progress of the placed orders.

In the following sections, the focus lies on the intraenterprise integration between MES and business systems. It has broad applicability across several industries such as chemical, food, primary pharmaceutical, and to some extent discrete manufacturing. It is also of importance in the context of process industries and utilities, where the trend of interaction between production and back-office becomes more and more apparent.

Interenterprise Integration Scenarios

Table 101.1 summarizes the transactional "data" interfaces between production planning and materials management modules of an ERP system and the MES systems that typically result from the above-outlined

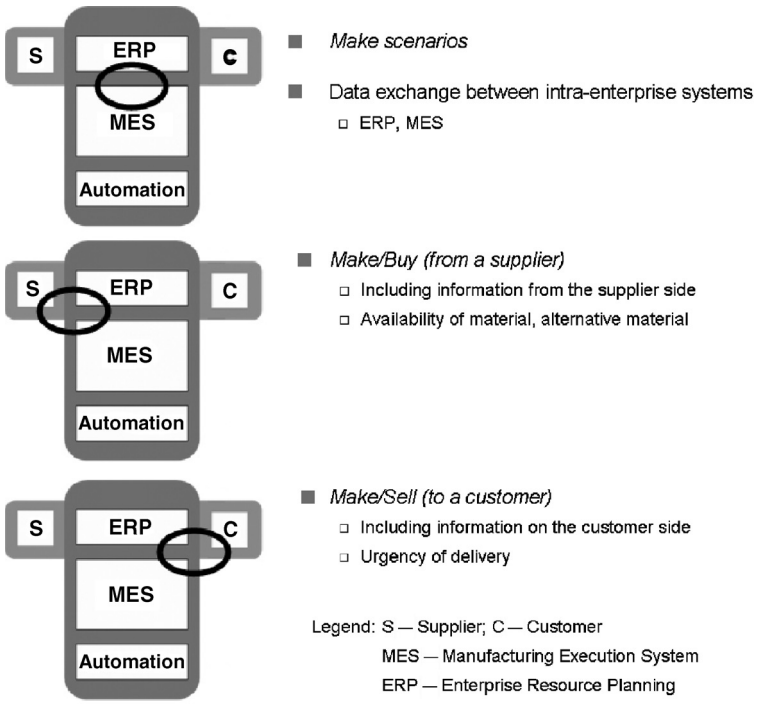

FIGURE 101.1 Integration usage: three main scenarios.

© 2005 by CRC Press LLC

TABLE 101.1 Sample Functional Integration Requirements for the "Make" Process

From	To	Description
Production planning	MES	Released production orders — Production orders created in production planning or scheduling are released and then sent to MES.
Production planning	MES	Production order changes (dates, quantity, released bill-of-materials [BOMs], recipes and production parameters, routings, and cancellations) — Production order changes are sent from ERP to MES.
Production planning	MES	Master data (BOMs, recipes, routings) and changes are sent to MES.
MES	Production planning	Production order start/stop (typically included in confirmation transactions) — MES users input command: START/STOP and data are sent to ERP system.
MES	Production planning	Production confirmations (in-process and final confirmations) — MES sends production confirmations to ERP.
MES	Production planning	Production order and schedule changes (quantities, dates, cuts, adds) — MES input changes and data are sent to ERP.
MES	Production planning	Material and process deviations (changes to released BOM, recipe and routings) — MES users input command: CHANGES and data is sent to ERP.
MES	Production planning	Real capacity information — Data sent from MES to ERP for improving scheduling.
MES	Production planning	Execution events (batch history) — Data are sent from MES to ERP.
MES	Material management	Inventory transactions (moves, issues, receipts) — Data from MES is sent to ERP.
Plant maintenance	MES	Maintenance time is synchronized with production plan and spare parts.
Plant maintenance	MES	Maintenance schedule of a device in order to chose alternate production routings.
MES	Plant maintenance	Detection that an asset is performing poorly. Send a work order notification to plant maintenance.

application scenario of ERP and MES functionality, showing the many interfacing points for optimizing and automating data exchange.

Out of the above, the most generic patterns of the functional interaction between production and business systems can be extracted and are outlined in the following sections.

Download of Production-Relevant Information to an Execution System

This step typically involves scheduled production orders, which are released from the business system (production planning) and are transferred to a production execution system. During this process, a number of data mappings take place: the order recipe is mapped to a production recipe and recipe parameters are resolved (e.g., quantity, production line, equipment, and time and date). If unplanned, late changes occur, information must be communicated to the production system, as, for example, order size or order quality since such changes may impact the current production schedule.

Upload of Status Information from a Production System

Upload of status information from the production system includes deviations of the produced order from the actual production status, by, for example, order size, quality, material locations, and material usage. Furthermore, if the status information is continuously sent to the business system, the data can be used for detailed tracking of the production progress.

Data Exchange Between a Production System and a Maintenance Management System

Automating the process of creating work orders due to equipment malfunctions and performing rescheduling of production due to lines in service can be achieved by synchronizing events from maintenance and production planning modules. Maintenance planning can be taken into account in order to calculate actual and planned capacity of production lines. This allows timely shifting production to alternate lines if maintenance actions are necessary in parts of the production facilities. Users can access equipment

© 2005 by CRC Press LLC

maintenance reports to identify causes for degrading production quality and schedule an order on alternate production lines already on the planning level.

Data Exchange between a Production and Scheduling System

Using history information from production (e.g., planned vs. actual material used or time needed to perform a production recipe in planning systems) allows more accurate forecasts and optimized production schedules. A planning system allocates all equipment resources for a specific recipe during the execution of the order. If the production system additionally provides detailed information on the equipment usage (e.g., when and how long an equipment is needed), capacity forecasts and scheduling can be optimized.

Summarizing, the integration scenarios range from simple data exchange to complex data mapping and routing functionality. To each of these, one or several appropriate technical integration solutions can be mapped.

101.3 Technical Integration

Integration Options

Depending on the functional integration requirements of data exchange, synchronization, and user access, four technical integration options (Figure 101.2) can be distinguished. They differ with respect to the number of involved systems and therefore the level of complexity, which in turn has a direct effect on the customization effort and adaptations that have to be made. While less complex systems with fewer numbers of interfacing points can be productized quite easily, larger systems with a high number of intersystems communications are usually tailored toward customer requirements.

View integration allows access to a target system, for example, ERP through its Graphical User Interface (GUI), which is embedded in the calling system. This can either be realized by linking the application GUI by simple command calls or through web-based navigation, which effectively depends on the display capabilities of the target system. In other words, for example, a user has access to transaction screens in an ERP system from his MES workplace and therefore can update order changes or material consumptions directly. View integration becomes more powerful if context-based information is shared between the source and target system, as, for example, a device or batch identifier is shared between the systems, which in turn eases the usage for users since it minimizes navigation effort to the requested information. View integration is a real-time user interaction with another system — accessing ERP transaction from

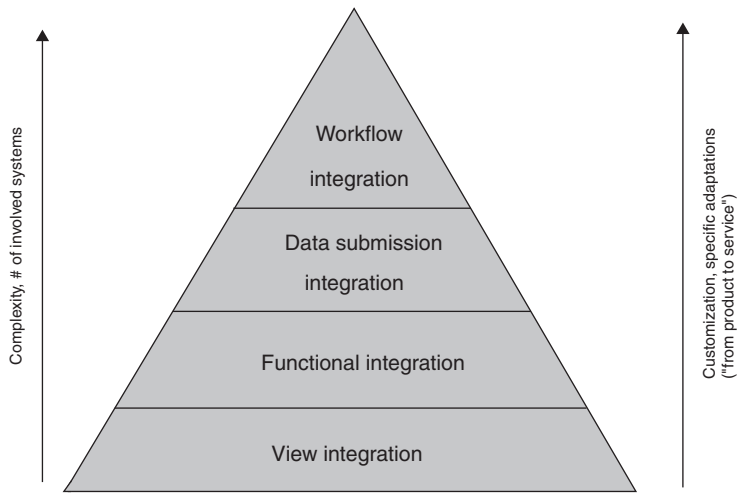

FIGURE 101.2 Technical integration options.

© 2005 by CRC Press LLC

within MES environment — and by thus blocking other activities while a transaction is in process. Also, changes to data do not become visible until the transaction has completed.

The *functional integration* option realizes interaction between plant-floor and business systems through Application Programming Interfaces (APIs). Data are exchanged through programmable services at two sides, the production and the business system, by thus separating user input (GUI) and data exchange points. View access to the data can be fit to specific requirements of certain user groups such as operators or production engineers. Similar to the view integration, the functional integration also requires context information to be shared between the systems.

An Enterprise Application Integration (EAI) component provides the integration layer for the *data submission* scenario. The component provides data transformation and message-based routing as key functionalities, since both involved end-points (business and production systems) do not track the published information, such as releases of production orders (business system) or the status of the production itself (production system). Data submission requires APIs on all involved systems.

Data submission functionality is either triggered from *events,* or scheduled in the form of *bulk data transfer*. Since EAI components, in most cases, work through message queues, both the business and the production system must not be connected all the time — the information is stored in queues and delivered as soon as the message channel is available.

- *Event-based* functionality is primarily used to monitor for events on one system, such as a data change, that immediately initiates a transaction on the other system. A context (message identification) is required to decide how to handle the information received.
- *Bulk data transfer* is used for interfaces that are either time dependent or involve large volumes of data. It allows the scheduled extract of multiple records from one system an intermediate transformation and the scheduled import into the other system. The architecture is developed to address interfaces originating in either ERP or MES.

Workflow processing components manage their own data sources and computation states and update this information while processing data flows. A simple workflow (e.g., based on the content of the data) can create, modify, or delete order entries in the production or business system. Examples for advanced workflow processing are advanced scheduling and balancing algorithms or order management, which might not be available as functional modules in either business or production systems themselves.

All components — view and functional integration, as well as data submission — are needed for workflows as the functionality is a mix of user-driven and event-based business process steps.

In general, two concurrent concepts can be distinguished in terms of workflow definition, administration and execution.

- A *centralized* solution using standard EAI tools. They provide means to define workflows through an orchestration engine, which supports the users in graphically defining the steps involved in a business workflow, the specification of data exchange maps for the single steps of the workflow, and the integration of the components from, in our case, MES and ERP system.
- A *decentralized* solution where each participating component administers its own workflow part (function, engine, data translation) but does not know of the overall business scenario. The entry point of the function is responsible for orchestrating the different subfunctions, which are registered in a lookup service (e.g., UDDI) on a domain basis (e.g., each participating system registers a function supporting "outage management"). A component manager on both systems supports the translation from the service lookup to the individual services and functions on the systems that are included in the workflow. Each participating function will only know of its subworkflow and performs the individual services lookup for the following step.

However, both concepts still have to be tested and evaluated with respect to both their applicability in a production environment and their performance for the general characteristics such as reliability, transaction safety, or scalability, which are of utmost importance for a guaranteed execution of workflows. Therefore, they will not be covered in detail in this chapter.

© 2005 by CRC Press LLC

Guiding Principles

The following principles shall be used to guide the development of the technical architecture and product selection decisions throughout the design process:

- utilize standards to ensure compatibility with current and future IT developments and encapsulate existing APIs of MES and ERP;
- design for large-scale, complex enterprise environments and provide an infrastructure for secure, reliable, and predictable execution;
- facilitate the rapid generation of new functional interfaces by leveraging "off-the-shelf" technology and tools from known vendors; and
- create an extensible integration architecture that can eventually be used to integrate MES with other applications in addition to ERP.

The following characteristics were taken into account for the design of the prototype architectures:

- *Reliability*: Guaranteed transaction processing, logging, and audit trails.
- *Scalability*: Support for multiple processor machines and server farms; distribution across multiple tiers.
- *Interoperability*: Support for multiple platforms and message transport protocols; support for web service technologies.
- *Adaptability*: Highly configurable allowing for fast adoptions; support the ability to adopt new client user interfaces, and modular to isolate changes within a tier.
- *Availability*: No single points of failure; support for clustering, load balancing, backup, and restore; and monitoring services.
- *Maintainability*: Tools that assist in interface development, usage of widely available technologies, and support for templates and programming standard guidelines.

Integration Approach and Typical Use Cases

The integration concept supports large-scale, high-volume integration scenarios typically encountered in enterprise environments.

Table 101.2 describes real-life examples in a business context of different types of integration that are usually found across a production environment. These include a subset of the user interface and "data"-oriented interfaces. Subsequent sections will refer back to this table.

In the following chapters, the main technical concepts for the integration scenarios are described covering in detail the *view*, *functional*, and *data submission (event-based and bulk data)* approach.

For each scenario, a typical use case is presented from both a manufacturing- and process industry-related scenario or from an energy production and delivery scenario of electric utilities. The main technical concept behind the integration is presented and a prototype integration that uses specific technologies is outlined.

Prototype Components

MES

Today's MES systems are of a monolithic architecture exposing a system-level interface only to exchange production-relevant information, such as product information (recipes, parameters) or production status information. Scheduling is most often provided from the ERP or advanced planning level; however, the MES application will often perform the detailed scheduling of operations that are highly dependent on the manufacturing process (e.g., creating a detailed schedule to consume a roll of paper to produce an end product, where the production scheduling optimization depends on the quality of the paper as it relates to the location on the roll) [9].

© 2005 by CRC Press LLC

TABLE 101.2 Example Scenarios

Description	Real-Life Example	Illustrated Approach
Production orders and confirmations — Production orders from ERP are downloaded into MES. These orders include recipes stored in ERP.	Production orders created in ERP production planning or scheduling are released and then sent to MES. Recipes are copied at the time of a production order release and sent to MES. The MES creates line-specific versions of the recipes, prepares, and initiates production.	Data submission (event)
	Under control of the control system, a box is filled with a product. After packaging, one unit of production is recorded in the MES system. Once an hour, material production confirmations for a production order are summarized, by material, and sent to ERP as a single production confirmation.	Data submission (bulk)
	Alternatively, the single unit of production is sent immediately from the MES to ERP.	Data submission (event)
Detailed status and schedule changes — Dates, quantities, and cancellations are input by a scheduler into ERP or by a shop floor supervisor into MES.	A master scheduler receives a phone call from customer service with an urgent request to increase a released production order by 10%. After ensuring that the order has not started and that there are sufficient components, the scheduler increases the order by 10%. This change is sent to the MES for execution.	Data submission (event)
	Alternatively, at the beginning of a production order the supervisor discovers that a key component is 50% short and that additional components cannot be expedited into the shop. The supervisor navigates to the ERP production order screen and changes the quantity expected by 50% giving visibility to customer service and production scheduling.	View or functional (UI)
Materials — A shop floor supervisor may make a material supply inquiry or a material demand inquiry.	The material pick list in the MES system is calling for more material than is physically present. The shop floor supervisor navigates to the material supply screen in the ERP system to investigate alternate locations for the required materials.	View or functional (UI)
	Additionally, a shop floor supervisor must decide which of two different high-priority component orders to run. From the MES system, the supervisor navigates to the material demand function in the ERP system to view the "pegged" demand for that component.	View or functional (UI)

Throughout this chapter, the MES referenced to is ABB's batch production system, based on ABB's Industrial^{IT} architecture. Production equipment and recipes can be configured and managed from the framework. Users can view progress of production orders or details on the execution.

The following paragraphs summarize the architectural building blocks as realized in ABB's Aspect Integrator Platform (AIP) being the central component of ABB Industrial IT architecture (Figure 101.3) AIP constitutes the glue between all components of the control system and the MES system.

Aspect Objects and Aspect Object Types. Concepts, actors, and entities that are relevant within the enterprise and plant context, for example, motors, robots, productions cells, valves, pumps, products, processes, customers, or locations are represented in the control and production system as aspect objects. In the following, we will refer to it shortly as objects.

Each object in the system is an instance of an object type. Object types, which are related by inheritance hierarchies, determine which aspects and aspect systems (see below) are associated with each object instance.

Instances of objects are organized hierarchically in so-called structures — means to define groupings from a user perspective, such as a location or functional structure. Structures also describe the dependencies between real objects in a certain navigation context. An object can exist in multiple structures (Figure 101.4), for example, a motor object in both a functional and location unit structure. Each structure represents one meaningful context and notion of relatedness between objects. For example, an

© 2005 by CRC Press LLC

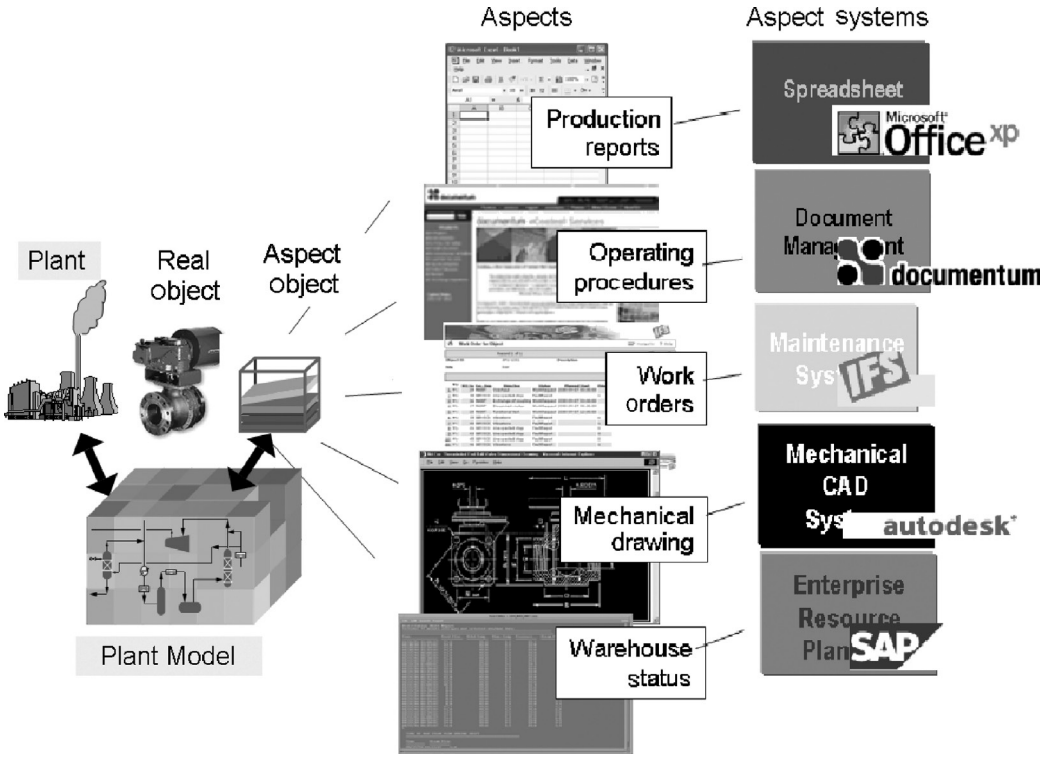

FIGURE 101.3 Aspect Systems and Aspect Objects.

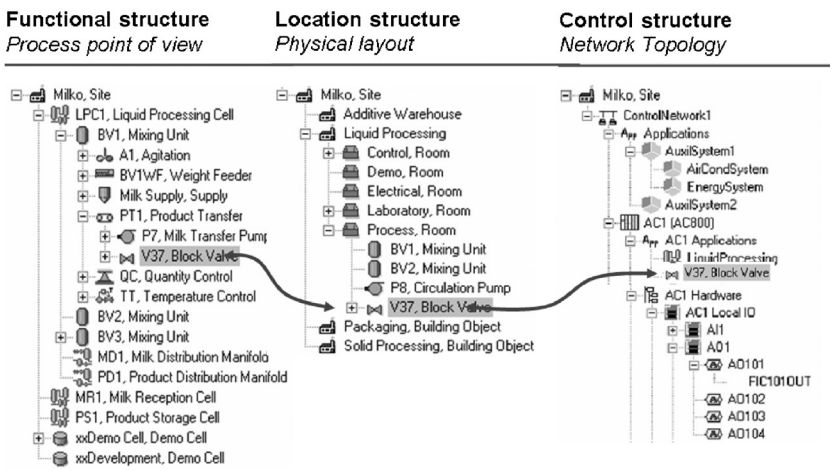

FIGURE 101.4 Structuring concept of Aspect Object.

asset is (a) a technical equipment, (b) a member of an organizational unit such as a production cell, (c) located at a certain place, and (d) participates in a production process.

Aspects and Aspect Systems. Each object carries a number of so-called aspects. An aspect is a component encapsulating a subset of data (attributes) and corresponding methods, associated with the object and relating to a common context or purpose (e.g., all maintenance attributes of the equipment objects of a production cell object are part of the consolidated maintenance data aspect of the, e.g., pump object).

© 2005 by CRC Press LLC

Aspects also serve as ports to external data sources. Data are exchanged via protocols like OPC, HTTP, or specific connectors to various ERP systems. Aspect systems are the information access applications with or without user interface, which are used to view, edit, maintain, store, and process the information contained in the aspects of an object.

Within AIP, aspect systems can also transparently access any other aspects that allow navigating between aspects in the same context. From the process-related information displayed as process graphics, the user can thus navigate seamlessly to the maintenance related information (e.g., a work order) without losing the context of the object (e.g., object name, object identifier).

Its Aspect Object architecture assumes a system of computers and devices that communicate with each other over different types of communication networks. This layered network (Figure 101.5) consists of

- The *Intranet,* user for communication with thin clients such as mobile devices or browser-only work panels, but also access to third-party nonproduction systems, such as ERP.
- The *plant network,* used for communication between *servers*, and between servers and *workplaces*. Servers run software that provides system functionality, and workplaces run software that provides various forms of user interaction, such as process graphics, alarming, or trending.
- The *control network,* a Local Area Network (LAN) that is optimized for high performance and reliable communication with predictable response times in real time. It is used to connect c*ontrollers* to the servers. Controllers are nodes that run control software.
- *Fieldbuses,* used to interconnect field devices, such as I/O modules, smart sensors and actuators, variable speed drives, or small single loop devices. These devices are connected to the system, either via a controller or directly to a server through, for example, OLE for process control (OPC).

ERP System

SAP's Production Planning and Plant Maintenance modules act as the respective ERP components in the outlined prototype scenarios.

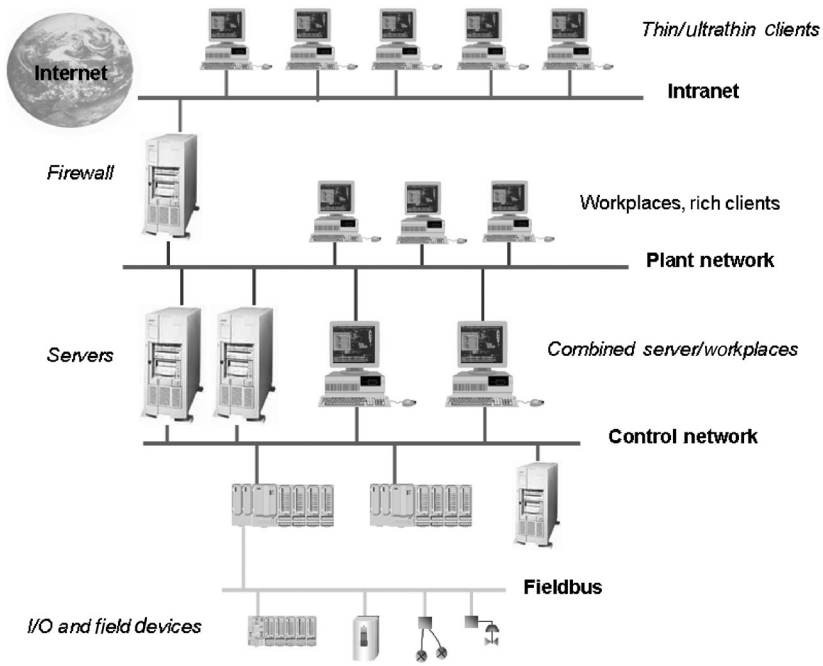

FIGURE 101.5 Industrial IT network architecture.

© 2005 by CRC Press LLC

Calling specific functionality in SAP is available through different mechanisms. In this scope, the Business Application Programming Interfaces (BAPI) and Intermediate Documents (IDoc) mechanisms are covered. While the first one is a functional interface, IDocs utilize message queues.

An object-oriented approach for access to SAP systems has been introduced by SAP providing business processes and their relevant data as business objects. External applications can access the SAP business objects via standard interfaces called BAPIs. BAPIs offer an abstract, object-oriented view and keep implementation details well concealed. As a consequence, BAPIs represent the building blocks for the construction of interacting components, with the outside world being accessible through a variety of technology connectors (e.g., JAVA, COM, .NET).

IDocs are used in an SAP context to exchange messages with other SAP systems or third-party systems. Messages are sent asynchronously, possibly even as batches. A message carries data, which typically are split into multiple semantically meaningful segments. These segments may be structured hierarchically. Together with the data, a message exchange is accompanied by a control record, which specifies the source and routing of the message, and a status record, which tracks the life cycle of the message.

The IDoc and partner definition process consists of the following sequence of activities:

- IDoc definition (segment definition and message type definition).
- Linkage of IDoc to message type.
- Definition of ports and RFC destination.
- Definition of partner profile.
- Linkage of IDoc and message type to application object.

Figure 101.6 graphically describes an inbound IDoc message exchange. Typically, two partners (two connected software systems) exchange a message, which in this case is a request for a list of active work orders. The message is called GetActiveWorkOrders. Both the external partner, BIZTALKCH, and the message type, GetActiveWorkOrders, have to be registered in the SAP system and configured with appropriate settings. As many partners as needed may be configured in an SAP system.

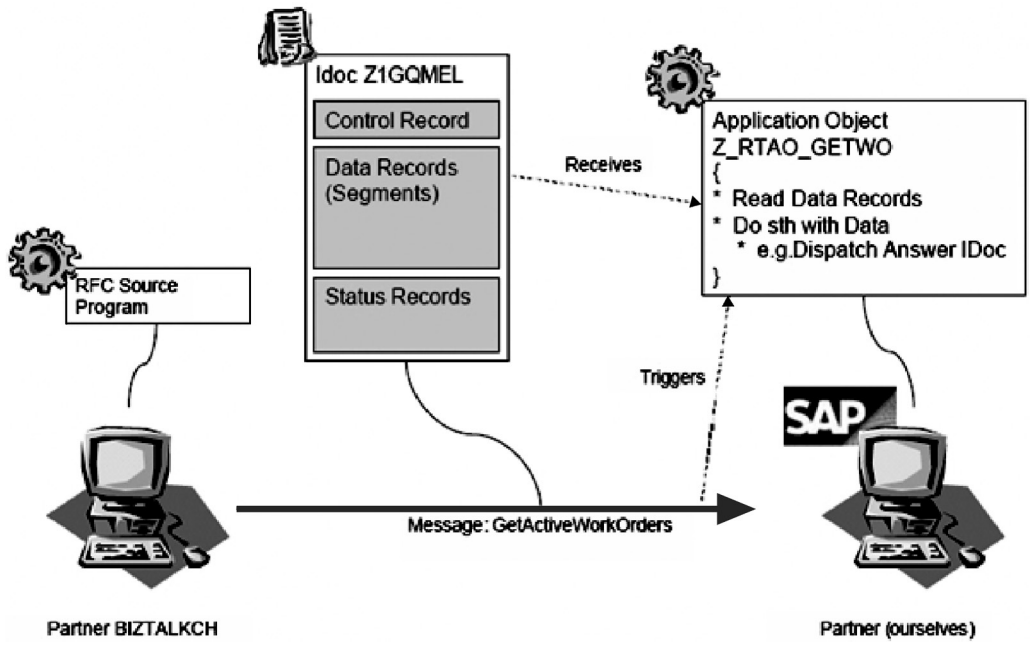

FIGURE 101.6 IDoc exchange between business partners.

101.4 View Integration

The view integration architecture is intended to provide a solution to user interface access to all business system functionality from the MES user environment. The architecture allows a production system user direct access to all user-relevant ERP transactions with context information and allows them to view, update, create, or delete data. For example, a user would be able to go directly to the list of material associated with a specific production order.

Use Case

The responsible engineer of a paint shop production line notices that the output quality of a production cell is poor; in fact, looking at color quality trends, he notices that the numbers of repainting have increased steadily over the last 24 h. With integrated ERP-CMMS (Computerized Maintenance Management System) connectivity into MES workplaces, he can access the maintenance history for the paint shop cell and its components in order to identify possible causes for the poor quality. Selecting the paint shop cell on the workplace screen, he can invoke "show maintenance history" as an action.

Last planned maintenance on the cell has been done 3 weeks ago, and the report summary indicates that a "normal" maintenance service has been carried out. Also, the performance history of the paint shop cell components does not reveal any unusual behavior.

Navigating on a GUI, the workplace, the user can select a piece of equipment and invoke through interaction with the UI one of the available CMMS functions for accessing maintenance information, which is stored in the CMMS system for the selected equipment. The CMMS data are displayed through the proprietary CMMS user interface (Figure 101.7).

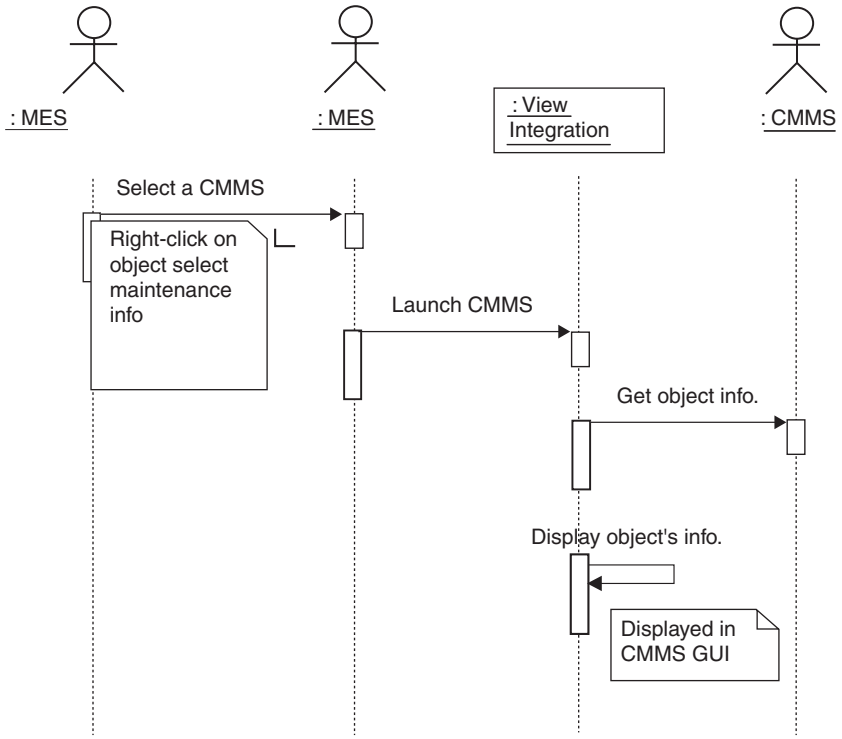

FIGURE 101.7 Accessing maintenance information.

© 2005 by CRC Press LLC

Technical Concept

The user is given the possibility to invoke an ERP transaction screen from an MES workstation. While this is a relatively easy solution to implement, it does not provide navigation from the ERP screen to other production system applications nor does it provide for data translation between the systems.

The architecture utilizes the "wrapper" capabilities of available software components such as Internet Explorer or other to encapsulate the client's transactions (ERP GUI). Through these containers, a variety of target components in the form of ActiveX controls, HTML pages, or Java applets can be accessed. To alleviate the manual configuration required, "smart wrappers" can be developed for specific ERP transactions, which automatically collect relevant context data associated with the entity when the function is initiated and embed it into the ERP GUI invocation. The equipment identifier and ERP transaction number are examples of context data that are passed. The concept of embedded context information allows navigating directly to the required transaction screens and avoiding that the user has to step through a number of menus. The architecture also provides a single sign-on capability to enable access to ERP transactions without having to provide credentials for each transaction. The primary components and message flow required for this architecture are illustrated in Figure 101.8.

Prototype Realization

The prototype builds upon the concept of representing a real-world object through the AIP Aspect Object container. By attaching relevant context information, such as an equipment identifier from the different systems (MES, ERP) as aspects, this concept allows to map and share this information when invoking the view functionality.

The prototype architecture with specific technologies is illustrated in Figure 101.9. The focus of the implementation builds on the functionality of the SAP Internet Transaction Server (ITS), which allows accessing any SAP transaction through a URL as an HTML page. Therefore, a distribution of client software to each MES workstation is not required, which in turn increases the likelihood of supporting direct access to specific transactions. Simple HTML wrappers are used to provide application access to SAP transactions with static or hard-coded context data, whereas the "smart" wrappers are able to collect the required context data to navigate to a specific instance of a transaction.

The user is able to enter the original SAP screen and to navigate in the transaction context with all SAP functionality being available (Figure 101.10). The main disadvantage of this concept is that the screens typically are not customized toward their specific needs by, for example, limiting the information presented, but present the ERP transaction screen that was usually built on requirements from other user groups.

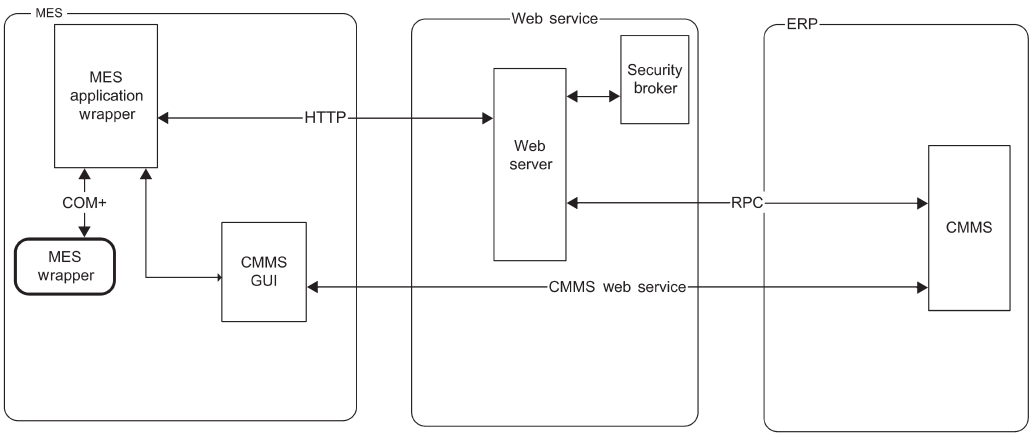

FIGURE 101.8 View integration concept.

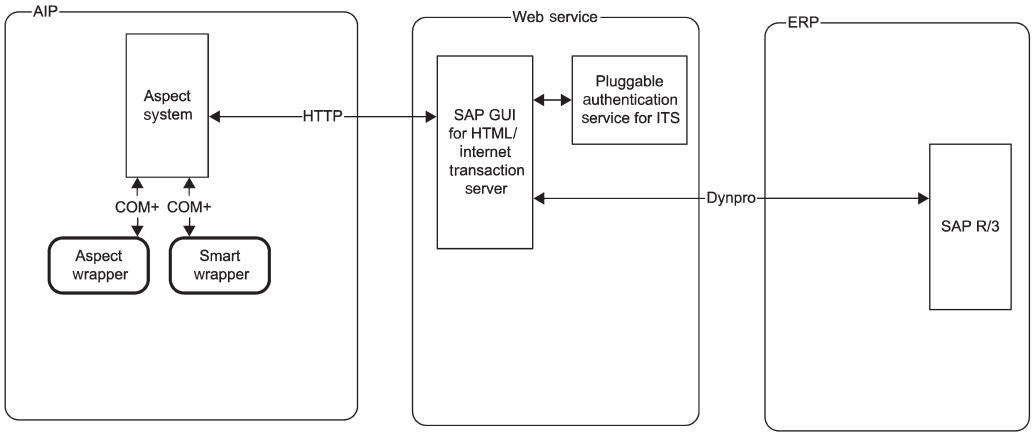

FIGURE 101.9 Prototype: view integration.

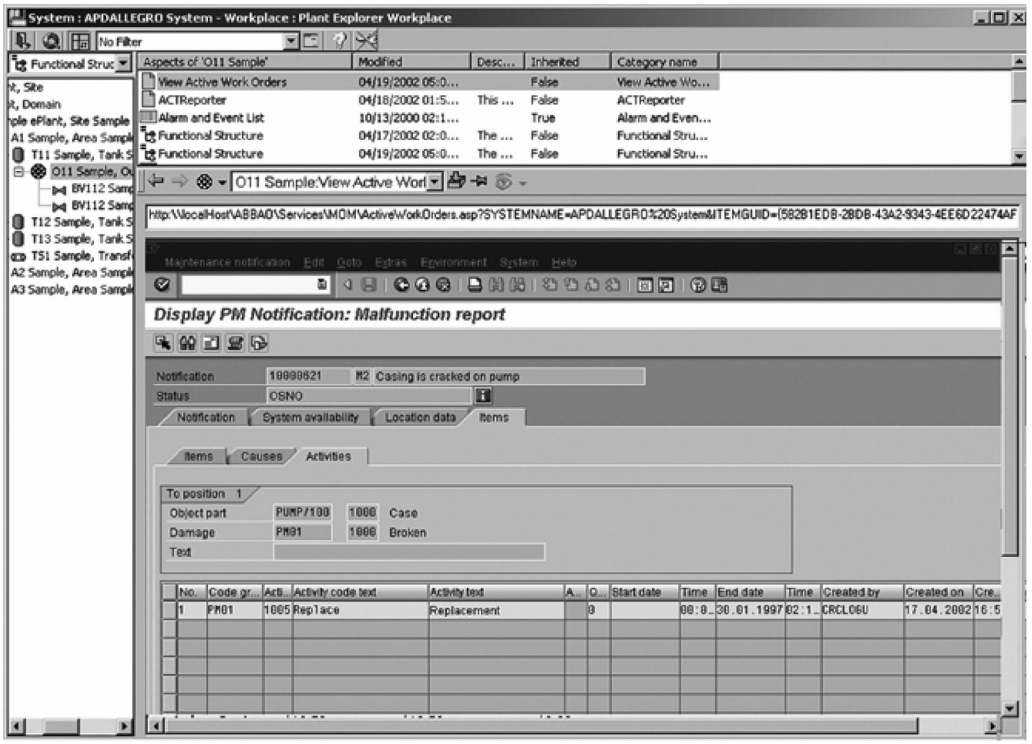

FIGURE 101.10 View integration — example screenshot.

101.5 Functional Integration

This architecture provides interface integration from MES to specific transactions in ERP and vice versa through APIs. This is enabled by defining a set of interfaces exposed toward either MES or ERP. Data exchange through interfaces and graphical representation of the data is separated, allowing developing custom GUI depending on user requirements while reducing the interface development efforts. Through

© 2005 by CRC Press LLC

definition of domain interfaces, for example, for maintenance or production, only the adapters to the various ERP systems have to be developed, while the exposure of interfaces toward the integration system remains consistent. Thus, adapting to other systems is eased, since only the adapter needs to be exchanged.

Use Case

In the production scenario from the paint shop production line, the user still is not satisfied with the quality of the cell. The next planned maintenance shutdown is scheduled in 1 week. However, since the engineer could not identify the root cause of the quality degradation, he decides to issue a maintenance request for the paint shop cell with severity "high."

Creating a maintenance request with integrated CMMS connectivity is simply done by selecting the paint shop cell on his workplace screen, and invoking "maintenance request" as action. A data screen is shown to the engineer, which already has data entered specific to the selected cell, such as cell identifier, date and time, name of the user, etc. The engineer selects priority "high," and attaches links to the quality trend diagrams. As soon as the work order is submitted, a new notification is generated within the CMMS system and the corresponding data sets are stored. Now, the maintenance planning department can analyze the attached information and decide if an unplanned shutdown is necessary (Figure 101.11).

In addition to retaining a common context as already described in the previous section on view integration, the data semantics between the systems have to be defined, ideally through a common application data model that abstracts specific application functions calls into domain APIs, such as managing maintenance requests or scheduling orders. Only such domain interfaces guarantee interoperability between systems from various vendors.

Technical Concept

Functional integration offers the ability to separate data representation and the communication between involved systems through defined APIs. In this architecture, the MES initiates a call to a web service that

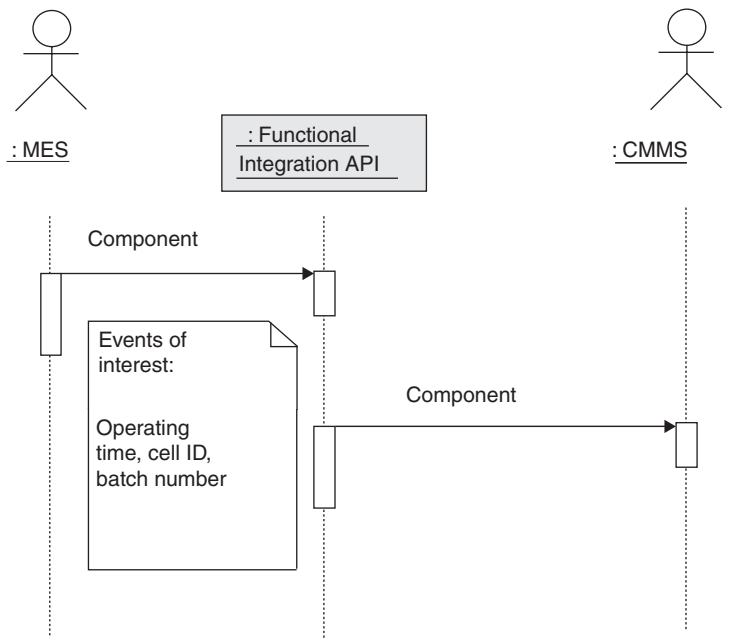

FIGURE 101.11 Transfer of quality information from MES to CMMS.

© 2005 by CRC Press LLC

exposes domain interfaces (e.g., for maintenance) and in turn uses specific ERP APIs to implement the functionality. The web service brokers access either directly to ERP through an ERP proxy component or through an EAI component and works across firewalls. The latter provides functionality such as context-based data mapping and translation. User interface components use the web services to request or post data; the transaction itself is executed with the call to a specific method on the web service itself.

The primary components and message flow required for this architecture are illustrated in Figure 101.12.

As with the view integration, this architecture could be utilized for integration points as described in Table 101.2.

Prototype Realization

The prototype architecture with specific technologies is illustrated in Figure 101.13. The user interface component gathers the required information necessary to request or process information in SAP and package it into a Simple Object Access Protocol (SOAP) packet. The SOAP packet is then submitted via HTTP to a web service, where the information from within the SOAP message is used to identify the

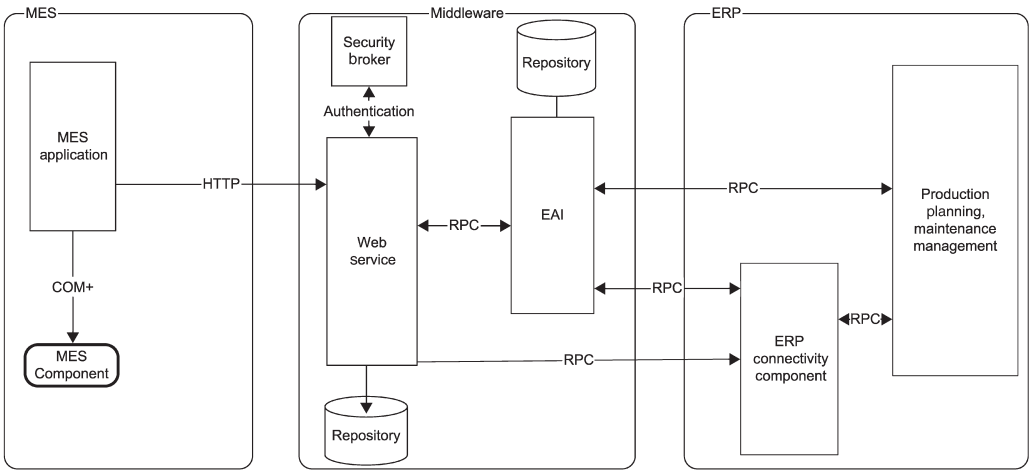

FIGURE 101.12 Functional integration concept.

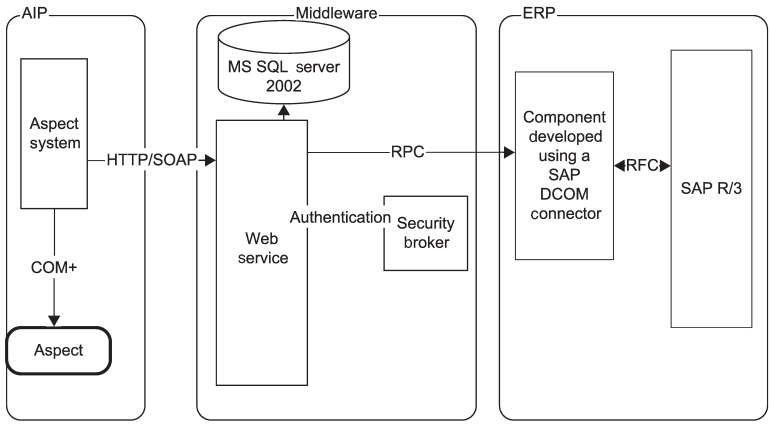

FIGURE 101.13 Prototype: functional integration.

© 2005 by CRC Press LLC

required request for SAP. As a next step, the web service queries the repository for the necessary information needed to call the SAP Microsoft Distributed Component Model (DCOM) generated proxy, instantiate the proxy, and pass the necessary information gathered from the SOAP message.

In the functional integration architecture, GUIs are typically customized (Figure 101.14) and only context-relevant information is shown in order to perform a specific task. Changing requirements result in coding efforts to adapt data mapping and API calls. Information from the ERP on the selected object is retrieved and displayed to the user through a customized screen that is tailored to his needs and omitting information which is more specific for, for example, maintenance planning. For example, a user would be able to go directly to the fault notification site associated with a specific piece of plant equipment. However, the interface definitions and the ERP specific code do not change.

101.6 Data Submission

Data submission requires functional interfaces as described in the preceding section on both business and plant-floor systems. An EAI component provides the integration layer for the data submission scenario. This component provides data transformation and message-based routing as key functionalities, since both involved end-points (business and production systems) do not track the published information, such as releases of production orders (business system) or the status of the production itself (production system). The EAI component uses functions, which query or listen for information from one system and convert data from the format delivered from the source to the format required by the target system. Since EAI components, in most cases, work through message queues, both the business and the production systems must not be connected all the time — the information is stored in queues and delivered as soon as the message channel is available. A context (message identification) is required to decide how to handle the information received through the queues.

Event-Based Data Submission

Use Case

As a precondition to the described scenario, a customer order is received by a dispatcher, who enters the order into the planning system as specified by the customer: product type, quantity, and delivery date. The manufacturing plant is manually chosen by the dispatcher. After the order has been entered into the

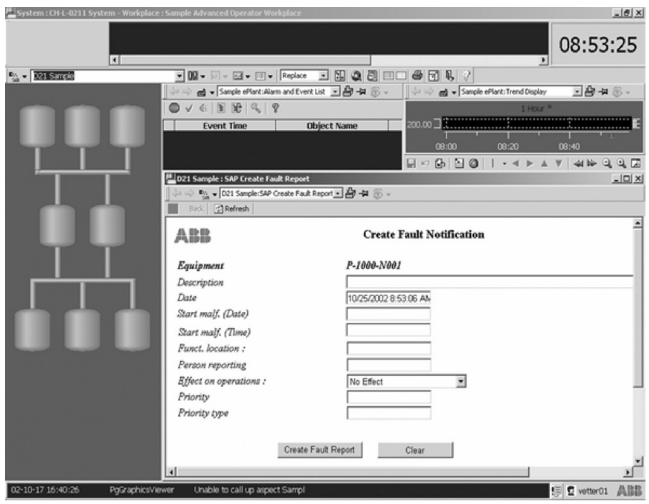

FIGURE 101.14 Functional integration — example screenshot.

© 2005 by CRC Press LLC

planning system, verification is carried out against available material in stock. The order can be released to the production system, and the relevant data are transferred.

As soon as the order is completed, status information (e.g., material used) is transferred back to the production planning system, which triggers an update of the material and inventory stocks (planned vs. actual). The dispatcher can look up the inventories and check if the order has been executed against the given customer order. As soon as the information is updated in the inventory, the customer can be notified and the delivery can be initiated.

Technical Concept

The presented architecture provides a loosely coupled integration between the MES and a production planning system. This will be beneficial in the cases where the transaction has the potential to "block" the user's workstation while they wait for a response from ERP. Instead, a user can make the asynchronous request and perform other tasks while waiting for a message to return indicating that the transaction has been processed. Requests are submitted automatically through system-generated events originating in either ERP or production system.

The implementation involves an EAI component, which interacts both with the ERP system, as well as with the production system. It is the central component of the integration architecture. Many of the other integration architecture components are determined by the EAI application selected. Utilizing an off-the-shelf EAI application greatly reduces the effort involved in developing and maintaining the integration architecture between production systems and ERP. EAI applications typically provide the following functionality:

- *Process flow integration and management*: GUI tools for process integration and management, workflow, and state management across applications and enterprise boundaries.
- *Development tools*: Including configuration management, source control, debugging tools, and general coding environment.
- *Technology architecture*: Reliability, scalability, availability, adaptability, as well as operations support.
- *Transformation and formatting*: Transformation, translation, mapping, and formatting for integration purposes (i.e., to reconcile the differences between data from multiple systems and data sources).
- *Business-to-business capabilities*: Integration with trading partners, partner management, and Internet standards support — XML, HTTP, SMTP, FTP, SSL.

Utilizing an EAI application to develop interfaces helps to reduce the long-term maintenance effort by providing a central repository for data mapping between data sources and targets. The repository allows developers to reuse mappings and translations consistently across multiple interfaces. EAI also provides customers with a platform to integrate the MES with other applications in addition to production planning.

Interaction with the production system is realized by two custom services (Figure 101.15), which hook up to the proprietary APIs provided by the production system. One service listens to production orders from the EAI component, while the other polls the status interface of the production system.

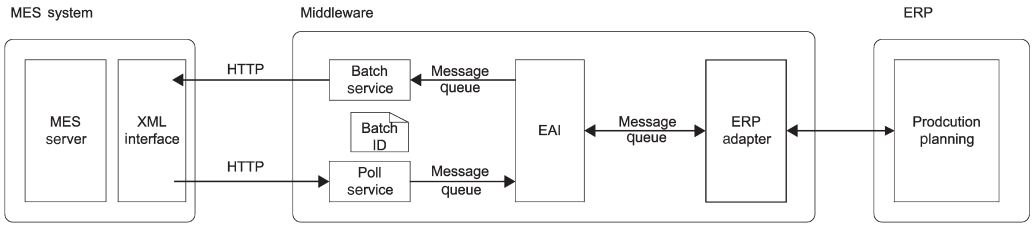

FIGURE 101.15 Event-based data submission concept.

© 2005 by CRC Press LLC

Production orders are sent from ERP to the EAI component as ERP messages and are placed in an EAI inbound message queue. The information contained in the message is read and transformed according to the defined mapping and placed in an outbound message queue. The custom service listens to outbound messages, reads the message, and calls the appropriate CreateOrder function on the production system and passes the corresponding parameters. At the same time, a log file is created containing the batch identifier number that allows the second service to correlate the status to active orders.

The second service continuously polls the status interface of the production system and checks the status of the order number that is logged. As soon as the production status changes from "running" to "completed," the service reads the status information (actual material used) from the production system, composes a message, and places the message to an EAI inbound message queue. Again, the message content is read and mapped according to the PollStatus mapping definition, and the resulting message is placed in an outbound message queue. Finally, the EAI architecture for ERP reads the message, composes an ERP message, and routes it into the ERP system.

Prototype Realization

Microsoft BizTalk Server 2002 has been chosen as an EAI component, providing the server, tools, and plug-ins needed to integrate and automate the business between the production system and ERP. A key benefit of BizTalk Server is its ability to integrate XML web services and to supply a central repository for mappings and transformations, which are stored natively in XML. BizTalk Server comes with Software Development Kits (SDKs) available for transports, document types, and application architectures. Custom BizTalk mapping functions (functoids) can be developed and reused for multiple interfaces to accommodate the specific transformations of batch data to ERP data and vice versa.

Development is performed using wizard-based design tools such as BizTalk Mapper, Orchestration Designer, and Message Manager. If needed, C# and scripting languages (as, e.g., VBScript) supporting COM or the .NET framework can be used as well.

Biztalk supports Remote Function Call (RFC), BAPI, and iDOC integration with SAP through plug-ins. There are a number of different connectors available both from Microsoft and independent system vendors that provide ERP-specific integration capabilities for BizTalk. The chosen Microsoft connector provides the following:

- retrieves iDoc structure, and generates XML schemas for iDoc automatically;
- defines routes for documents within BizTalk Server environment;
- guarantees successful delivery of an iDoc both into and out of ERP; and
- supports both BizTalk Orchestration Services using a COM component and the BizTalk Messaging Manager using a BizTalk Application Integration Component (AIC).

The architecture makes extensive use of the data mapping and transformation capabilities of EAI. Figure 101.16 depicts how BizTalk Server as one example of an EAI integration product can be utilized to define data mappings between batch and ERP, while highlighting BizTalk Server's Message Mapper tool.

Two mappings have been defined for the architecture: CreateOrder and PollStatus. The first one defines the relationship between ERP's message format and a custom message format in order to deliver the necessary information with corresponding parameters to schedule and initiate a production order. The second mapping contains status information definition for updating ERP's inventories.

The prototype architecture provides two means of submitting asynchronous requests. Requests can be submitted either through an MES user interface or automatically through system-generated events originating in either SAP or MES.

Custom UI control that collect the required input data from the user and submit or receive requests are developed through the web services features of the .NET framework. The user will receive a message indicating that the transaction has been processed as the response corresponding to the initial transaction.

An MES service monitor receives system generated events from the production system. When an event is received, the MES service formats the request into a SOAP packet and submits the packet into an

© 2005 by CRC Press LLC

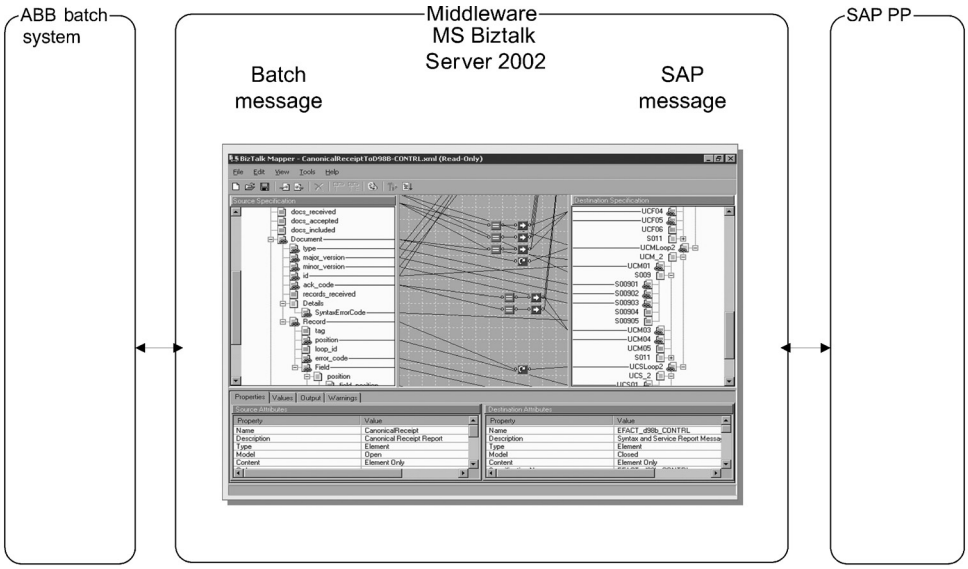

FIGURE 101.16 Message mapping.

outbound message queue. The architecture utilizes Microsoft Message Queue (MSMQ) as the transport mechanism between MES and BizTalk Server to enable HTTP as the transport protocol. The data transported using MSMQ are received by BizTalk Server, transforms, or maps the XML stream received from the MSMQ into an IDoc format to be processed by SAP. BizTalk Server then invokes BizTalk Adapter for SAP connector to submit the IDoc into SAP. BizTalk Adapter utilizes the DCOM Connector to initiate the receipt of the IDoc from SAP.

Requests from SAP to MES travel a similar route. SAP initiates the Remote Function Call (RFC) Server, COM4ABAP, through a transactional RFC (tRFC) call. COM4ABAP deposits the IDoc into an MSMQ. Once the IDoc is in MSMQ, BizTalk Server can initiate any transformations needed for the MES integration. The transformed message is dropped on an outgoing MSMQ to be delivered to an MES inbound MSMQ. The MES service reads the MSMQ, and based on the information supplied within the message, the appropriate production system API is called.

The prototype architecture with specific technologies is illustrated in Figure 101.17.

Data Submission using Bulk Data Transfer

Bulk data integration architecture provides the ability to extract data from either MES or ERP, apply a custom data transformation, and import it into the other system. The architecture is used for moving large volumes of data and for transactions that are time dependent. An example would be the periodic update of selected master data records from ERP to MES. Another example would be the scheduled summarizing of material production confirmations.

Use Case

Production schedules are released to the MES according to the incoming orders from the customer. While the MES performs a detailed scheduling of the production orders and distributes the schedules among the available production lines, the ERP system has to be notified of finished production in order to initiate delivery to the customer and fill up material stocks for remaining production. Therefore, finished production batches are collected at the MES and sent in bulk to the ERP. Additionally, every 24 h, the material consumption or the various production lines is recorded at the MES and sent to the ERP for updating stock lists and initiating further material orders (Figure 101.18).

© 2005 by CRC Press LLC

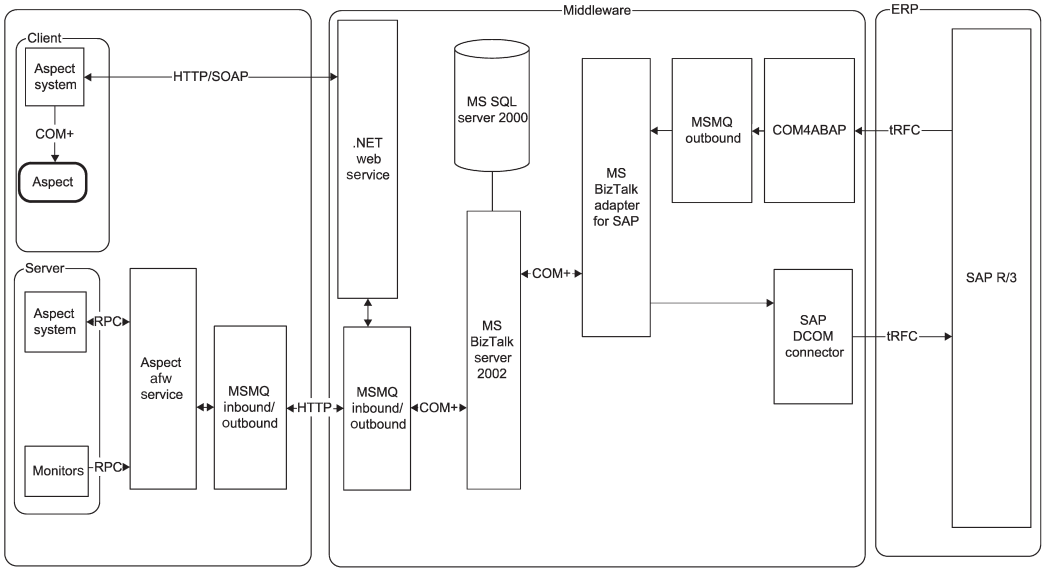

FIGURE 101.17 Prototype event-based data submission.

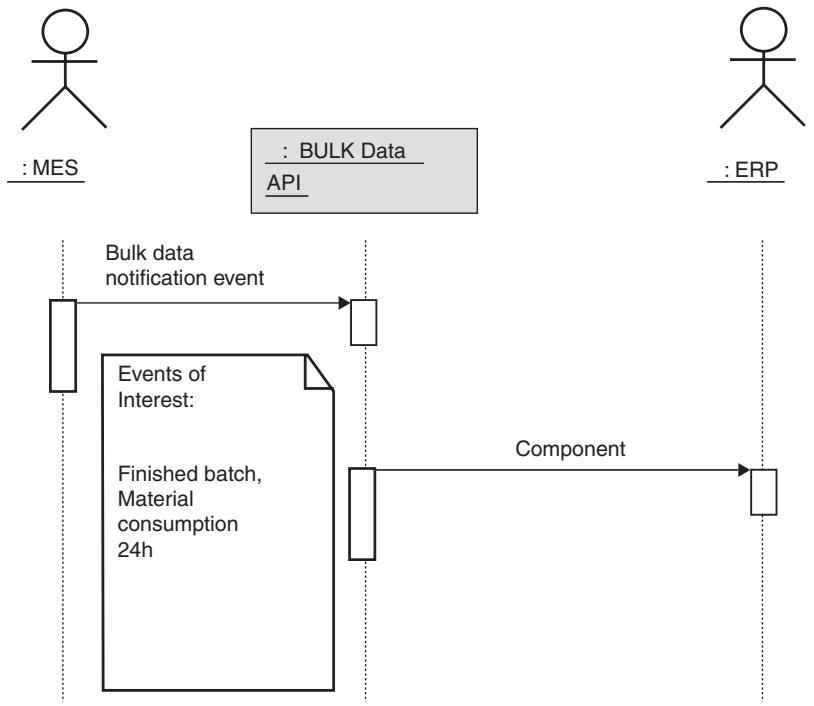

FIGURE 101.18 Transfer of quality information from MES to ERP.

Technical Concept

Bulk data integration architecture is driven by an external scheduling system that initiates jobs on each system through a scheduling agent.

© 2005 by CRC Press LLC

A scheduling agent on the MES system triggers export and import jobs through a custom data manager, which determines the appropriate import and export routines to execute, log audit data, and initiate outbound data transfers. The scheduling agent on the EAI server initiates the data transformation routines and outbound data transfers. On the ERP system side, the scheduling agent initiates export and import jobs through a data manager that determines the appropriate import and export objects to execute, log audit data, and initiate outbound data transfers.

The primary components and message flow required for this architecture are illustrated in Figure 101.19.

The architecture relies on the availability of an enterprise job scheduling application that can initiate jobs across multiple systems and platforms. The scheduling agents are provided by the enterprise scheduler, required on the MES and ERP servers where extracts and imports are running. The agent is also required on the EAI server. The agents initiate jobs on the local servers and report status back to the enterprise scheduler.

Providing the correct containers for moving large data volumes is of equal importance as the scheduling architecture. The following protocols are being considered for transporting files from server to server.

- *File Transfer Protocol (FTP)* — FTP is a commonly used client–server protocol that allows a user on one computer to transfer files to and from another computer over a TCP/IP network. FTP is often used as a reliable data transfer method between dissimilar systems. Utilities to ensure the complete transfer of files could easily be developed or purchased at a nominal cost.
- *File System* — The files could be transferred by copying files between file system shares. This would most likely be supported in a Windows-based environment, but would require additional utilities if the ERP server was on a platform other than Windows.
- *HTTP* — Utilizing HTTP would ensure access through firewalls; however, HTTP has been shown to have poor performance in transferring larger files.
- *Message Queues* — MQ support the guaranteed delivery of messages. Using message queues for this architecture would require the development of a utility to break large files into smaller pieces depending on the maximum message size.

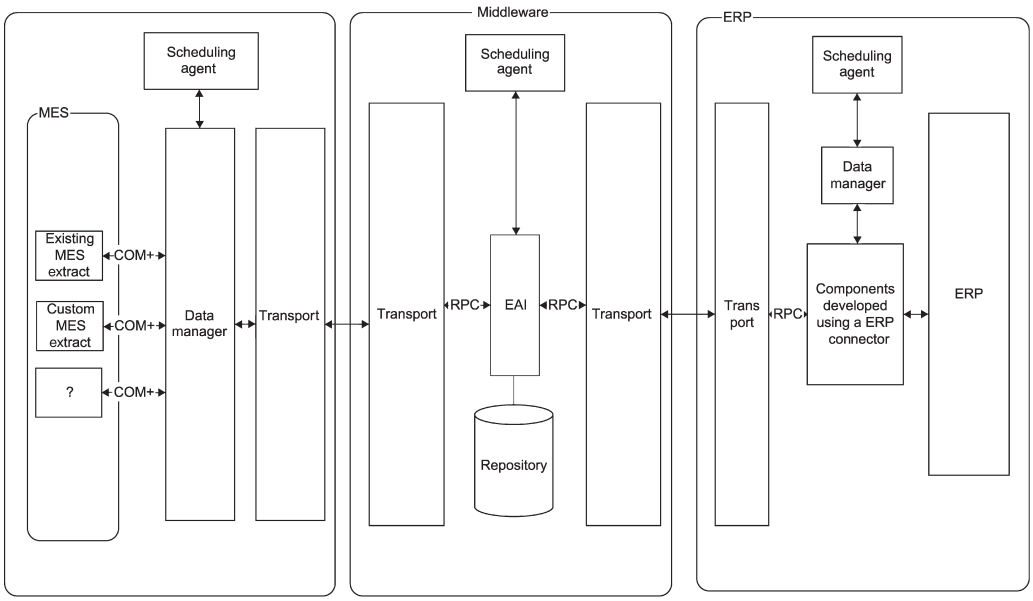

FIGURE 101.19 Bulk data submission concept.

© 2005 by CRC Press LLC

Prototype Realization

The prototype architecture utilizes the customer's enterprise scheduling system and agents to control the execution of the bulk data integration interfaces. The scheduler provides agents for the MES, BizTalk Server, and the SAP system.

The scheduling agent on the MES calls the import and export programs directly. Upon successful completion of an export, the scheduling agent initiates an FTP transfer of the export file to BizTalk Server. The scheduling agent then calls a component on the BizTalk Server to audit the file, confirms a successful transfer, and initiates an XLANG schedule in BizTalk Server. XLANG is an extension of the Web Service Definition Language (WSDL) and provides both the model of an orchestration of services as well as collaboration contracts between orchestrations. The XLANG schedule performs any required transformations and mappings, adds new audit information to the file, and transfers the file to the SAP R/3 server. BizTalk Server utilizes a connector component for FTP to send the file to the SAP server. On the SAP side, the scheduling agent calls the file transfer audit program to confirm the successful file transfer, and then initiates the data import and log the results. A similar process is implemented for interfaces from SAP to MES.

The realized architecture with specific technologies is illustrated in Figure 101.20.

101.7 Conclusions and Outlook

We have presented integration scenarios in an intraenterprise production environment, and have outlined technical integration options as building blocks for reusable integration architectures. Prototype concepts were outlined for each of the use cases presented.

The following conclusions can be drawn regarding integration between plant-floor and business systems:

- point-to-point data exchange solutions restrict integration flexibility;
- an integration solution is composed of different technical components;
- for a reusable solution, domain interfaces have to be standardized and developed, which allow connecting different systems without the need to redevelop the whole architecture;
- systems with fewer numbers of interfacing points can be productized quite easily; larger systems with a high number of intersystems communications are usually tailored toward customer requirements;

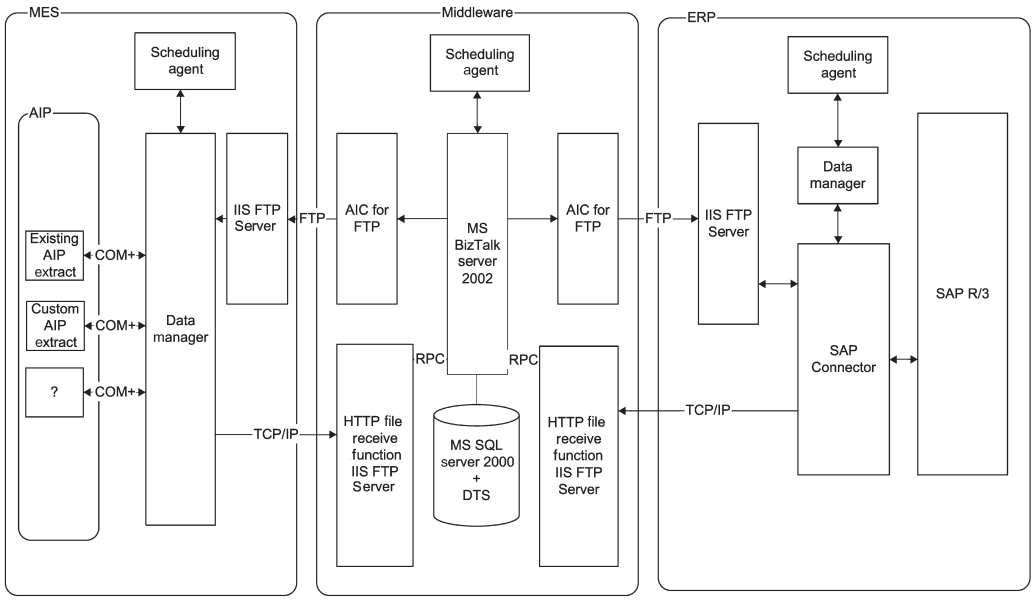

FIGURE 101.20 Prototype bulk data submission.

© 2005 by CRC Press LLC

- standards serving cross-system integration, such as ISA S95, will further strengthen the role of EAI as a bridging layer between automation and business systems through their data mapping and orchestration capabilities; and
- using standard technologies such as XML and web services eases the task of application integration across vendors and platforms.

However, the full solution potential can only be achieved if the following integration issues are carefully taken into account:

- *Data Consistency and Engineering*: Data entry must be facilitated and promoted across the various subsystems and must, by all means, be kept synchronized across the various subsystems; this implies detecting changes (insert, modify, delete) in systems on objects (e.g., equipment, batches) and their attributes (e.g., status data) and replicate changes to "connected" systems according to replication rules and in a defined sequence.
- *Data Exchange*: Common sets of functionality for various subsystems (such as production planning), high-level APIs to facilitate the access to these systems, and common data description to overcome semantic differences of the involved systems must be developed. A uniform data access for users and applications, hiding the origin of data from different systems, can be achieved by combing functional and data integration capabilities as described in this document. To the outside (user or application), a uniform access interface allows requesting information of a specified "category" — for example, operational data, maintenance-related information, performance-related information, etc, which are composed of attributes of object instances from different systems.

In order to achieve this functionality, additional concepts, such as data and attribute views (i.e., typed concepts) should be introduced with the assignment of object instances to types, and the ability to define relations between the content of types.

Transparent access to object attribute information will be the functionality that enables applications and users to access information according to defined "data views" independent of the information sources. The origin of the information (source systems) is hidden. Benefits of this functionality include a better access management to applications, simplified aggregation of data across systems, and the synchronization of objects and their attributes between systems.

102.1 Introduction

Automation technology is undergoing continuous change due to the ever-shorter innovation cycles for new products. The use of field bus technology in recent years has represented a significant innovation. It has enabled the migration of automation systems from centralized to decentralized systems. In this regard, PROFIBUS has set the standard as the market leader for more than 15 years.

Moreover, in today's automation technology, information technology (IT) with established standards, such as TCP/IP and XML, is increasingly dictating changes. Integration of information technology into

© 2005 by CRC Press LLC

automation is opening up significant advances in communication options between automation systems, far-reaching configuration and diagnostic options, and networkwide service functions. These functions have been a fixed component of PROFINET from the start.

PROFINET is the open standard for industrial automation based on Industrial Ethernet. PROFINET enables problem-free realization of distributed automation, integration of existing field devices, and operation of demanding, time-critical applications (such as motion control).

In addition to utilization of IT technology, protection of investment also plays an important role with PROFINET. PROFINET enables existing field bus systems such as PROFIBUS to be integrated without modifications with existing devices. This protects the investments of plant operators, machinery/plant construction firms, and device manufacturers.

Automation technology requirements are thoroughly covered by PROFINET. It was possible to transfer the many years of experience in the PROFIBUS sphere to PROFINET standardization. The use of open standards, simple handling ability, and integration into existing plant units have defined PROFINET from the start. PROFINET is currently integrated in IEC 61158.

A long-term perspective is offered to users through continuous advancements in PROFINET.

Costs incurred by plant or mechanical system engineers for installation, engineering, and startup are minimized through the use of PROFINET. For plant operators, PROFINET enables plants to be easily expanded and achieve a high level of availability through independently operating plant units.

Establishment of certification by the PROFIBUS User Organization (PNO) guarantees a high standard of quality for PROFINET products.

This chapter describes in detail how experience gained with IT standards in the PROFIBUS sphere has been converted to PROFINET.

102.2 PROFINET at a Glance

The motivation to create PROFINET comes from the user requirements outlined in Section 102.1 and the anticipated cost reduction resulting from manufacturer-independent, plantwide engineering. With PROFINET, a modern automation concept has emerged that is based on Ethernet and enables simple integration of existing field bus systems (in particular, PROFIBUS). This represents an important aspect for satisfying uniformity of requirements from the corporate management level to the field level.

Decentralized Field Devices (PROFINET IO)

Simple field devices are integrated in PROFINET using PROFINET IO and are described by the familiar IO view in PROFIBUS DP. Decentralized peripherus for PROFINET are also integrated using this approach. The essential feature of this integration is the use of decentralized field devices with their input and output data, which are processed in the PLC user program (Figure 102.1).

PROFINET IO describes a device model that differentiates slots and channels in a similar way as the model for PROFIBUS DP. The device properties are described by an XML-based description file (GSD).

PROFINET IO devices are engineered using the same approach that has long been familiar to system integrators of PROFIBUS DP. This includes assignment of the decentralized field devices to a controller during configuration. Productive data are then exchanged between the controller and the assigned field devices.

Distributed Automation (Component Model)

Distributed automation systems typically consist of several subunits that act autonomously for the most part and coordinate with each other using signals for synchronization, sequence control, and information exchange.

The PROFINET component model refers to these subunits as *technological modules*. The technological modules form an intelligent functional unit. Through the use of the component technology proven in the IT sphere, the overall functionality of a technological module is encapsulated in an associated software

© 2005 by CRC Press LLC

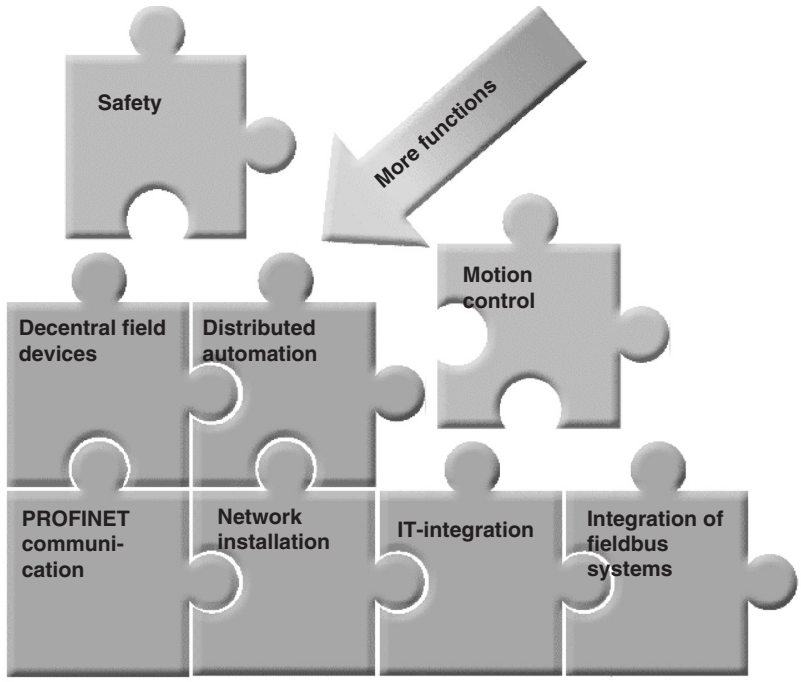

FIGURE 102.1 Architecture of PROFINET IO.

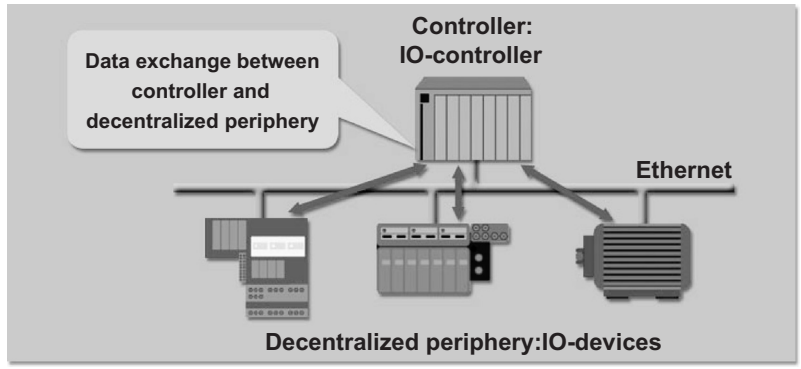

FIGURE 102.2 Mechanical, electrical/electronic, and software aspects are combined in technological modules.

component. Such a component is modeled as an object and regarded as a black box. An outside technological component interface is defined in order for the component to communicate with other components within the distributed system (Figure 102.2).

A distributed automation system designed in this way constitutes the prerequisite for modularization of plants and machinery and hence for reuse of plant and machine parts. This significantly reduces engineering costs.

A technological module is described in PROFINET within the component model using PROFINET Component Description (PCD). PCD is XML-based and produced either by a component generator of a manufacturer-specific configuration tool or the PROFINET Component Editor.

A manufacturer-neutral *engineering concept* is available for user-friendly configuration of a PROFINET system.

© 2005 by CRC Press LLC

Engineering of distributed automation systems distinguishes between programming of control logic for individual technological modules (manufacturer-specific configuration tools) and the technological configuration of the entire system (interconnection editor). A systemwide application is formed in the three steps: create components, interconnect components, and download interconnection information.

Communication

Different performance levels are available for PROFINET communication.

Parameters, configuration data, and interconnection information that are not critical with respect to time are transferred in PROFINET via the standard channel based on TCP/UDP and IP. This satisfies the prerequisites for interfacing the automation levels with other networks (MES, ERP). For transfer of time-critical process data within the production plant, the real-time channel known as Soft Realtime (SRT) is available. This channel is implemented as software on the basis of existing controllers.

For isochronous applications, the Isochrone Realtime Communication (IRT) is available that enables clock pulse rates of less than 1 msec and a jitter accuracy of 1 μsec.

Network Installation

PROFINET network installations are oriented toward specific requirements for Ethernet networks in industrial environments. The "PROFINET Installation Guideline" provides plant construction engineers and plant operators with simple rules for installing Ethernet networks and associated cabling. This guideline provides device manufacturers with clear specifications for device interfaces.

IT Integration

The network management includes functions for administration of PROFINET devices in Ethernet networks. This includes the device configuration, network configuration, and network diagnostics. In the case of web integration, PROFINET makes use of the Ethernet-based technologies and enables access to a PROFINET component by means of standard Internet technologies. In order to preserve an open connection to other system types, PROFINET supports OPC DA and DX.

Field Bus Integration

An important aspect of PROFINET is the seamless transition from existing field bus solutions such as PROFIBUS DP to Ethernet-based PROFINET. This contributes significantly to protection of investments by the device manufacturer, the plant construction/mechanical system engineer, and the end user (Figure 102.3).

PROFINET offers two alternatives for integrating field bus systems:

- *Integration of field bus devices by means of proxies*: The proxy is the representative for the lower-level field devices on the Ethernet. Through the proxy principle, PROFINET offers a completely transparent transition from existing to newly installed plant units.
- *Integration of whole field bus applications*: A field bus segment represents a self-contained component. The representative for this component is the PROFINET device that operates a field bus such as PROFIBUS DP at a lower level. The entire functionality of a loswer-level field bus is thereby implemented in the form of a component in the proxy, which is available on the Ethernet.

102.3 Decentralized Field Devices (PROFINET IO)

Decentralized field devices are integrated directly on the Ethernet using PROFINET IO. To accomplish this, the master–slave system familiar in PROFIBUS DP is transferred over to a provider–consumer

© 2005 by CRC Press LLC

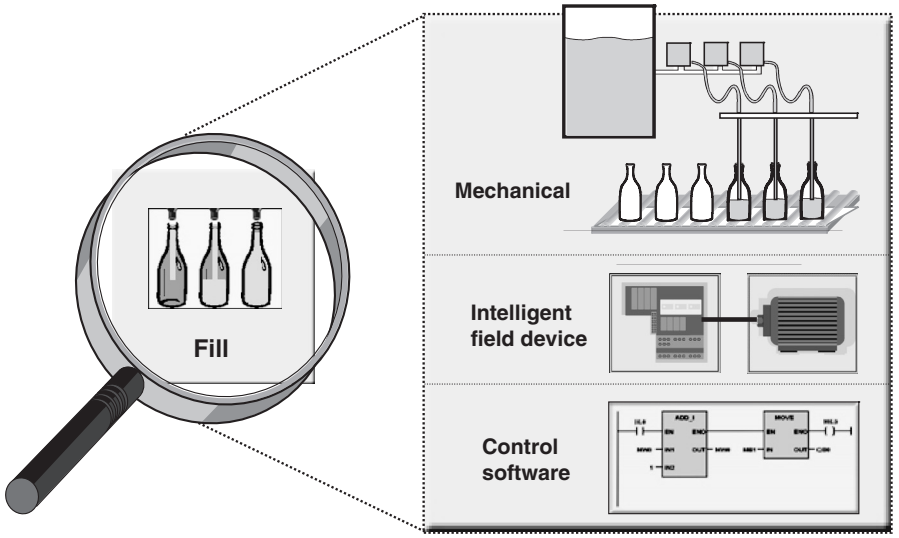

FIGURE 102.3 PROFIBUS systems, for example, can be integrated in PROFINET using a proxy.

model. Although all devices on the Ethernet have equal communication rights, the configuration specifies which field devices are assigned to a centralized controller. In this way, the familiar user view in PROFIBUS is transferred to PROFINET IO. I/O signals are read in, processed by the PLC, and resent to the outputs.

Functional Scope

PROFINET IO distinguishes between three device types: PN-IO controller, PN-IO device, and PN-IO supervisor (Figure 102.4):

- *PN-IO controller*: A PLC on which the automation program runs.
- *PN-IO device*: Decentralized field device that is assigned to a PN-IO controller (such as remote IO, valve terminals, frequency converters).
- *PN-IO supervisor*: Programming device or PC with commissioning and diagnostic functions.

Data can be transferred between the IO controller and IO device by means of the following channels:

- Cyclic user data via the real-time channel.
- Event-triggered interrupts (diagnostics) via real-time channel.
- Parameter assignment and configuration as well as reading of diagnostic information via the standard channel based on UDP/IP.

At the start, a communication relationship called Application Relation (IO-AR) is established between the IO controller and the IO device based on the acyclic UDP/IP channel. Then, the IO controller transfers the configuration data for the IO device by means of this established channel. Based on the configuration data: (1) the correct operating mode is determined, for example, and the IO device is uniquely identified, (2) high-speed, cyclic useful data exchange via the real-time channel (IO-CR) is started. If a diagnostic event occurs (such as a wire break), an interrupt is sent to the IO controller via the high-speed, acyclic real-time channel (interrupt CR) for processing in the PLC program located on the IO controller (Figure 102.5).

© 2005 by CRC Press LLC

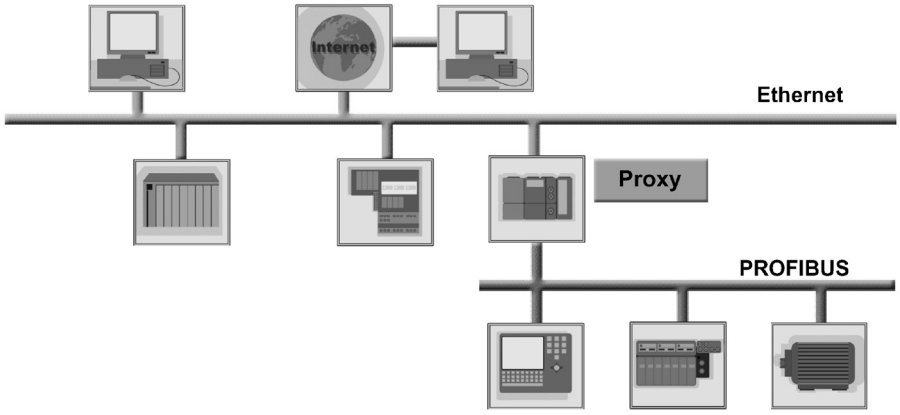

FIGURE 102.4 Device types in PROFINET IO.

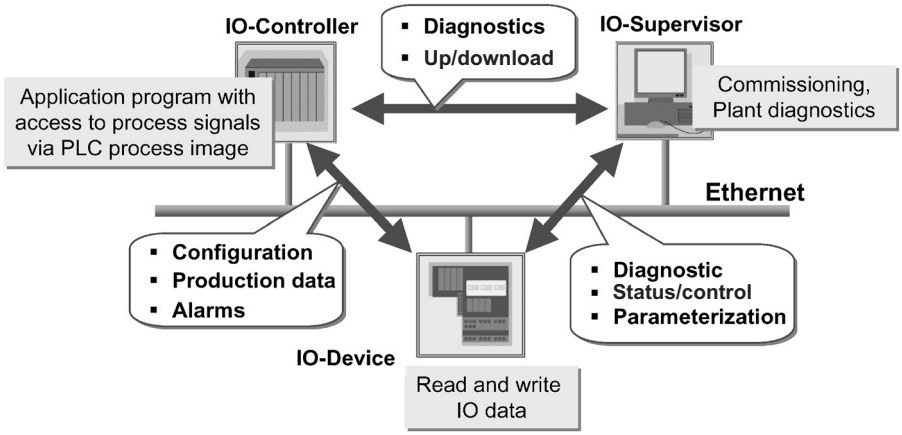

FIGURE 102.5 Communication relationships in PROFINET IO governed by the consumer/provider model.

Device Model

A uniform device model has been specified for the PROFINET IO device. This model enables modular and compact field devices to be modeled. This model is oriented toward the main features in PROFIBUS DP and extends the advantages of these features into the future (Figure 102.6).

An IO device with a modular configuration consists of slots in which modules are inserted. The modules contain channels over which process signals are read in or read out. The representative of the IO device is the interface module, which receives data from the IO controller and forwards it to the modules via the backplane bus. Conversely, it receives the process and diagnostic information from the modules via the backplane bus and forwards this information to the IO controller. Each IO device receives a global device identification that is uniquely assigned within the framework of PROFINET IO. This 32-bit device ID number is divided into a 16-bit manufacturer identifier and a 16-bit device identifier. This device ID is assigned by the PROFIBUS user organization (PNO).

Device Description (GSD)

As in PROFIBUS, a device description is used to integrate a PROFINET device into the configuration tool of an IO controller. The properties of an IO device are described in the form of General Station

© 2005 by CRC Press LLC

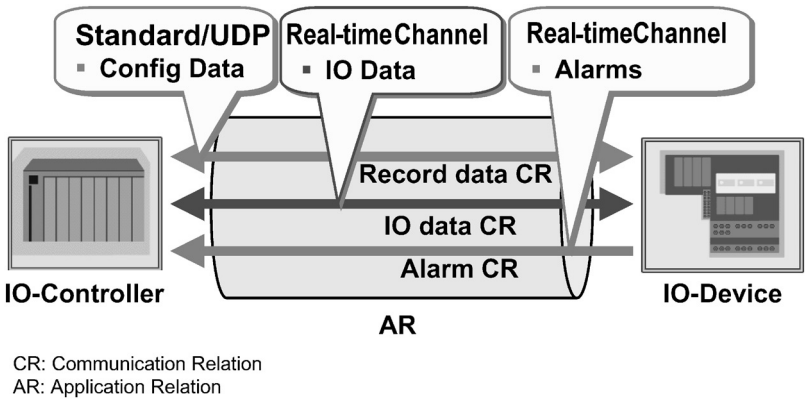

FIGURE 102.6 PROFINET IO device model is similar to that of PROFIBUS DP.

Description (GSD), which contains all necessary information:

- Properties of the IO device (e.g., communication parameters).
- Insertable modules (number of type).
- Configuration data for individual modules (e.g., 4 to 20 mA analog input).
- Parameters of modules.
- Error texts for diagnostics (e.g., wire break, short circuit).

XML is the description basis for the GSD of PROFINET IO devices. Because XML is an open, widespread, and accepted standard for describing data, appropriate tools and derived properties are automatically available, including:

- creation and validation through a standard tool,
- foreign language integration, and
- hierarchical structuring.

The GSD structure corresponds to ISO 15745 and consists of a header, the device description in the application layer (e.g., configuration data and module parameters), and the communication properties description in the transport layer.

Configuration and Data Exchange

The description files of the IO devices are imported into the configuration tool. IO addresses are assigned to the individual IO channels of the field devices. The IO input addresses contain the received process values. The user program evaluates and processes these values. The user program forms the IO output values and outputs them to the process via the IO output addresses. In addition, parameters are assigned to the individual IO modules or channels in the configuration tool, for example, 4 to 20 mA current range for an analog channel.

After conclusion of the configuration, the configuration data are downloaded to the IO controller. The IO devices are assigned and configured automatically by the IO controller and then enters into the cyclic data exchange (Figure 102.7).

Diagnostics

PROFINET IO supports a multilevel diagnostic concept that enables efficient fault localization and correction. When a fault occurs, the faulty IO device generates a diagnostic alarm to the IO controller. This alarm triggers a call in the PLC program to the appropriate program routine in order to be able to

© 2005 by CRC Press LLC

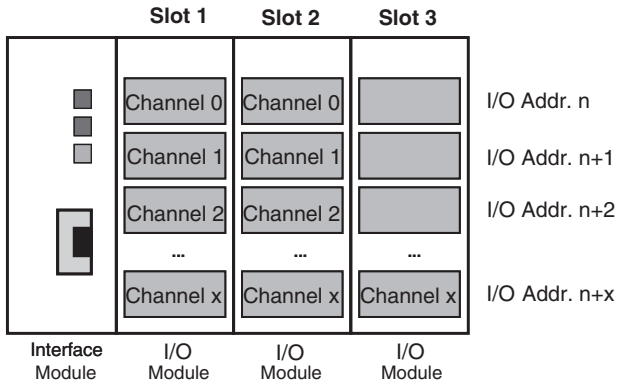

FIGURE 102.7 Configuration path for data exchange.

respond to the fault. If a device or module defect requires a complete replacement of the device or module, the IO controller automatically performs a parameter assignment and configuration of the new device or module.

The diagnostic information is structured hierarchically:

- Slot number (module).
- Channel number.
- Channel type (input/output).
- Coded fault cause (e.g., wire break, short circuit).
- Additional manufacturer-specific information.

When an error occurs in a channel, the IO device generates a diagnostic alarm to the IO controller. This alarm triggers a call in the control program to the appropriate fault routine. After processing of the fault routine, the IO controller acknowledges the fault to the IO device. This acknowledgment mechanism ensures that a sequential fault processing is possible in the IO controller.

102.4 Distributed Automation

Automation development has given rise to modular plants and machinery. This structuring has triggered further development in automation to produce distributed automation systems. PROFINET also offers a solution in this area. The PROFINET solution involves separation of plant units into technological modules.

Technological Modules

The function of an automated plant or machine — for a goods manufacturing process — is produced by a defined interaction of mechanical, electrical/electronic, and control logic/software aspects. According to this principle, PROFINET defines the mechanical, electrical/electronic, and control logic/software aspects for a *technological module* (see Figure 102.2). A technological module is in turn modeled by a software component, that is, the PROFINET component.

PROFINET Components

The representative of a technological module during plant engineering is the so-called PROFINET component. Each PROFINET component has an interface that contains the technological variables to be exchanged with other components.

© 2005 by CRC Press LLC

The PROFINET components are modeled using the standardized COM technology. COM is an advanced object orientation that enables applications to be developed on the basis of preassembled components. The components are characterized by the formation of complete units that can be in relationship to other components. Like blocks, the components can be combined flexibly and easily reused, irrespective of how they are implemented internally. Access mechanisms to the component interfaces are uniformly defined in PROFINET.

Granularity of Technological Modules

When the granularity of modules is being specified, the ability to reuse the modules in different plants must be examined with cost and availability in mind. The objective is to be able to merge individual components into an overall plant as flexibly as possible according to the building block principle. On the one hand, with too fine a granularity the technological view of the plant can become more complex, resulting in higher engineering costs. On the other hand, with too coarse a granularity, the degree of reusability is reduced. This, in turn, results in higher implementation costs.

The machine or system manufacturer creates the software component. The *component design* has a major influence on reduction of engineering and hardware costs and the time response of the automation system. When a component is being designed, the granularity (i.e., size of machine/plant or the specified machine parts/plant units) can extend from an individual device to a complete machine containing a number of devices.

PROFINET Engineering

A manufacturer-neutral engineering concept has been created for user-friendly configuration of a PROFINET system. For one thing, this engineering concept enables development of configuration tools that can be used for components of different manufacturers. Also, it permits manufacturer-specific and application-specific function expansions.

The engineering model distinguishes between programming of control logic for individual technological modules and the technological configuration of the overall plant. A plantwide application is generated in three stages.

Component Creation

Components are created as an image of the technological modules by the machinery or plant construction firms. Devices are programmed and configured as before with the respective manufacturer-specific tools. That way, available user programs and the know-how of programmers and service personnel can continue to be used. Then the user software is encapsulated in the form of a PROFINET component. In so doing, a component description (PCD) in the form of an XML file is created. The contents of the

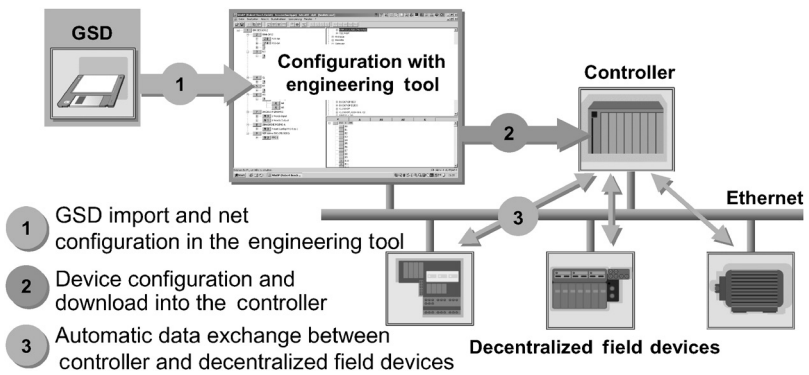

FIGURE 102.8 Component creation is standardized in PROFINET.

© 2005 by CRC Press LLC

component description are specified in PROFINET. These component descriptions are imported into the library of the interconnection editor (Figure 102.8).

Component Interconnection

The created PROFINET components are moved from a library to an application and interconnected at the click of a mouse using the PROFINET *interconnection editor* (Figure 102.9).

Interconnection replaces the previous labor-intensive programming of communication relationships with simple graphical configuration. During programming, detailed knowledge about the integration and sequence of communication functions in the device is required. At the time programming is performed, the following must already have been specified: which devices will communicate with one another, when the communication will occur, and which bus system will be used for the communication. By contrast, knowledge of the communication functions is not required during configuration because these functions run automatically in the devices. The interconnection editor consolidates the individual distributed applications on a plantwide basis. Operation of the interconnection editor is manufacturer-neutral, that is, the editor interconnects any manufacturer's PROFINET components.

Downloading

Following component interconnection, the interconnection information as well as the code and configuration data for the components are downloaded to the PROFINET devices at the click of a mouse. As a

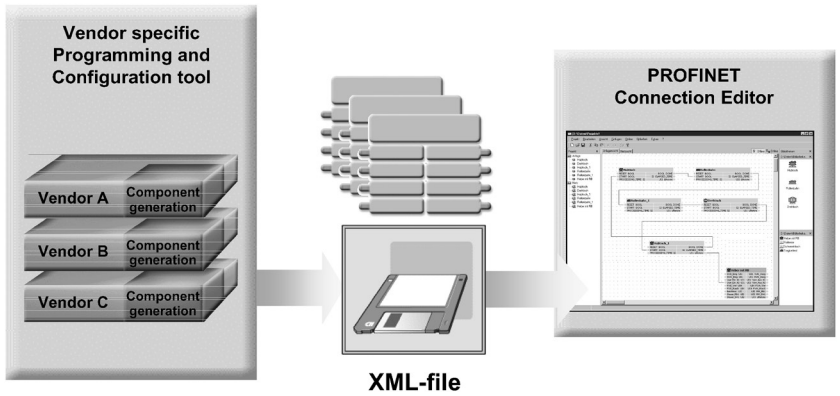

FIGURE 102.9 Interconnected components.

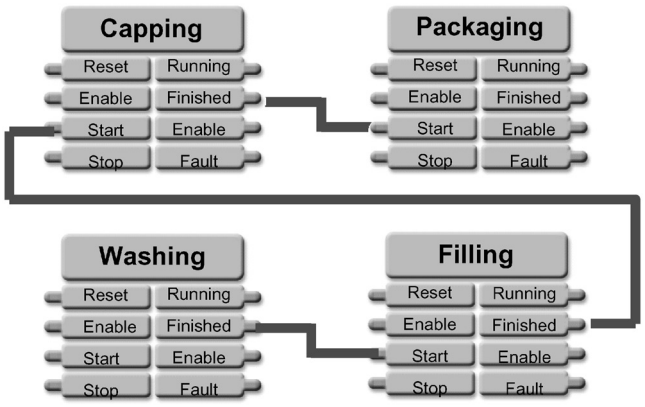

FIGURE 102.10 Downloading the interconnection information for PROFINET devices.

© 2005 by CRC Press LLC

result, each device knows all of its communication peers, communication relationships, and information to be exchanged. The distributed application can be executed afterward (Figure 102.10).

Component Description (PCD)

The PCD is an XML file, which is created by manufacturer-specific tools. This assumes that these tools have a component generator. Alternatively, a manufacturer-neutral "PROFINET Component Editor," available for download on the PROFIBUS website, can be used to create the PCD file. The PCD file contains information on the functions and objects of the PROFINET component. Specifically, this information includes:

- Description of components as library elements: component ID, component name.
- *Hardware description*: IP address storage, diagnostic data access, interconnection download.
- *Description of software functionality*: software <-> hardware assignment, component interface, properties of variables such as technological name, data type, and direction (input or output).
- Storage location of component project.

Component libraries are generated to support reusability.

Interconnection Editor

In general, an interconnection editor has two views: plant view and network view.

In the plant view, required components are imported from the library and placed on the screen, and the individual interconnections are established. This yields a *technological* structure and its local relationships within a plant. By contrast, the *topological* structure of the automation system is created in the network view. Here, the field devices and automation devices are assigned to a communication system or bus system, and the device addresses are specified according to the rules for the underlying bus system (Figures 102.11 and 102.12).

PROFINET Runtime

The PROFINET run-time model defines functions and utilities that require cooperating automation components to accomplish an automation task. This model establishes and monitors the interconnec-

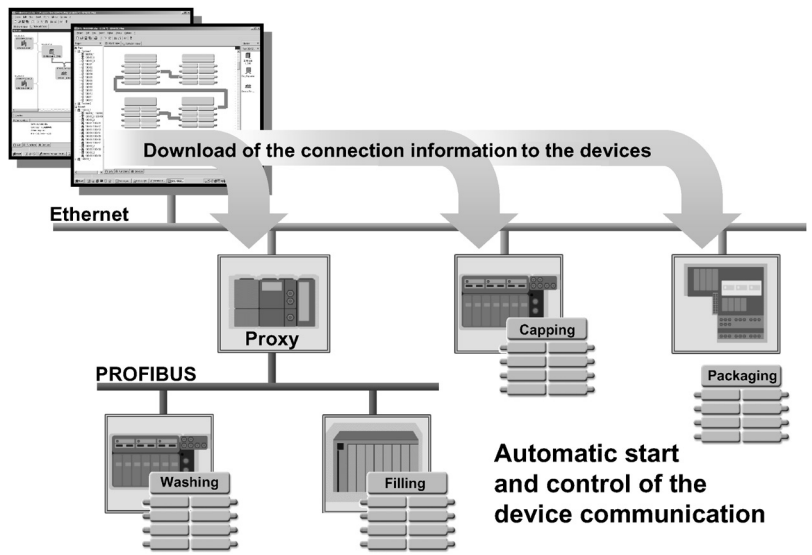

FIGURE 102.11 Plant view in the interconnection editor shows the interconnected components.

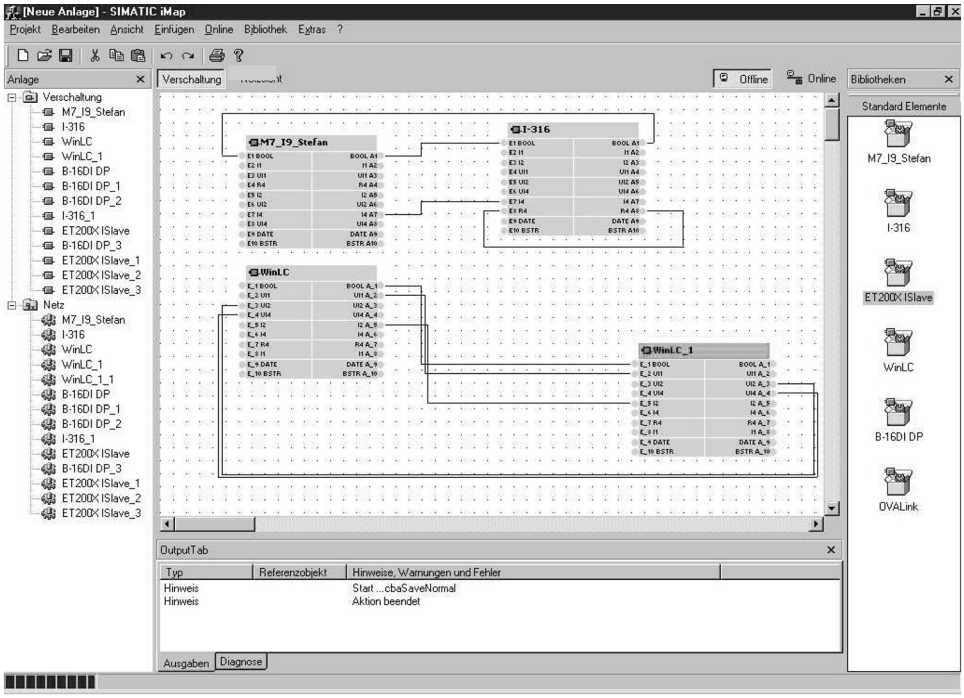

FIGURE 102.12 Network view in the interconnection editor shows the connected field devices.

tions between PROFINET components that have been configured by engineering. The PROFINET runtime model sets up a provider–consumer model in which the provider creates and sends data and the consumer receives and processes data.

102.5 PROFINET Communication

Ethernet-based communication is scalable in PROFINET. The following three performance levels are differentiated:

1. TCP/UDP and IP for data that are not time critical, such as parameter assignment and configuration data.
2. SRT for time-critical process data in factory automation.
3. IRT for particularly challenging application requirements, such as those for motion control.

These three PROFINET communication performance levels cover the spectrum of automation applications in their overall diversity. The PROFINET communication standard is characterized by the following in particular:

- Coexisting utilization of real-time and TCP-based IT communication on one line.
- Uniform real-time protocol for all applications both for communication between components in distributed systems and for communication between the controller and the distributed field devices.
- Scalable real-time communication from performant to high-performant, and isochronous mode.

Scalability and a uniform communication basis represent two of the major strengths of PROFINET. They guarantee continuity to the corporate management level and fast response times in the automation process.

Standard Communication with TCP/UDP

PROFINET uses Ethernet and TCP/UDP with IP as the basis for communication. TCP/UDP with IP is a *de facto* standard with respect to communication protocols in the IT landscape. However, for interoperability

© 2005 by CRC Press LLC

(i.e., the interaction between applications), establishment of a common communication channel over the field devices, based on TCP/UDP (layer 4), is insufficient. TCP or UDP represent only the foundation on which Ethernet devices can exchange data via a transport channel in local and distributed networks. Therefore, additional specifications and protocols beyond TCP/UDP — the so-called application protocols — are required. Interoperability is only guaranteed if the same application protocol is used on the devices. Typical application protocols are SMTP (for e-mail), FTP (for file transfer), and HTTP (used on the Internet).

Real-Time Communication

Real-time applications in manufacturing automation require update, or response times, in the range of 5 to 10 msec. The update time refers to the time that elapses when a variable is generated by an application in a device, then sent to a peer device via the communication system, and then received updated by the application. For devices, the implementation of a real-time communication causes only a small load on the processor so that execution of the user program continues to take precedence. From experience, in the case of Fast Ethernet (100 Mb/sec Ethernet), the transmission rate on the line in proportion to the execution in the devices can be disregarded. Most of the time gets lost in the application. The time it takes to provide data to the application of the provider is not influenced by the communication. This also applies to processing of data received in the consumer. As a result, noteworthy improvements in update rates and thus the real-time performance can be obtained primarily through proper optimization of the communication stack in the provider and consumer.

RT

In order to satisfy real-time demands in automation, PROFINET uses an optimized real-time communication channel (Figure 102.13).

This channel is based on Ethernet (layer 2). The solution minimizes the throughput time in the communication stack considerably and increases performance in terms of the process data update rate. By doing away with several protocol layers, the message frame length is reduced. By not including these

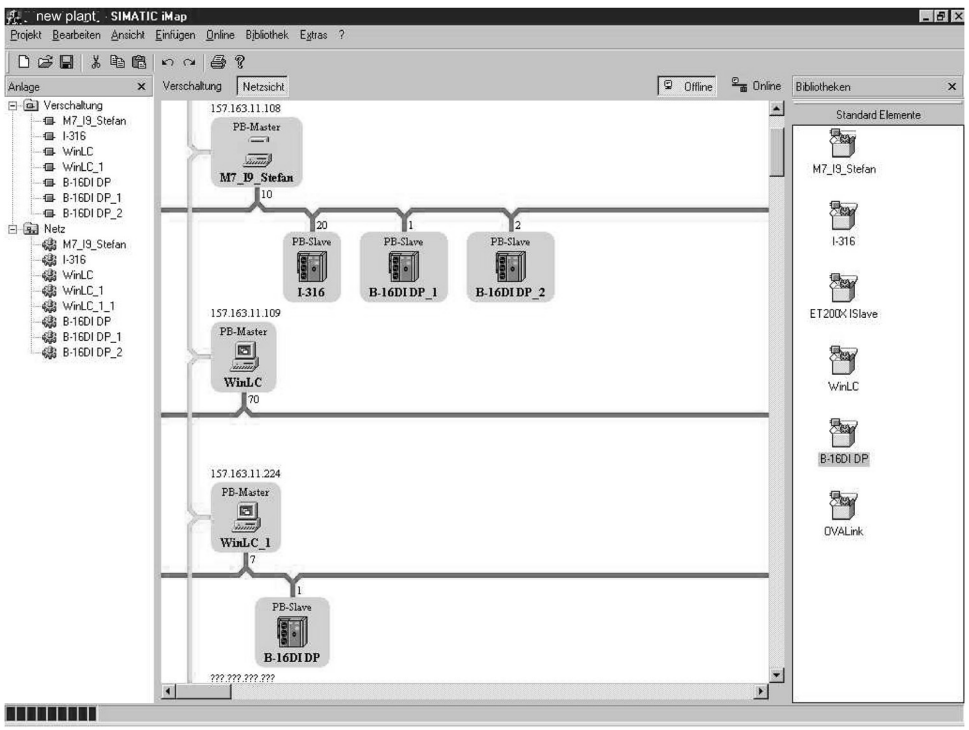

FIGURE 102.13 Communication channels in PROFINET.

© 2005 by CRC Press LLC

additional layers, the data to be transmitted from the provider can be sent sooner, or are available earlier to the application on the consumer side. At the same time, this significantly reduces the processor power required for communication in the device.

Optimized Data Transmission through Prioritization.
In addition to the minimized communication stack in the automation devices, the transmission of data in the network is also optimized in PROFINET. In order to achieve an optimal result, the packets are prioritized in PROFINET according to IEEE 802.1Q. The network components use this priority to control the dataflow between the devices. The standard priority for real-time data is based on Prio 6. Thus, priority handling over other applications, such as Internet telephony, is guaranteed because they are using Prio 5.

IRT

The presented solutions are not sufficient for motion control applications, in particular. These applications require update rates in the range of 1 msec along with a jitter for consecutive update cycles of 1 μsec for cases involving up to 100 stations. To satisfy these requirements, PROFINET defines the IRT time slot-controlled transmission process on layer 2 for Fast Ethernet. This means every device knows exactly in which time slot it is allowed to send data over the bus. Through synchronization of the devices involved (network components and PROFINET devices) with the accuracy indicated above, a time slot can be specified during which data critical for the automation task are transferred. The communication cycle is split into a deterministic part and an open part. The cyclic real-time message frames are dispatched in the deterministic channel, while the TCP/IP message frames are transported in the open channel. The process is comparable to the traffic on a highway where the left lane is reserved for time-critical traffic (real-time traffic), and the remaining traffic elements (TCP/IP traffic) are prevented from switching to this lane. Even if there is a traffic jam in the right lane, the time-critical traffic is not affected.

Isochronous data transmission is realized based on hardware, for example, it is burned in an ASIC. Such an ASIC covers the cycle synchronization and time slot reservation functionality for the real-time data. Realization in hardware ensures the accuracy requirements to be achieved within the order of magnitude required. Furthermore, the processor in the PROFINET device is relieved from communication tasks. The resulting additional runtime can be made available for automation tasks.

Communication for PROFINET IO

For PROFINET IO, RPC based on UDP/IP is used in the startup phase for initiation of the data exchange between devices, parameter assignment of distributed field devices, and diagnostics. Through the open and standardized RPC protocol, HMI stations or engineering systems (IO supervisor) can also access PROFINET IO devices. The PROFINET real-time channel is used for transmission of user data and alarms.

In a typical IO configuration, there is an IO controller that exchanges the user data cyclically by means of communication relationships that are established during the startup phase with multiple distributed field devices (IO devices). In each cycle, the input data are sent from the assigned field devices to the IO controller and, in return, the output data are sent back to the appropriate field devices. The communication relationship is monitored by keeping track of cyclic messages. If, for example, cyclic messages fail in three cycles, the IO controller recognizes that the corresponding IO device has failed.

The data transmission layer of PROFINET is defined in IEEE 802.3, which describes the protocol design and malfunction monitoring. A user data message frame consists of a minimum of 64 bytes and a maximum of 1500 bytes. The overall protocol overhead for real-time data is 28 bytes.

Communication between Technological Modules

Distributed Component Object Model (DCOM) is specified in the PROFINET component view as the common TCP/IP-based application protocol between PROFINET components. DCOM represents an enhancement to Component Object Model (COM) for distribution of objects and their interaction in a network. DCOM is based on the standardized RPC protocol. DCOM is used for loading of interconnections,

© 2005 by CRC Press LLC

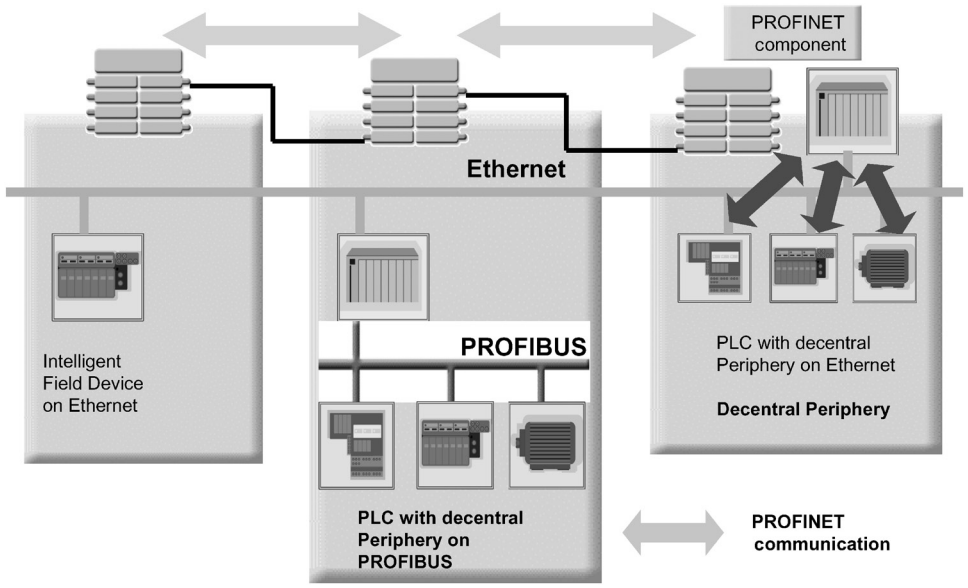

FIGURE 102.14 PROFINET communication between PROFINET components and PROFINET IO devices.

reading of diagnostic data, and device parameter assignment and configuration, establishing interconnections and, to some extent, for exchanging user data between components in PROFINET. However, DCOM does not have to be used for exchange of user data between PROFINET components. Whether user data exchange is to take place via DCOM, or the real-time channel is configured by the user in the engineering system, devices can then negotiate the use of a real-time-capable protocol. This is because communication between such plant or machinery modules can require real-time conditions that cannot be satisfied through TCP/IP and UDP.

TCP/IP and DCOM form the common "language" that can be used to start communication between the devices in all cases. The PROFINET real-time channel is then used for real-time communication between individual stations in time-critical applications. In the configuration tool, the user can select the update time, the so-called quality of service, to determine whether the values are to be transferred between components cyclically during operation or when a change is made. A cyclic transfer is more advantageous for high frequently update times since checking for changes and acknowledging them imposes less processor load than cyclic sending (Figure 102.14).

102.6 Installation Technology for PROFINET

The international standard ISO/IEC 11801 and its European equivalent EN 50173 define an application-neutral, information-oriented standard networking for a complex of buildings. The content of the two standards is essentially identical. Both standards assume that the buildings are similar to an office environment and assert a claim to being application-neutral. The following specific requirements for Ethernet networks in the industrial environment are not taken into consideration in the two standards:

- Plant-specific cable routing.
- Individual degree of networking for each machine/plant.
- Linear network structures.
- Robust industrial cable and connectors with special requirements for EMC, temperature, moisture, dust, and vibration.

© 2005 by CRC Press LLC

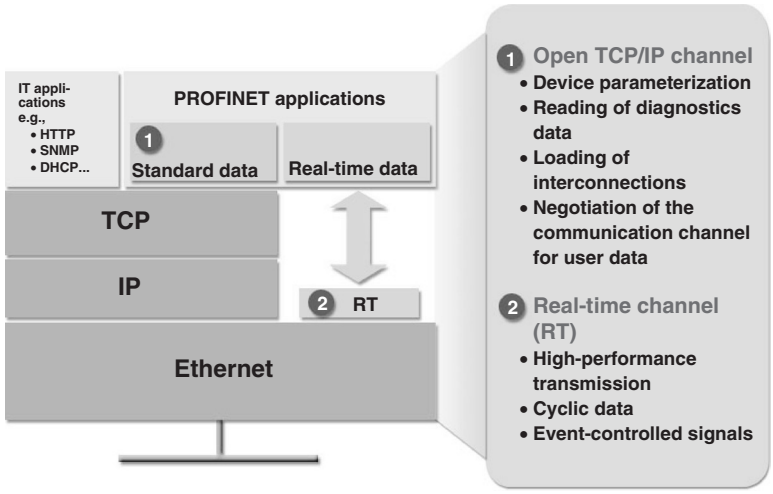

FIGURE 102.15 Structure of Ethernet networks in office systems.

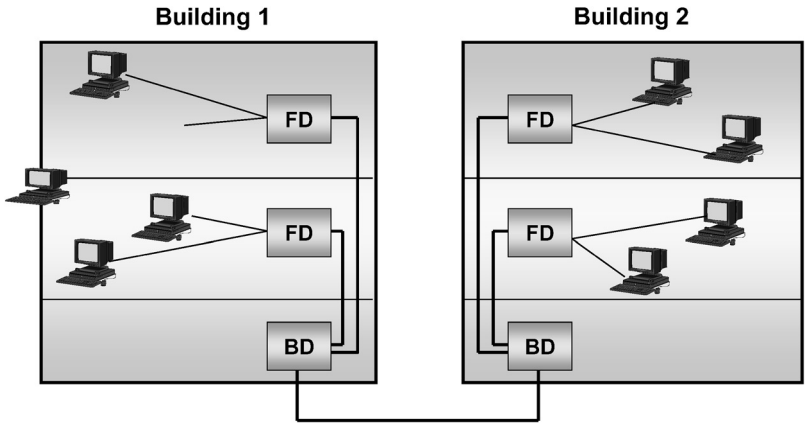

BD = Building Distributor, FD = Floor Distributor

Office Setting	Manufacturing and Field Setting
Fixed basic installation in buildings	Robust plant-independent cabling
Cabling in false floors	Plant-specific cable routing
Variable device connection at workspace	Connection points seldom changed
Precut/assembled device connection cable	Device connections can be field assembled
Tree-shaped network structures	Linear network structures and (redundant) ring structures are frequently used
Large data packets (e.g., pictures)	Small data packets (measured values)
Average network availability	Very high network availability
Moderate temperatures	Extreme temperatures
No humidity	Humidity possible (IP65)
Minimal vibration	Vibrating machinery
Low EMC-load	High EMC-Load
Low mechanical hazard	Mechanical damage hazard
Minimal chemical hazard	Chemical hazard through oil or corrosive atmosphere

FIGURE 102.16 Differences in cable installation in office systems and automation systems.

© 2005 by CRC Press LLC

For this reason, the "PROFINET Transmission Technology and Cabeling" guideline defines an industrial cable installation for the "Fast Ethernet" application based on the fundamental requirements in IEC 11801 (Figures 102.15 and 102.16).

PROFINET Cable Installation

PROFINET Cable Installation with Symmetrical Copper Cable

Signals are transmitted over symmetrical copper cable (twisted pair) in accordance with 100BASE-TX at a transmission rate of 100 Mbits/sec (Fast Ethernet). The transmission medium is a two-pair, twisted-conductor, shielded copper cable (twisted pair or star quad) with a characteristic impedance of 100 Ω.

Only shielded cable and connection elements are permitted. The individual components must satisfy Category 5 requirements according to IEC 11801. The overall transmission line must satisfy the Class D requirements according to IEC 11801. Removable connections are produced using an RJ45 or M12 connector system. Sockets are used as device connections. Connecting cables (device connection cables, marshaling cables) are provided with suitable plugs at both ends. An active network component is used to connect all devices. To ensure that installation is as simple as possible, the transmission cable has been defined to be identical at both ends. This connecting cable satisfies the function of a cable assembly with two identical ends (Figure 102.17).

The maximum segment length is 100 m.

PROFINET Cable Installation with Optical Fibers

PROFINET can be operated with multimode or single-mode fiber optic cables. Signals are transferred over two-strand optical fibers in accordance with 100BASE-FX at a transmission rate of 100 Mbits/sec. The optical interfaces comply with the ISO/IEC 9314-3 (multimode) or ISO/IEC 9314-4 (single-mode) specifications. For applications external to the control cabinet, the outer sheath must satisfy the applicable requirements at the point of use (mechanical, chemical, thermal). The maximum segment length is 2 km for multimode and 14 km for single-mode specifications.

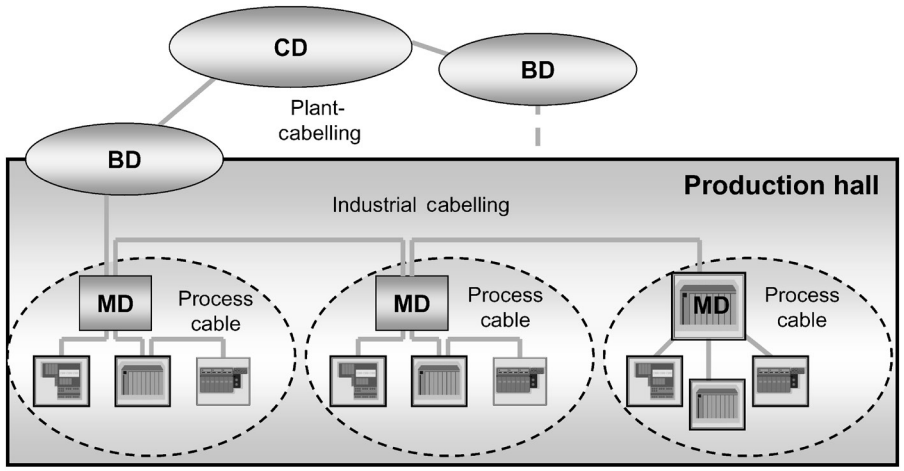

FIGURE 102.17 Ethernet networks in an industrial environment.

© 2005 by CRC Press LLC

Plug Connectors

Plug connectors for M12 and for RJ45 are available in PROFINET. They can be easily cut to length and terminated on site (Figure 102.18).

RJ45 type is used in control cabinet settings in PROFINET. It is compatible to an office connector. Plug connectors external to the control cabinet must notably accommodate industrial requirements. The RJ45 types in IP65 or IP67 or the M12 type are utilized in this case (Figure 102.19).

Fiberoptic connections are implemented according to ISO/IEC 11801, preferably with a duplex SC plug connector system. This system is described in IEC 60874-14. Devices are equipped with the socket, and the connecting cable is equipped with the plug. Alternatively, the fiberoptic plug connector BFOC/2,5 in accordance with IEC 60874-10 can be used.

The hybrid plug connector is used in situations where decentralized field modules are connected using a combined plug connector containing data and power supply. A plug connector that is completely protected against accidental contact enables the use of plug connectors that are identical at both ends because a pin-socket reversal is not required due to the integrated accidental contact protection (Figure 102.20).

FIGURE 102.18 Example of an RJ45 plug connector in IP20.

FIGURE 102.19 Example of an RJ45 plug connector in IP67.

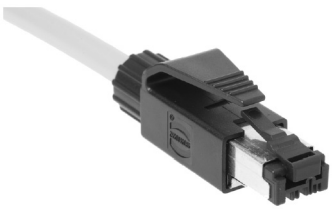

FIGURE 102.20 Example of a hybrid plug connector with RJ45 in IP67.

© 2005 by CRC Press LLC

This example involves an RJ45 in IP67 with a two-pair, shielded data cable for communication and four copper conductors for voltage supply.

Switches as Network Components

PROFINET uses general switches as a network component. Switches are devices that are situated in the transmission path between the end devices and regenerate received signals and forward them selectively. They are used to structure networks. ISO/IEC 15802-3 contains the basic specifications. Switches suitable for PROFINET are sized for Fast Ethernet (100 Mbits/sec, IEEE 802.3u) and full duplex transmission. During full duplex operation, a switch receives and sends data simultaneously at the same port. No collisions occur when switches are utilized. As a result, bandwidth is not lost due to the Ethernet collision process. Network configuration is simplified significantly because route length checking is not required within a collision domain. To ensure compatibility with old plants or individual, older end devices or hubs, 10BASE-TX (10 Mbits/sec, CSMA/CD) is supported.

Moreover, a PROFINET switch supports prioritized message frames in accordance with IEEE 802.1Q, standardized diagnostic paths, and auto polarity exchange, autonegotiation mode, and auto crossover function. Port mirroring for diagnostic purposes is optional.

As a general rule, office-type switches cannot be used, even if the functionality described above is satisfied. Special switches are applied for industrial use. For one thing, these are designed for harsh industrial use based on their mechanical (IP degree of protection, etc.) and electrical (24 V power supply, etc.) properties. For another thing, they must fulfill the EMC requirements for industrial machine applications to enable safe operation.

102.7 IT Integration

In addition to the automation functionalities described, the use of Ethernet as a communication medium in the PROFINET context enables IT functions to be integrated in PROFINET as well. As is the case in the field bus world, Ethernet places additional network management requirements in connection with TCP/IP. In order to manage all technical aspects of integration of PROFINET devices in such networks, a concept for network management has been specified in PROFINET. The topics of network infrastructure, IP management, network diagnostics, and time-of-day synchronization are the primary elements of the concept. Network management simplifies Ethernet administration and management through the use of standard protocols from the IT world. The use of Internet technologies in automation systems represents an additional aspect. PROFINET has specified a concept under the scope of web integration that enables access to a PROFINET component. This access is achieved by using web utilities based on standard Internet technologies, such as http, XML, and HTML.

Network Management

Network management comprises all functions for administering the network, such as configuration (assignment of IP addresses), fault monitoring (diagnostics), and performance optimization.

IP Management

The use of TCP/IP in the PROFINET context means that an IP address has to be assigned to the network stations (i.e., PROFINET devices):

- *Address assignment with manufacturer-specific configuration systems:* This alternative is required because a network management system is not always available. In PROFINET, the DCP (Discovery and Basic Configuration) protocol is specified, enabling IP parameters to be assigned using

© 2005 by CRC Press LLC

manufacturing-specific configuration/programming tools or during plantwide engineering (e.g., in the PROFINET interconnection editor). The use of DCP is mandatory for PROFINET devices. In this way, a uniform behavior of PROFINET devices is ensured.

- *Automatic address assignment with DHCP*: The Dynamic Host Configuration Protocol (DHCP) has been established for assigning and managing IP addresses in office networks with network management systems. PROFINET provides for the use of this standard and describes how DHCP can be applied in a useful way in the PROFINET environment. Implementation of DHCP in PROFINET devices is optional.

Diagnostics Management

The reliability of network operation has a very high priority in network management. The *Simple Network Management Protocol (SNMP)* has been established in existing networks as the *de facto* standard for maintaining and monitoring network components and their functions. In order for PROFINET devices to be monitored with established management systems, it is useful to implement SNMP. SNMP provides for both read access from (monitoring, diagnostics) and write access to (administration) a device.

To begin with, only read access of device parameters was specified in PROFINET. Like the IP management functions, SNMP is optional. When SNMP is implemented in components, only the usual standard information for SNMP is accessed (MIB 2).

A specific diagnostic for PROFINET components is possible by means of the mechanisms described in the PROFINET specification. In this context, SNMP will not open an additional diagnostic path. Rather, SNMP enables integration in network management systems that do not normally process PROFINET-specific information.

Web Utilities

In addition to the use of modern Ethernet-based technologies in PROFINET, it is also possible to access a PROFINET component using web clients based on standard Internet technologies, such as http, XML, HTML, or scripting.

Data are transmitted in a standardized format (HTML, XML), and through standardized frontends (browsers such as Netscape, MS Internet Explorer, Opera, etc.). This enables integration of information from PROFINET components into modern, multimedia-supported information systems. The advantages of web integration in the IT sphere, such as utilization of browsers as uniform user interfaces, access to information on any number of clients from any location, platform independence of clients, and reduced effort for installing and servicing software on the client side, are thus also made available for PROFINET components.

Functional Properties

Web integration of PROFINET has been designed with an emphasis on commissioning and diagnostics. Web-based concepts can be used very effectively within these application areas.

- No special tools are required to access components. Established standard tools can be used.
- Global accessibility means that user support can be easily obtained when commissioning is performed by the component manufacturer.
- Auto description of components enables access with a standard tool without configuration information.

Possible scenarios for PROFINET web integration in the areas of commissioning and maintenance include: testing and commissioning, overview of device database, device diagnostics, and plant and device documentation.

The information provided should be represented both in a human-readable format (e.g., via a browser) and a machine-readable format (e.g., via a XML file). Both variants can be provided in integral form using the PROFINET web integration. For certain information, the PROFINET web integration also provides standardized XML schemes.

© 2005 by CRC Press LLC

Technical Properties

The basic component of web integration is the web server. The web server forms the interface between the PROFINET object model and the basic technologies for web integration.

The PROFINET web integration can be scaled according to the performance and properties of the web server. This means that, in addition to a PROFINET device with an "MS Internet Information Server" or "Apache Webserver," small PROFINET devices equipped with only an "embedded web server" can also participate in the web integration with equal rights.

The web integration for PROFINET has been created in such a way that it can be made available optionally for each device. Certain functions are optional and can be used for the device depending on its load capacity. This enables implementation of scalable solutions that are adapted to the respective use case to the maximum extent possible. The PROFINET-specific elements can be integrated seamlessly in an existing component web implementation. Based on uniform interfaces and access mechanisms, the creator of a technological component can provide his technology-related data via the web. Through the namespace specified in the PROFINET web integration and the addressing concept, elements of the PROFINET component object model (technological variables) can be referenced by the web server. In this way, dynamic web sites configured with current data from the PROFINET component can be created.

Scope

The basic architecture model for the web integration concept is shown in Figure 102.21. Web integration is optional for PROFINET.

With respect to the system architecture of an automation system with PROFINET, all architectural forms are supported by web integration. In particular, the use of proxies for interfacing to any field bus is supported. The specification contains appropriate models that describe the relationships among the PROFINET components, the existing web components, and the PROFINET web integration elements.

Security

The PROFINET web integration specification has been created in such a way that access to the PROFINET devices is the same whether it occurs from the Internet or an Intranet. As a result, all advantages of web integration can be reaped even if the device itself is not connected to the Internet. In the case of local access, there is little risk for an unauthorized access (comparable to today's HMI systems).

For networking within a larger factory or over the Internet, the PROFINET web integration is based on a graded security concept. PROFINET web integration recommends a security concept that has been optimized for the specific use case and includes one or more upstream security zones. No structural restrictions are imposed in the web integration concept because the security measures are always arranged around PROFINET devices. As a result, PROFINET devices are not burdened, and the security concept can be optimized to the changing security requirements for a continuous automation solution.

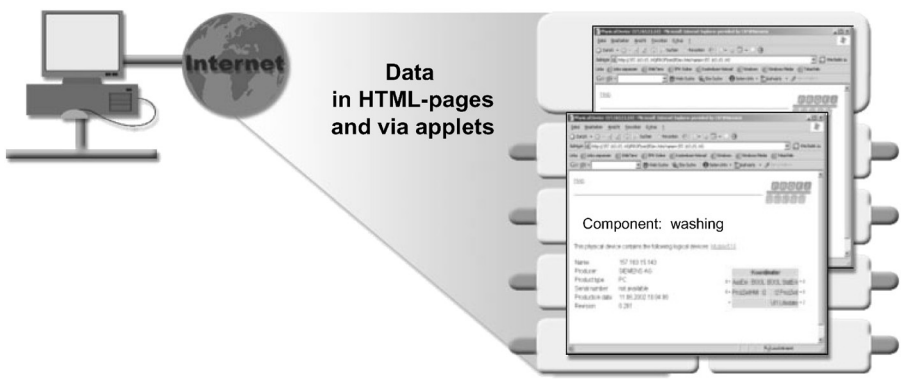

FIGURE 102.21 Web integration enables web access to PROFINET components

© 2005 by CRC Press LLC

The best-practice recommendations for PROFINET web integration contain scenarios and exam-ples of how requirement-dependent security measures can be implemented around PROFINET devices.

In this way, for example, security mechanisms can be used in the transport protocols (TCP/IP and HTTP). In addition, encoding, authentication, and access management can be scaled in the utilized web servers. Advanced security elements such as application gateways can be added for web services, if required.

OPC

The PROFINET component model and OPC have the same technological basis, that is, DCOM. This yields user-friendly options for data interchange between different plant units. OPC is a widely used interface for data exchange between applications in automation systems. OPC enables a flexible selection of stations of different manufacturers and data exchange between the stations without programming. OPC is not object-oriented like PROFINET, rather, it is tag-oriented. That is, the automation objects do not exist as COM objects but rather as names (tag).

OPC Data Access

OPC Data Access (DA) is an industry standard that defines a uniform user interface to access process data. As a result of this standard, the following are harmonized: access to data of process and control devices, locating of OPC servers, and simple browsing in the namespaces of the OPC servers.

OPC Data Exchange

OPC Data Exchange (DX) defines a communication standard for the higher-level exchange of non-time-critical user data on the system level between controllers of different manufacturers and types (e.g., between PROFINET and Ethernet/IP. However, OPC DX does not permit any direct access to the field level of another system. OPC DX represents an expansion of the OPC DA specification and defines interfaces for interoperable data exchange and server-to-server communication in Ethernet networks.

OPC DX is commonly used by the following:

- User and system integrators who integrate devices, controllers, and software of different manufacturers and want to enable access to jointly used data in multivendor systems.
- Manufacturers who want to offer products that are based on an open industry standard for interoperability and data exchange.

OPC DX and PROFINET

OPC DX was developed with the objective of having a minimum degree of interoperability between the different field bus systems and Ethernet-based communication protocols. In order to maintain an open connection to other systems, OPC DX was integrated in PROFINET. Integration is accomplished as follows:

- Each PROFINET node can be referenced as an OPC server because the basic capacity already exists in the form of the PROFINET Runtime implementation.
- Each OPC server can be operated as a PROFINET node by means of a standard adapter. This is accomplished by the OPC objectizer, an SW component that implements a PROFINET device on the basis of an OPC server in a PC. This SW component need only be implemented once and can then be used for all OPC servers.

The functionality and performance of PROFINET are significantly greater compared to OPC. Moreover, PROFINET offers the required real-time capability for automation solutions. On the other hand, OPC exhibits a higher degree of interoperability (Figure 102.22).

102.8 Integration of Field Bus Systems

PROFINET offers a model for integrating the existing PROFIBUS and other field bus systems. This enables any combination of field bus and Ethernet-based subsystems to be established. In this way, a continuous technology transfer from field bus-based systems to PROFINET is possible.

Migration Strategies

In view of the large number of existing PROFIBUS systems, it is essential for purposes of protection of investment that these systems be able to be easily integrated into PROFINET (migrated) without any changes. The following cases are distinguished:

- The *plant operator* would like to be able to easily integrate his existing installations into a new PROFINET automation concept that is to be installed.
- The *plant construction engineer* would like to be able to use his proven and documented range of devices for PROFINET automation projects without any changes.
- The *device manufacturer* or OEM would like to be able to integrate his existing field devices in PROFINET systems without expending any effort on changes.

There are two ways available in PROFINET for connection of field bus systems:

- Integration of field bus devices by means of proxies and
- integration of field bus applications (Figure 102.23).

Integration by Means of Proxies

The proxy concept in PROFINET enables simple, highly transparent integration of existing field bus systems. The proxy is the representative on the Ethernet for one or more field bus devices (e.g., on the PROFIBUS). This representative ensures transparent communication (no protocol tunneling) between the networks. For example, the representative forwards cyclical data to the field bus devices transparently. In the case of PROFIBUS DP, the proxy is, on the one hand, the PROFIBUS master that coordinates data exchange among the PROFIBUS stations and, on the other, an Ethernet station with

© 2005 by CRC Press LLC

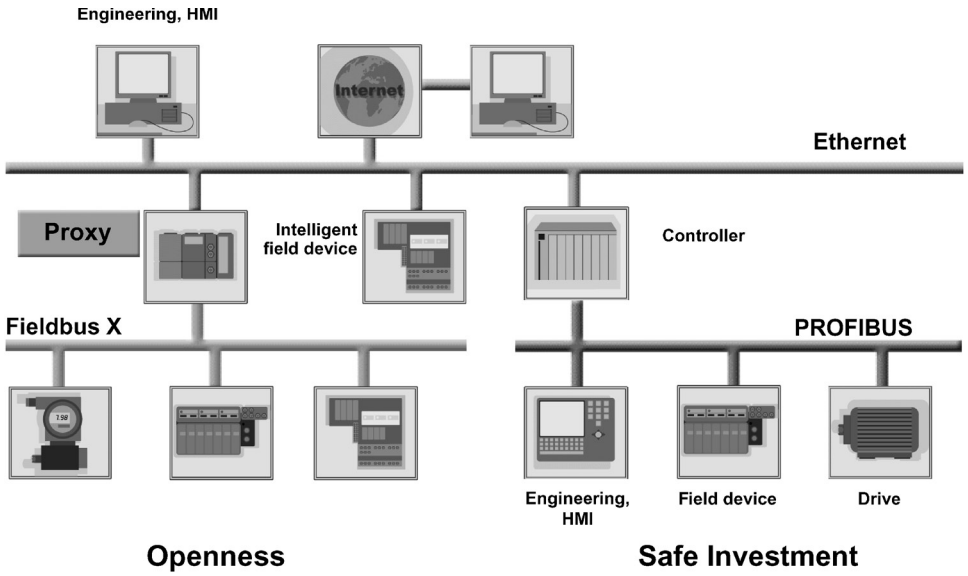

FIGURE 102.23 PROFINET offers openness and protection of investment to device manufacturers and end customers.

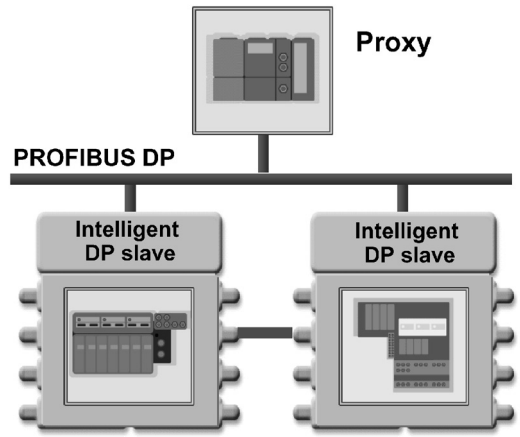

FIGURE 102.24 Principles of integration of individual field bus devices using a proxy: PROFIBUS example.

PROFINET communication. A proxy can be implemented, for example, as a PLC- or PC-based control or purely as a gateway (Figure 102.24).

The DP slaves on the PROFIBUS are handled as IO devices in the PROFINET IO context. In the component view, the intelligent DP slaves are used as stand-alone PROFINET components. Within the PROFINET interconnection editor, such PROFIBUS components cannot be distinguished from the components on the Ethernet. The use of proxies enables transparent communication between devices on different bus systems.

Integration of Field Bus Applications

An entire field bus application can be copied as a PROFINET component within the framework of the component model. This is always important if an existing operating plant is to be expanded using PROFINET. Which field bus was used to automate the plant unit plays no role in this case (Figure 102.25).

© 2005 by CRC Press LLC

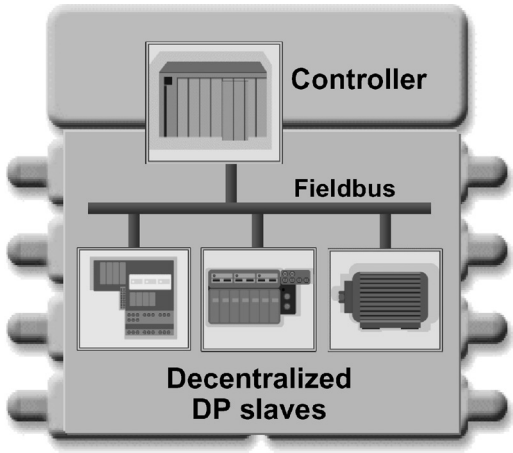

FIGURE 102.25 Principles of integration of field bus applications: PROFIBUS example.

To communicate with the existing plant using PROFINET, the field bus master in the PROFINET component must be PROFINET-capable. Consequently, the existing field bus mechanisms (e.g., PROFIBUS DP) are used within the component and the PROFINET mechanisms are used outside the component.

This migration options ensures that the investment of the user (plant operators and plant construction engineers) in existing plants and cabling is protected. In addition, existing know-how in the user programs is protected. This enables a seamless transition to new plant units with PROFINET.

PROFINET and Other Field Bus Systems

The proxy concept can be used to integrate other field bus systems besides PROFIBUS in PROFINET (e.g., Foundation Fieldbus, DeviceNet, CC-LInk, etc.) A bus-specific image of the component interfaces must be defined and stored in the proxy for all possible data transmissions on each bus. This enables any field bus to be integrated in PROFINET with a manageable amount of effort.

102.9 PNO Offer

Optimal support by the PROFIBUS User Organization (PNO) is important for rapid dissemination of PROFINET in the market. In order to guarantee this, a powerful offer of services and products has been established (Figure 102.26).

Technology Development

PROFINET IO

A specification is available for PROFINET IO, which provides a detailed description of the device model and the behavior of a field device in the form of protocols and communication sequences (so-called state machines). This type of description has already been proven with PROFIBUS DP. The level of detail in the PROFINET IO specification permits software creation of a standard stack from different stack suppliers.

It must therefore be anticipated that different implementations by a few firms will be offered. For example, Siemens offers implementation in the form of a development package.

Component Model

Like PROFINET IO, the PROFINET component technology is available as a detailed specification. The specification includes all aspects including communication, device model, engineering, network

© 2005 by CRC Press LLC

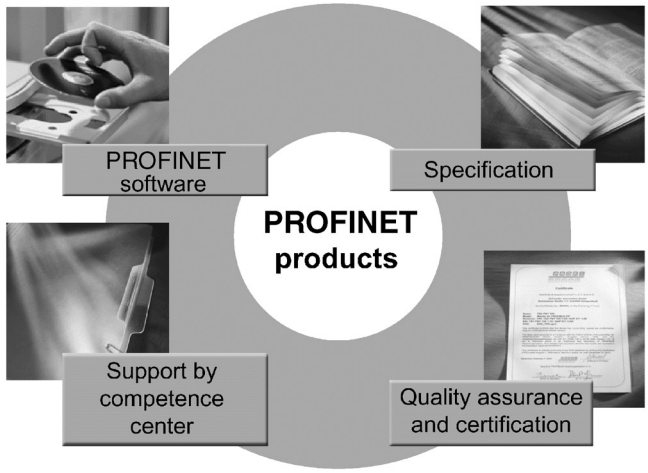

FIGURE 102.26 PROFIBUS User Organization (PNO) offer.

management, web integration, and field bus connection. In addition to the specification, the PROFIBUS User Organization (PNO) is offering PROFINET software (in the form of source code) for the component technology. The PROFINET software includes the entire run-time communication. The combination of a specification and operating system-independent software (as source code) has created the opportunity for easy, time-saving integration of PROFINET into a wide range of device operating system environments.

The PROFINET run-time software is structured in such a way that it supports a simple integration of existing application software in the run-time object model. Sample portings for Win32, Linux, VxWorks, and WinCE are already available for PROFINET. The PROFINET run-time software has a modular design and consists of various layers that must be adapted to each system environment. These adaptations are confined to the porting interfaces for the different functional parts of the environment, the operating system (e.g., WinCE), and the device application (e.g., PLC). Instructions for porting are available, enabling the device developer to easily understand the individual porting steps.

Quality Measures

From the start, the PROFIBUS User Organization (PNO) has developed PROFINET with the assurance that the entire life cycle from the PROFINET specification to plant engineering is supported by measures that guarantee a high level of quality in each phase.

QA for the Specification and Implementation Processes

The PROFINET specification and software are created in a working group represented by multiple companies ("PROFINET Core Team"), whose mission is to ensure that the entire development process ranging from the initial formulation of requirements to the release of the PROFINET software is conducted under the auspices of quality management (QM). Quality measures are governed by a QA manual adapted to the boundary conditions of the multicompany development team. This ensures that the source code corresponds to the quality management rules in effect at that time. The QA manual describes the process model to be applied. It defines the terms, methods, and tools that must be applied in the QA measures. It also specifies the responsibilities in the overall QA process. Defect management represents a major component. Defect management includes a unique error classification and understandable error message communication.

Testing and Certification

To ensure the interaction of all PROFINET devices and a high level of product quality from the start, a certification system has been established. Proven models for PROFIBUS products in accordance with the certification system have been established. Certification tests by accredited test laboratories authorized by the PROFIBUS User Organization (PNO) form the core of the process. The test for obtaining a test certificate

© 2005 by CRC Press LLC

by these competent test laboratories ensures that the products offered conform to specifications and are free of errors.

Defect Database

In order for defects and requests from end customers and device manufacturers to be systematically addressed in the run-time software, defect databases have been set up by the PROFIBUS user organization (PNO). A defect database containing a record of all defects and their status is available. The entries in the database comply with the QA process rules.

Technical Support

An important factor for the success of PROFINET is that a sufficient number of PROFINET products from different manufacturers are available on the market within a short time.

Competence Center

The PROFINET Competence Center has been established for support of the product development process. This ensures that porting to the different operation systems and adaptation to product-specific boundary conditions occurs in an optimal manner, particularly in the initial phase when companies lack experience. The Competence Center builds up know-how in interested companies so that development departments can develop additional products skillfully without additional support. The services of the PROFINET Competence Center also include a telephone hotline and customized workshops.

Tools

A tool for device manufacturers is required for creation of a component description of Ethernet devices in the form of an XML file. The PROFIBUS User Organization offers the PROFINET Component Editor — similar to the GSD Editor in PROFIBUS DP — for download on its website (Figure 102.27).

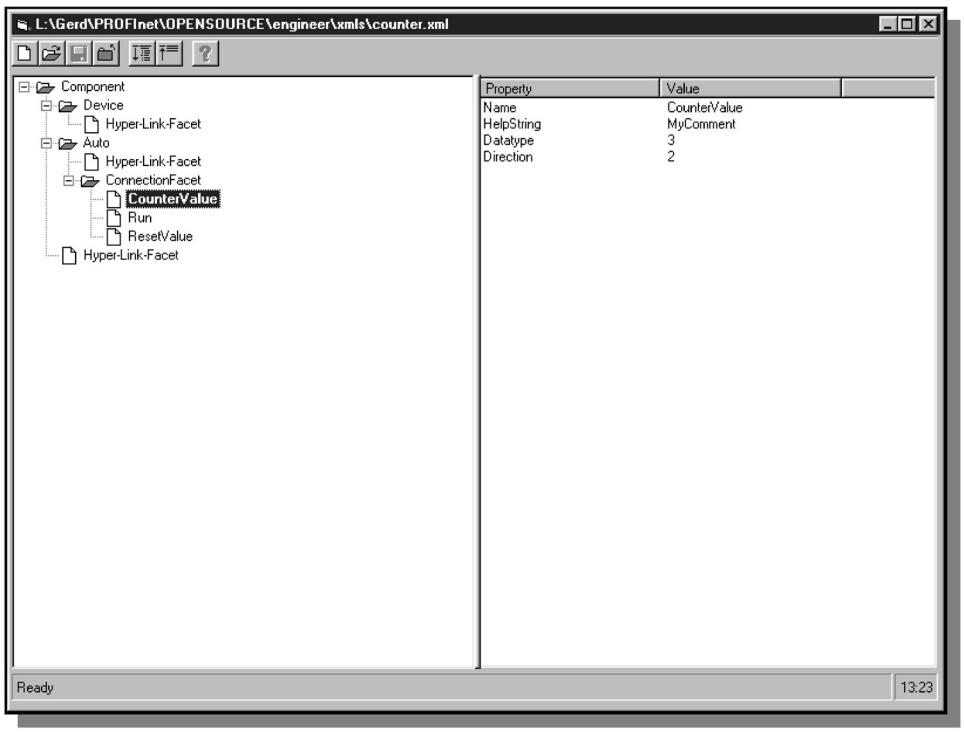

FIGURE 102.27 PROFINET component editor.

© 2005 by CRC Press LLC

In order to prepare newly developed products for certification, the PROFIBUS User Organization (PNO) offers a PROFINET testing tool for download on its website. The PROFINET testing tool enables the device manufacturer to perform static tests prior to certification (Figure 102.28).

The IDA Standard

103.1 Introduction
103.2 A Comprehensive Specification is Available
103.3 IDA Architecture
103.4 The IDA Communication Model
103.5 IDA and Modbus TCP/IP
103.6 Using Web Technologies
103.7 Safety Technology Integrated
103.8 Summary

Martin Buchwitz
Jetter AG, Germany

103.1 Introduction

IDA stands for "Interface for Distributed Automation." It is an open standard for automation technology, based on distributed intelligence, aiming to achieve the interplay of tools and devices in a nonhierarchical network, in which each participant is able to communicate with any other participant in realtime.

IDA is based on Ethernet, containing IT and Web technologies, besides safety technology. This goes to show that IDA is far more than just Ethernet technology or simply a protocol. The specifications presented in this chapter illustrate significant elements of the standard.

The Modbus-IDA is an association with the aim to develop a comprehensive standard for distributed intelligence in automation technology, containing software, hardware (i.e., devices as well as their description), and communication. IDA includes all automation devices, even the company's electronic data processing. Whenever standards can be used, IDA integrates them into its standard, thus, for example, the Internet protocols FTP, http, and others, as well as OPC from the automation world. IDA consists of the following functions and technologies:

- Ethernet TCP/IP and web technologies.
- All communication services and interfaces to devices and software.
- Interoperability of devices by differing manufacturers.
- Horizontal integration, that is, communication without interfaces or extra programming.
- Vertical integration, that is, the connection between production and data processing, including the Internet.
- Safety on Ethernet is integrated in the concept.

The aim of all this is to be able to use software and devices by differing manufacturers in a common network with distributed intelligence, which can then be integrated into the overall network by plug and play. What we are talking about are devices such as PLCs, Soft-PLCs, drive controllers, remote I/Os, as well as user interfaces. Any Modbus-IDA compatible tool may be chosen for programming, (Figure 103.1).

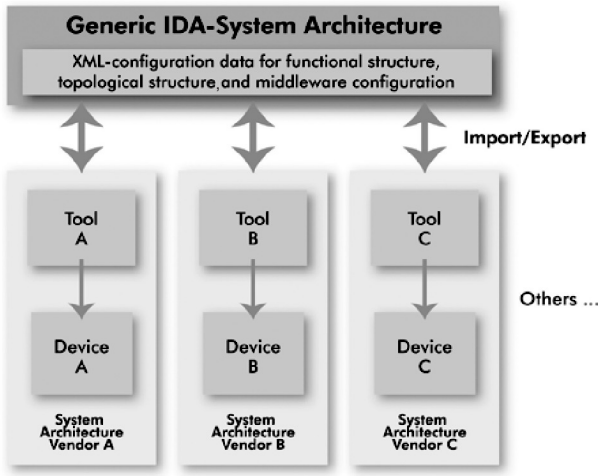

FIGURE 103.1 IDA is a multivendor standard that gives priority to interoperability of devices.

103.2 A Comprehensive Specification is Available

The specification available goes to show as to what is at the core of IDA technology: it is subdivided into the areas architecture, communication, web technologies, and safety, just like the respective work-groups. The specification is supplemented by chapter XDDML (Extensible Device Description Markup Language). XDDML is a system and network-independent description language for devices. This language may contain descriptive elements in various languages in an XML file.

The IDA specification is available and it is open for anyone, ready for download from the IDA website http://www2.modbus-ida.org/idagroup/. The main features of the specification will be outlined in this chapter (Figure 103.2).

103.3 IDA Architecture

The IDA system architecture model is based on the following technological pillars:

1. The application model describes the structure and basic elements of a modular application, based on the reference architecture defined in IEC 61499. Thus, the foundation is laid for subdividing an automation application into any structure of hierarchy, which makes for an optimum detailed presentation of the individual functions required for a specific task.
2. The engineering model contains the plant and machine model, illustrating the relationship between the application model and the engineering framework components. It describes how a concrete automation application is set up, which conditions have to be met, as well as the relationship between the individual elements.
3. IDA defines the logical layer of the programs within the application model, independent of the physical layer of the devices concerned. The process model describes the image of application model elements for their execution, thus forming a bridge between logic and physics, which now merely needs to be configured and will have no influence on the program structure.
4. The presentation model includes the description of the external behavior of the application model elements. To this end, all model elements supply ports of a defined structure through which individual elements may be connected to form an overall network. For an IDA block, these are the Input and Output ports of the event and data connections through which the IDA block cooperates with other IDA blocks. Within an active network of co-operating IDA blocks, the presentation model projects this structure onto the communication aspects of the real-time middleware.

© 2005 by CRC Press LLC

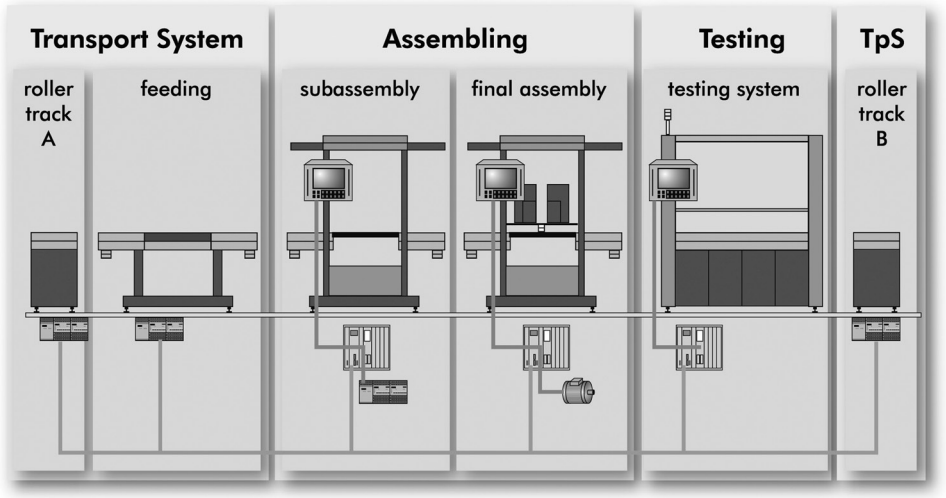

FIGURE 103.2 Especially with modular arrangement of machines, the advantages of distributed intelligence with Ethernet, such as transparent communication structures, become noticeable.

5. Within a distributed automation system, the static connection between visualization and control is difficult to handle, as logic and physics are principally deconnected. As a program can only be connected to the executing resource comparatively late and may even have to be reconfigured, visualization is connected to the logic in the HMI model independent of the physics. In order to have access from any visualization system or user interface simultaneously and independent of their location, the HMI model is based on Web technologies and supplies standardized access through a browser-based user interface for supervising and diagnosing an automation solution.

Thus, the IDA system model addresses all architectonic requirements that have to be met with the design and configuration of hierarchically structured distributed automation systems. As the development of the function block-oriented standard IEC 61499 is based on equivalent requirements, the model defined in this standard has been adopted as a reference architecture for distributed systems in the IDA system model. Proprietary manufacturer-bound technologies have been avoided (Figure 103.3).

103.4 The IDA Communication Model

Communication with IDA is based on an integrated approach containing the modeling of communication aspects as well as the network view of functionality. IDA device communication is based on existing Ethernet communication standards and protocols (such as IP, UDP, TCP, HTTP, FTP, SNMP, DHCP, NTP, and SMTP). Important is the fact that the IDA communication system offers real-time as well as non-real-time communication services. The non-real-time services are mainly based on the Ethernet communication protocols mentioned above, while real-time communication services (such as data distribution, Remote Method Invocation, and Event Notification) are working with the RTPS (Real-Time Publish/Subscribe) protocol, which is based on the UDP protocol. Publish/Subscribe means that information is sent directly from the information source (e.g., the sensor) to the user of the information (e.g., PLC). The source takes the initiative for sending the data, in contrast to the request/demand method in master/slave solutions. The publisher makes data available under a name in the network, which the subscriber will use to identify the data it wants to receive.

In order to realize the configuration and execution of real-time communication services, IDA specifies an object-oriented model building a hierarchy of communication objects, which can be accessed through a Application Program Interface (API). In the process, specific requirements of safety-relevant applications

© 2005 by CRC Press LLC

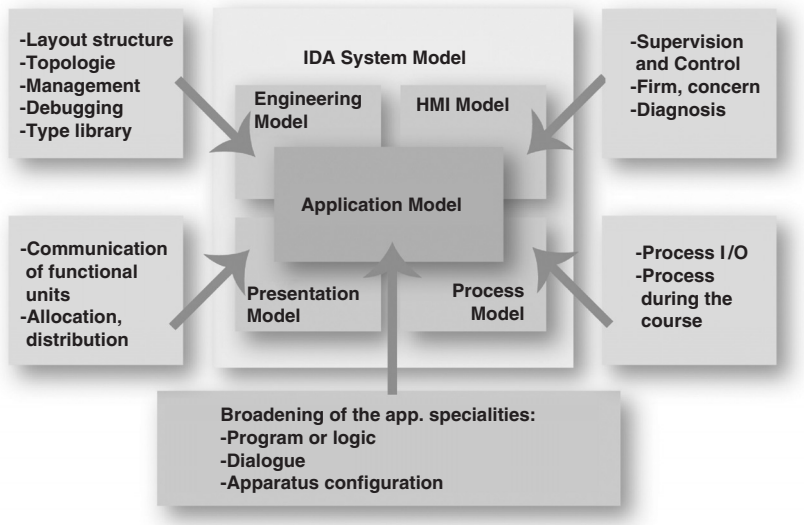

FIGURE 103.3 The IDA system model takes into account the whole cycle of an automation project, from configuration to runtime, and maintenance.

are supported through a special safety API. The illustration of IDA functions is based on a hierarchical view of objects describing the physical and logical structure of a devices with its communication performance and the application data connected to the network.

Real-time communication with IDA is based on the use of the RTPS protocol. In general, real-time services have top priority among all IDA communication services. Depending on the requirements of the application, various kinds of real-time communication relations and resulting network traffic will appear: preconfigured or dynamic, cyclical or on-demand, point-to-point or group oriented.

103.5 IDA and Modbus TCP/IP

Worldwide, most devices communicate via industrial Ethernet using Modbus TCP/IP. The IDA Group has decided to closely cooperate with the Modbus user group, and is adopting Modbus into their IDA Standard as a quasistandard for Ethernet communication in automation technology. Modbus TCP/IP has been presented to the IETF (Internet Engineering Task Force) in order to officially establish the protocol as an Internet standard. Thus, Modbus TCP/IP will be implemented as a standard in all common operating systems, as well as FTP or http. Apart from this, Modbus occupies one of the first 1000 defined ports, namely port no. 502. The fact that this port is no longer available for other applications is another factor that helps to establish Modbus as a standard (Figure 103.4).

Modbus TCP/IP is a part of the IDA standard, which leads to a situation where a large installed basis and several hundred manufacturers will be available for it. As Modbus TCP/IP is completely transparent, it perfectly fits into the IDA strategy of open standards. IDA will actively support the activities of the Modbus organization in their work groups, participating in the development of tool kits. Apart from this, there may be an even closer cooperation in the future.

Strategically, two things are achieved by integrating the Modbus TCP stacks into the IDA stack: firstly, the largest actually existing Ethernet standard for devices meets the lowest IDA conformity level, and has the option for other upward compatible services based on the Client–Server and the Publish–Subscribe model. Secondly, in this way, IDA is making itself available for being implemented in very low-performing devices, due to an especially lean stack.

© 2005 by CRC Press LLC

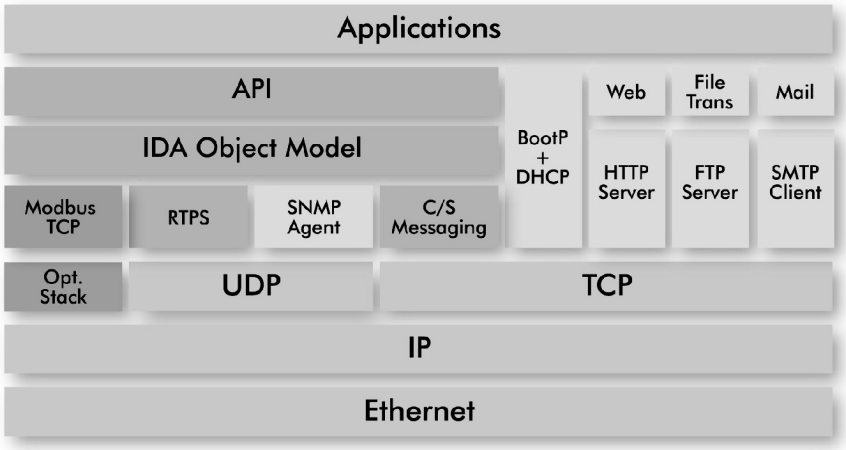

FIGURE 103.4 The IDA standard now also contains the Modbus protocol, thus addressing the major part of the Industrial Ethernet market. Modbus is in the process of becoming an Internet standard, which means that in the future, it will be available as standard in all relevant operating systems.

103.6 Using Web Technologies

The IDA standard defines varying web-based device services:

- access to device-specific data required for the definition of user-defined web-sites,
- display of device characteristics for device-specific web-sites,
- modification of the device configuration for the illustration of the state of the device, and of parameters,
- device diagnostics for local or remote maintenance,
- remote maintenance with save/restore function for data download by means of FTP,
- monitoring and user input,
- creating and saving of user-defined web-sites,
- device documentation, and
- Web HMI services for alarm functions, data history, and mathematical functions in the form of Java code.

The IDA standard defines four differing types of web servers: depending on the device and its performance and characteristics, there will be a scalable solution. The fact that CPU and memory resources for integrated systems are limited must be taken into consideration. In the case of IDA devices, these resources are mainly reserved for real-time functions, such as real-time communication.

The web server as such may contain various functions, as well as an installation capacity ranging from 7 to more than 50 kB, with a complete server. According to the large range of device characteristics, the server concept has been subdivided into four categories.

Each category describes a web server fitting into a certain type of device and meeting certain IDA Web requirements. The hardware and firmware characteristics as well as requirements regarding the server are decisive for the choice of a web server. The following classes have been defined (Figure 103.5):

- Minimum Server.
- Device Configuration Server.
- Configurable Server.
- Web Active Server.

© 2005 by CRC Press LLC

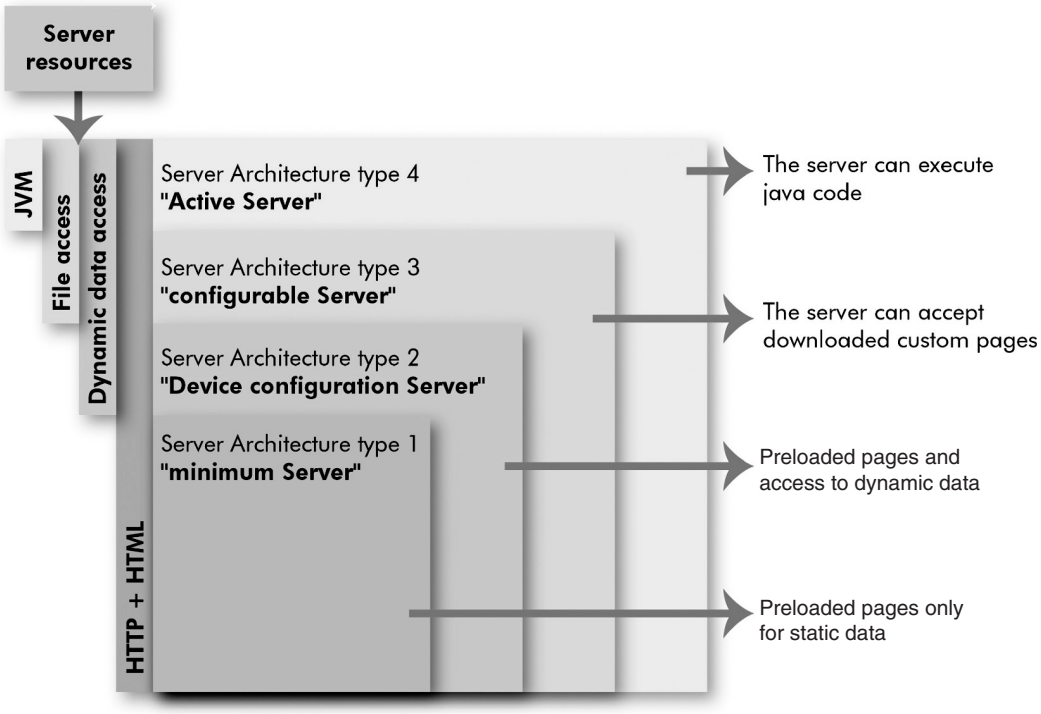

FIGURE 103.5 An important requirement for the universal use of Internet technologies is the availability of devices. To accelerate this process, the Modbus-IDA has developed a four-stage Web-server model for devices of differing performance.

103.7 Safety Technology Integrated

Basically, the current Ethernet transmission methods and formats do not meet the safety-oriented automation standards. Ethernet-specific safety measures are able to detect simple failures; effective algorithms for identifying and handling repetitive statistical or systematic faults are missing, however. Beyond this, the Ethernet standard is only relevant for data transmission, as well as their formats and services. Demands on a safety-oriented Ethernet, however, are much higher: in this case, the failure model must not only refer to the bus system and data traffic as such but also include application, interface technology, power supply, as well as the transmission medium.

The communication model chosen for Ethernet contains a specific safety layer (IDA Safety API), supplying all safety data with formats and services that are able to meet all common faults related to data transmission. As subordinate layers are not altered, the entire communication is fully compatible with standard Ethernet.

103.8 Summary

IDA is more than a simple protocol on Ethernet, and more, too, than just an Ethernet technology. IDA is a standard for modern structures of distributed intelligence, using the most recent software, hardware, and network technologies. IDA eliminates traditional barriers within automation technology (horizontal integration) as well as barriers between production and data processing (vertical integration). Whenever possible, already existing standards such as Ethernet TCP/IP, XML, http, OPC, and others are used and integrated into the entire IDA concept. IDA comprises the area of engineering using its tools, as well as the entire communication sector with its demands on realtime and safety.

Open System Architecture for Controls within Automation Systems (OSACA)

104.1 About OSACA

104.2 OSACA Technical Overview
Communication Platform • Reference Architecture • Configuration System

104.3 Applications
Demonstrators • Pilot Applications • OSACA CNC-kernels • HÜMNOS Applications • Tools • Projects Based on OSAC • OSACA Project Background and Phases

Michael Seyfarth
ISW-University of Stuttgart

Andreas Kahmen
Werkzeugmaschinenlabor

104.1 About OSACA

Open System Architecture for Controls within Automation Systems (OSACA) is a European initiative to define a vendor-neutral, open controller architecture in order to improve the competitiveness and flexibility of suppliers and users of control systems: machine tool builders, control vendors, and end users.

To cope with these aims, the requirements for a new generation of control systems were analyzed. Out of this preparatory work, an application programming interface (API) for control applications and an appropriate infrastructure (the so-called system platform) were specified and implemented.

104.2 OSACA Technical Overview

The control functionality was divided into several so-called Architecture Objects (AOs), which use the API and the underlying communication system to exchange data. Using this concept, the OSACA architecture supports the characteristics of an open control system: interoperability, portability, scaleability, and reusability of applications Figure 104.1.

Pilot applications and control prototypes were implemented on different operating systems in order to verify and improve the specifications.

© 2005 by CRC Press LLC

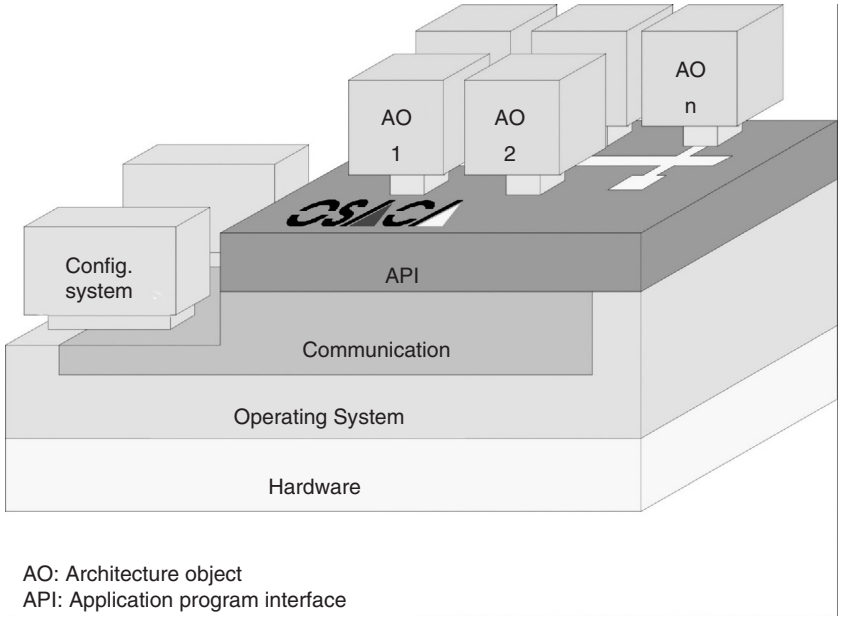

FIGURE 104.1 OSACA system architecture.

Three main features of OSACA include:

Communication Platform

This defines a hardware- and system-software-independent interface to exchange information between different application modules of a controller. The interface hides any specific details of the underlying transport system and therefore enables the combination of modules distributed on one or several processor-boards.

Reference Architecture

This determines the functional units of a controller, such as, for example, Motion Control (MC) and Logic Control (LC) and specifies their external interfaces. This makes it possible to use and integrate functionality of external units by interacting with internal data in a well-defined manner.

Configuration System

This enables the dynamic configuration of a controller by combining different application modules at bootup time. This allows not only the setup of a specific topology for a given functionality, but also the synchronization between distributed processes. A graphical configuration tool allows the simple projection of control applications.

Communication Platform

The communication system is the only means of the system platform for the exchange of data between application modules, so-called AOs. It must support both, the exchange of information between tightly coupled AOs, for example, located on the same processor-board as well as between AOs distributed over different hardware units connected through a bus-system. A standardized protocol is defined to ensure uniform data formats and a fixed set of messages. The protocol architecture is derived from the OSI base reference model. However, it comprises only two layers: a Message Transport System (MTS) equivalent to the OSI layers 1 to 4 and an Application Services System (ASS) equivalent to layers 5 to 7 (Figure 104.2).

The *MTS* offers connection-oriented services for a transparent transport of arbitrary messages between AOs. It can be adapted to use any kind of existing mechanisms for information exchange, for example, operating system services like message queues and shared memory, as well as LAN-protocols like TCP/IP.

© 2005 by CRC Press LLC

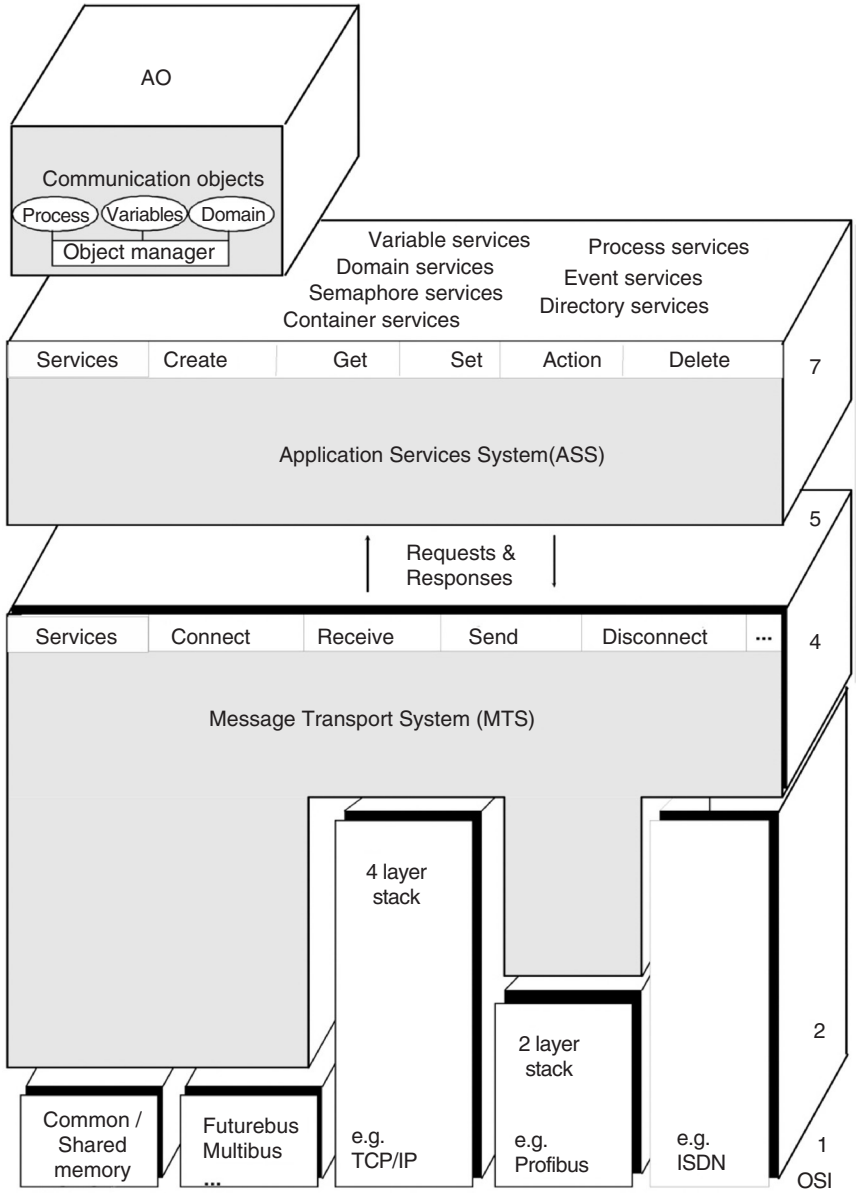

FIGURE 104.2 OSACA communication platform.

The *ASS* has the task to handle the application protocol. This includes connection management, the assembly/disassembly of messages, and data conversion between different data representations like Little and Big Endian. Additional functionality covers synchronous and asynchronous services as well as the segmentation of large data into smaller message units.

The OSACA application protocol is realized on a client/server basis using object-oriented principles. With the help of so-called communication objects, a server AO provides access to its data and functionality. From a client's point of view, a server includes a set of communication objects that can be accessed by sending and receiving messages using the communication system.

© 2005 by CRC Press LLC

There is a fixed set of classes for Communication Objects (Cos), which are managed by the so-called Communication Object Manager (COM). Through the separation of application and communication services, the application programmer can fully focus on solving his control-specific problem (Figure 104.3).

Reference Architecture

As described above, the OSACA communication system allows for a transparent exchange of information between client and server applications. In order to enable an unequivocal interpretation and use of the exchanged data, additional definitions are required. These definitions cover *first* the logical classification of functionality into so-called functional units, which in most cases are identical to the AOs. Examples of functional units are: Man Machine Control (MMC), LC, MC, and Axis Control (AC).

Second, for each of the identified units, the functionality and behavior of external modules have to be described. This is done by using communication objects that form the data interface and the process interface of an application module.

The *data interface* provides the read and write access to data located inside an AO. The access is enabled by the use of communication objects of the CO class "variable." Each internal variable, which should be accessible by the outside environment, must be mapped into an instance of that CO class. The tuple comprising the internal variable and the CO is called an attribute of the AO. From the outside, these attributes can be accessed by calling appropriate services of the communication system.

The *process interface* defines the dynamic behavior of an application module. It allows to trigger and control the functionality that is provided by an AO. The call to an internal function is initiated by an "action" service via the communication system to the corresponding CO of the class "process." To bring the functions into a logical relationship with necessary preconditions state machines are used. The figure below gives an overview on a subset of communication objects that are defined for the AO "Motion Control" (Figure 104.4).

The description of a single CO is made by using formal templates. With these templates, all the necessary information is provided to implement and use the specific communication objects in the different AOs.

Configuration System

Typically, the process of realizing a specific configuration of a control system is of a static nature. Before runtime, the software is completely compiled and linked, forming one executable that is downloaded to the control level. This solution is, however, inflexible and requires high efforts if modifications and additions are necessary after the delivery of the control level.

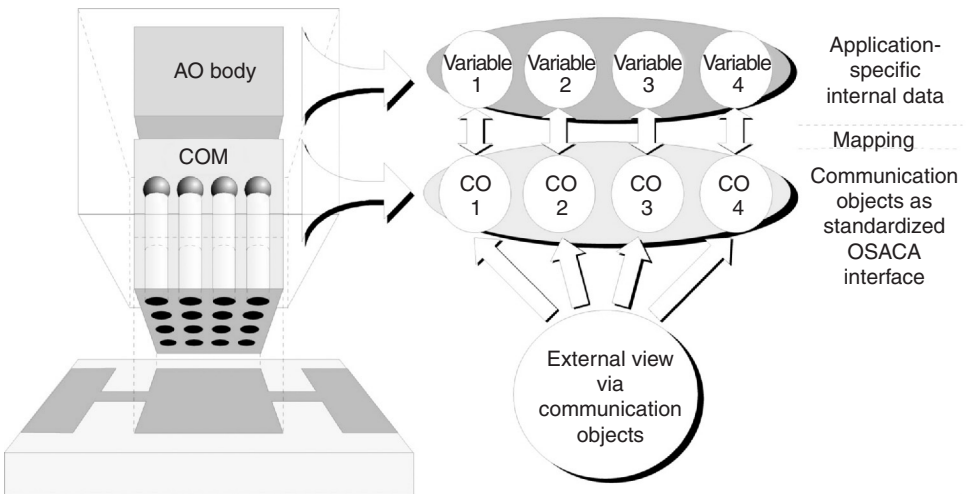

FIGURE 104.3 Data exchange via Cos.

© 2005 by CRC Press LLC

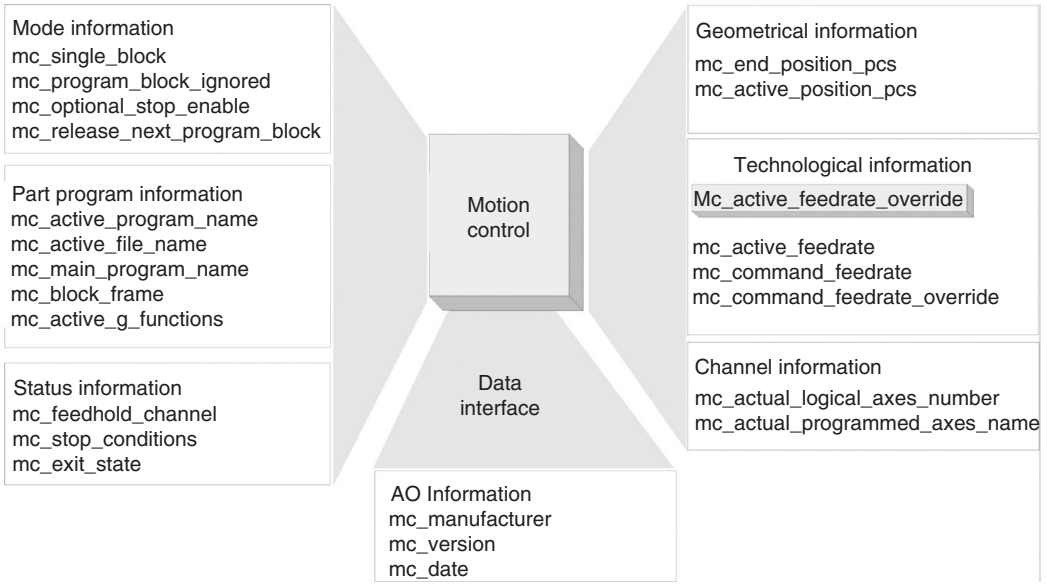

FIGURE 104.4 A subset of Cos.

To overcome this situation, a fully modular system is needed where the actual topology of the software is generated at the bootup of the system. For this, the system platform has to contain a configuration system that is able to handle a library of AO classes. At bootup, AOs of the different classes are instantiated and communication connections between AOs are established.

The actual topology of the control system is described in an externally generated ASCII configuration list, which is interpreted by the Configuration Run-Time System (CRS). A graphical configuration editor can be used to define the configuration order in the manner as CAD-systems are used to define the layout of a processor-board.

The configuration order contains a list of all AO instances that are necessary for a specific control system satisfying the requirements of a control application. It is possible that there are several instances of the same AO class, for example, class AC. For every AO, the client/server relationships are defined. Every relationship between a client and a server AO consists of a list of communication objects of the server, which will be used under specific names in the client (Figure 104.5).

104.3 Applications

Demonstrators

OSACA-Demonstrator at ISW

In order to demonstrate the benefits and capabilities of OSACA and to show the feasibility of a control based on its architecture, a demonstrator machine was set up at the Institute for Control Engineering of Machine Tools and Manufacturing Units (ISW), at the University of Stuttgart in 1994. It is a portable three-axis milling machine with conventional interfaces to the drives, the analog, and the digital I/Os. Figure 104.6 shows the front side of this demonstrator.

The control system runs on different hardware platforms, using Windows95 for operator-related functionality and VxWorks for machine-related control functionality. The NC-kernel is a compilation of software control units written in C-language. These units belong to a modular control construction system that is commercially available. For accessing the functionality of the NC-kernel, an OSACA compliant gateway process was implemented in the real-time part.

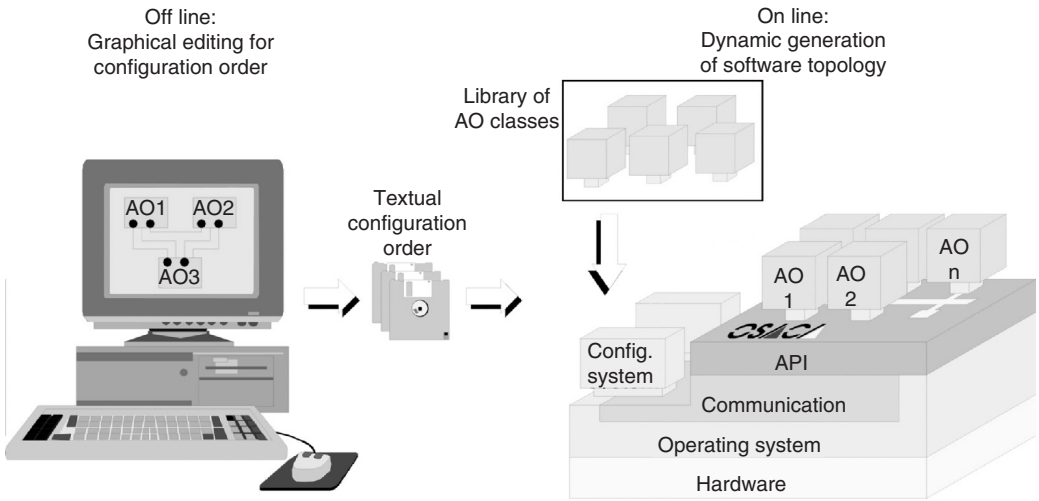

FIGURE 104.5 System configuration in OSACA.

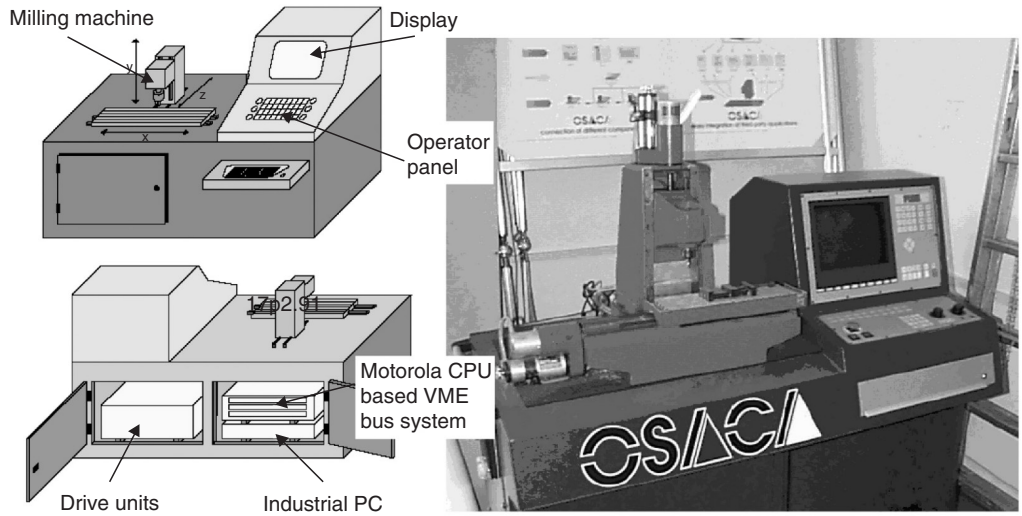

FIGURE 104.6 The OSACA demonstrator (three-axis milling machine).

The demonstration does not only show the communication between clients (e.g., HMC) and servers (e.g., NC-kernel) but also proves that existing control applications can easily be equipped with an OSACA-compliant access.

OSACA-Demonstrator at WZL

In the beginning of 1995, the development of a new NC-controller named "WZL-NC" commenced at the WZL (Laboratory for Machine Tools and Production Engineering). This was the time when the first OSACA software was available. It was decided to use OSACA as the platform basis for that controller to gain the benefits of OSACA (modular, configurable, extendible platform, independent from hardware and operating system). A second reason for choosing OSACA was to develop a test-bed for OSACA to gain experiences in an industrial environment and to improve the platform software.

© 2005 by CRC Press LLC

The WZL-NC is connected to a five-axis milling machine as shown in Figure 104.7. The NC offers fully spline-based algorithms for milling sculptured surfaces.

Pilot Applications

At the end of the HÜMNOS project, in 1998, one unit of a transfer-line at Daimler Benz was equipped with an OSACA-control System (CNC and SPS). A newly developed MMI Control Panel was connected via the OSACA interface. Another Pilot Application was realized at the BMW engine factory in Munich, also in 1998. Here, an assembling machine unit was driven by a SIEMENS S5-PLC with an OSACA architecture.

OSACA CNC-kernels

ISG-NC

The Industrielle Steuerungstechnik GmbH (ISG, www.isg-stuttgart.de) has realized an OSACA interface for their modular CNC-software-kit. The OSACA interface is running on the real-time operating system (VxWorks or OS-9) together with the CNC-kernel.

WZL-NC

At the Laboratory for Machine Tools and Production Engineering, a five-axis numerical control for milling was developed. This control serves WZL as a development platform and test environment for most diverse research tasks within the range of the numerical control technology.

The WZL-NC was realized as an OSACA control. Its software modules and its structure correspond to the OSACA reference architecture. Over the thus available open control interfaces, external developments can be integrated and tested simply in the control environment.

At present, the control runs on a serial 5-Achs MAHO milling machine and a Dyna-M kinetics.

HÜMNOS Applications

The HÜMNOS project (1995–1998) was based on the OSACA results. Within HÜMNOS, applications for the OSACA architecture were elaborated in different areas, such as CNC, PLC, HMI, Tool Management, Pallet Management, Maintenance and Diagnosis. Also, tools like a data monitor or a configuration system were developed (Figure 104.8).

- Windows-based Diagnosis Application for OSACA controllers.
- Windows-based MDA-Application for OSACA controllers.
- Windows-based Application for Order Administration and Processing Management on OSACA controllers.

Tools

Configuration Tool for OSACA Controls

New possibilities for flexibly generating control software of high quality result from using open control architectures; control systems can be configured uniformly and individually from libraries, using modular concepts in accordance to the demanded function range and efficiency. With the right tool, one can thus save cost and time. Therefore, a configuration tool for open controls was developed at the ISW (www.isw.uni-stuttgart.de).

The configuration process

Control software elements are deposited in a module library. They are encapsulated in the independent units, which contain both structural and functional information. This causes a high reusability of the modules.

Based on this library, new configurations are generated by dragging and dropping the modules into the project and by graphically connecting the communication interfaces. Due to this intuitive operation, the tool can be used by individuals after relatively short theoretical and practical training courses. With the help of automatic test mechanisms, configuration errors can be avoided.

After the configuration process has terminated, the target code for the control is generated.

Characteristics of the configuration tool

- Support of the model-based configuration: In a kind of "building plan," the project-neutral interactions of the control software elements that have been deposited in the library are described.
- Intuitive operation: Drags and drops elements from the library into the project, and provides an easy creation of communication relations by graphically connecting two pins (= communication interfaces).

© 2005 by CRC Press LLC

- Parameter setting of control software elements: The functionality of a module can be adjusted easily using comfortable editors.
- Automatic testing mechanisms: The generation process of a configuration is checked dynamically by integrated modules. In this way, faults can be avoided to the maximum.
- Generation of different control target codes: By using post processors that can be exchanged easily, the configuration result can be adapted to any arbitrary control.

Summary

Using the configuration tool, the time for creating a control configuration by using libraries can be reduced. Software can thus be produced at a lower cost. At the same time, the quality of software improves as a result of automated testing, and reuse of models.

OSACA Development Environment

For an efficient and user-friendly compilation of open control applications, a development tool has been realized by the Laboratory for Machine Tools and Production Engineering (WZL).

The OSACA Development Environment (ODE) enables the user to integrate process-specific know-how comfortably into controls without knowing details on how to program OSACA applications. The ODE continuously supports the software development all the way from the idea up to the finished application. It comprises the following functionalities:

Specification Editor

The Specification Editor supports the description of the modules' interfaces and the test of the system design already in early development phases.

Code Generator

The Code Generator provides a software framework for a module. Through this, the particularities of the communication system are completely hidden from the application programmer. In this way, he can concentrate on filling the framework with his specific functionality.

Data Monitor

The Data Monitor enables to analyze the interfaces of modular, distributed systems and to manipulate their contents. The optional logging and evaluation of exchanged data telegrams supports debugging on the lowest communication level.

OSACA-OPC Server

The OSACA-OPC (OLE for Process Control) Server is a Windows-based application for OSACA-compliant control systems to exchange data with OPC client applications, for example, Wonderware, Visual Basic, etc. The server application translates the OSACA protocol into the OPC protocol (Figure 104.9).

Projects Based on OSACA

SFB 368 "Autonomous Production Cell"

At Aachen University of Technology, a group of about 20 scientists from 10 different research institutes is currently developing the new concept of manufacturing systems called the autonomous production cell (APC) (http://sfb368.rwth-aachen.de/).

In this project, a "manufacturing cell" consists of a single machine including necessary handling systems and a worker. The goal is to develop the necessary technical means to enable such manufacturing cells to undertake complex machining tasks largely independent of other units within the company. To assure the failure-safety of the system, several process monitoring and process control modules are being incorporated into the control of the APC.

To realize the integration of the process monitoring and control functionality into the control, an open control system is needed. While first tests were undertaken using a commercially available control system offering limited openness, further implementations required a completely open control. The Laboratory

for Machine Tools and Production Engineering developed a fully OSACA-compatible NC, which is the basis of the APC control. This OSACA control offers the necessary preconditions for the realization of the cell´s autonomous functions.

SFB467 "Wandlungsfähige Unternehmensstrukturen für die variantenreiche Serienproduktion" (Transformable Business Structures for Multiple-Variant Series Production)

At the University of Stuttgart, a group of about 25 scientists from 9 different research institutes are currently working on the development of new concpts for changeable company structures demanded by high frequently changes driven by global competition.

One task is the realization of reconfigurable machining systems, including the control system. To include the new mechanisms of reconfiguration, there is a need for an fully open, modular, and configurable control system. The system is based on the principles of OSACA and OCEAN and allows the implementation of new modules like automatical reconfiguration.

OSACA Project Background and Phases

In Europe in 1992, the research project OSACA was started within the ESPRIT program of the European Commission. Within this project, the basics for a vendor neutral control architecture were defined. The focus was on the specification of a reference architecture for the system platform, the definition of a neutral application layer, and the development of communication mechanisms. This resulted in a strict division of hardware, system software, and application software. Furthermore, the OSACA architecture is characterized by the availability of its unique programming interface as well as the modular structure of its application software.

The OSACA project was carried out in the following phases:
OSACA Phase I (EP 6379); duration: May 1992 until October 1994.
OSACA Phase II (EP 9115); duration: November 1994 until April 1996.
OSACA - IDAS (EP 22168); duration: January 1997 until June 1998.
HÜMNOS; duration: January 1996 until December 1997.

In August 2002, the research project OCEAN, http://www.fidia.it/english/research_ocean_fr.htm (Open Controller Enabled by an Advanced Real-Time Network), funded by the European Commission, commenced. The OCEAN (IST-2001-37394) is envisaged to run from August 2002 until July 2005. This project aims at the development of a real-time capable platform for distributed control. This platform will enable a dynamic integration of control components that are based on an open specification. Through this approach, a flexible and application-specific configuration of the control system will be possible. The OCEAN project draws from OSACA by adopting solutions and incorporating newly available technologies such as Real-Time Linux and Real-Time CORBA.

105.1 OCEAN Background

Open Controller Enabled by an Advanced real-time Network (OCEAN) is a project funded by the European Commission under the Information Society Technologies (IST) priority. The activities are conducted through a consortium of ten partners, as of the end of 2003. The project started in August 2002 and will be completed by July 2005.

OCEAN is realizing a real-time-capable platform for distributed control applications. This platform will enable a dynamic integration of control components that are based on an open specification. Through this, a flexible and application-specific configuration of control systems will be possible.

The basic idea is to continue the approach of OSACA by adopting its benefits and realizing a fundamental improvement on the basis of newly available technologies. This strategy promises a broad industrial acceptance of open control technologies based on the DCRF.

© 2005 by CRC Press LLC

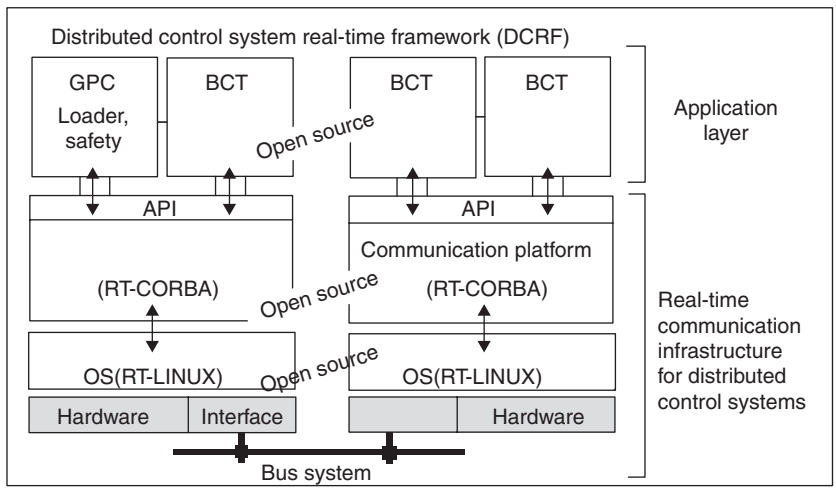
105.2 Objectives

The two main objectives of the project are:

1. The development of a "Distributed Control System Real-Time Framework" (DCRF) for numerical controls based on standardized communication systems and delivered as an open source. The DCRF is envisaged to host control components in distributed open platforms and provide a real-time communication Application Programming Interface (API). This framework is to be coupled with standardized interfaces enabling the integration of external real-time-critical and non-real-time-critical control components. The DCRF is based on open source components (e.g., RT-Linux as operating system, RT-Common Object Request Broker Architecture (CORBA) for standardized communication mechanisms) and will be available, as an open source, at the end of the project. Figure 105.1 shows the structure of the DCRF and motion control components.

   The communication within a complex, dynamic environment requires a maximum flexibility for the data transfer. Hence, the deployment of transparent communication standards is essential. Nowadays, reliable open communication systems like CORBA are available, which follow the object-oriented concept for data exchange. This property guarantees a transparent handling of data objects and furthermore makes use of the network transparency, which hides from the software developer the problems caused by the communication between distributed components. Embracing this philosophy means bringing a component-based view of the software to a network distributed environment. Applications use object interfaces without the need to know whether they use a local or a remote object. In terms of communication, this approach is the backbone of the DCRF that closes the gap between the distributed control components. With respect to communications, a main focus of the OCEAN project is on the real-time capability of the DCRF. Real-time communication is crucial for distributed control systems because it is a prerequisite for a productive, high-quality, and fail-safe production. The DCRF will be real-time capable in contrast to former approaches like OSACA, OPC, etc. This capability is crucial to distributed control systems.

   The DCRF will enable a flexible composition and reconfiguration of control systems with manufacturing task-specific functionality on the basis of a common communication platform. Suitable



BCT, Base component template; GPC, General purpose component; OS, Operating system;

FIGURE 105.1 Distributed Control System Real-Time Framework (DCRF).

© 2005 by CRC Press LLC

lower-level layers (hardware, bus system, RTOS) and the communication platform (RT-CORBA) have to be extended and integrated, so that they can serve as a distributed real-time framework for the whole control system with all its single components.

General-purpose components (GPC in Figure 105.1) for configuration, loader, and safety aspects are also a very important part of the DCRF. In particular, safety functions will be designed and implemented, which can assure a fail-safe operation of component-based control systems in industrial production.

2. The definition and realization of a component-based open numerical control reference architecture for machine tool; in order to take advantage of the open control systems, it is necessary to extend the existing reference architecture and to decompose the monolithic blocks into components with clearly defined interfaces, described in a standardized format. The open control reference architecture will not be delivered as an open source but with publicly available new standardized interfaces for motion control components of machine tools, which will make use of the DCRF. These interfaces will be published for further comments and implementations by users in the field of control techniques (the Base Component Templates (BCT) visible in Figure 105.1). Thus, it will become possible to integrate additional functionality and third-party software by just using the standardized interface description without a need to adapt interfaces. The component-based reference architecture, which will be developed in the OCEAN project, has to be seen as a starting point for the specification of further control system applications in the future. The first step is the design and implementation of motion control base components that are mandatory to operate a machine such as HMI, motion control kernel, PLC, and kinematics components (Figure 105.2).

   The second step aims at the design and implementation of motion control extension components that are not yet covered by any reference architecture, such as filter and process control components. Particular focus will be put on a new safety component that is specifically control related and includes mechanisms like real-time comparators for a multichannel environment. The component-based concept will be proved with tests and simulations of the single components as well as of the complete control system on different machine tool demonstrators.

Clearly, the OCEAN project has a potential to substantially influence the practices of major vendors by demonstrating that the adoption of the OCEAN open source-based architecture (Linux, CORBA, etc.) combined with standards like POSIX, IEC 61131, and IEC 61508 will stimulate the development of competitive products. In particular, the OCEAN project will allow to integrate additional functionality and

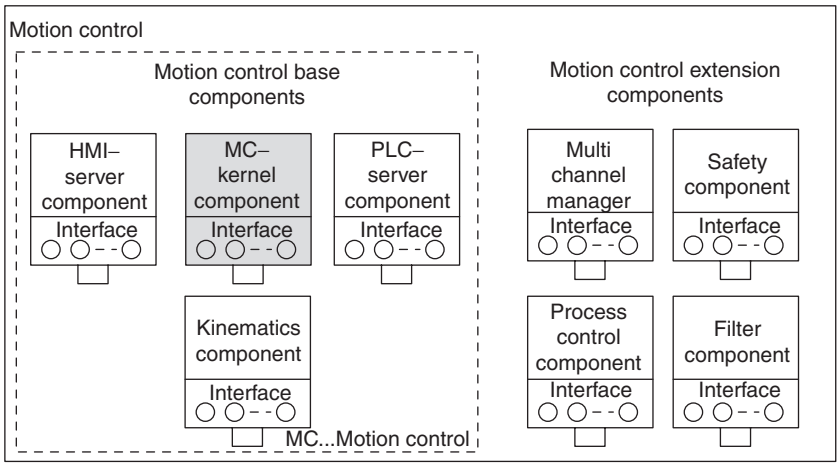


FIGURE 105.2 Subdivision of complex motion control structure based on components.

© 2005 by CRC Press LLC

third-party software by just using the standardized interface description, and to merge components provided by different CNC manufacturers. Two examples will clarify the importance of the results; it will become possible and easy for the machine tool builder to implement his own kinematics component or filter component and even reuse it for different CNCs from different control manufacturers. Moreover, the possibility to substitute the user interface leaving the rest of the numerical control unchanged (hardware and software) will overcome one of the major problems that machine tool builders have to face today, namely the obvious desire by end users to have uniform user interfaces for all machine tools in the same plant.

105.3 Status of the Project

Analysis of Communication Systems, Platforms, and Tools

The first part of the project dealt with the analysis of Communication Systems, Platforms, and Tools. The main objective was to find an appropriate communication infrastructure for a "DCRF," which would suit the technical and cost aspects, and could be provided to the end user as an open source.

CORBA implementations, as well as available Linux real-time extensions, were analyzed and compared. The two main criteria for this analysis were the real-time capability and the Open Source availability of the investigated software. As a result, TAO was found to be the most suitable CORBA Object Request Broker (ORB), and RTAI the preferable Linux real-time extension.

TAO has been developed at the Washington University of St. Louis with a special focus on its real-time capability. TAO offers a variety of CORBA services as well as the quality-of-service (QoS) functionality that can be applied to the supervision of modular software systems. Additionally, an implementation of the CORBA Component Model (CCM) is currently being developed for TAO. The CCM allows for a better software reuse and a dynamic configuration of CORBA applications. RTAI is preferred as the Linux real-time extension rather than RTLinux because RTAI offers the best real-time support, which is crucial for the realization of the DCRF. RTAI allows to run hard real-time processes in kernel space simultaneously with soft real-time processes in user space, for instance. Furthermore, RTAI offers the best C++ support and a more complete feature set. An additional criteria on is the availability of LXRT for RTAI that enables the operation of hard real-time tasks in user space. This allows the use of various standard operating system functionalities in real-time applications.

The consortium has performed analysis of the benefits of existing open controller approaches that can be considered for the design of the DCRF. Due to the fact that DCRF will be based on CORBA, the main focus of the analysis was on the comparison between CORBA as a middleware and the communication infrastructure of existing open controller approaches. The following open controller solutions were investigated:

- OSACA (Europe),
- OMAC (U.S.A.), and
- OSEC and FAOP (Japan).

With respect to the communication infrastructure and the communication system APIs, all benefits of the different open controller approaches are fulfilled by CORBA. Compared with OSACA, the total functional range of CORBA Services will even have to be reduced to the minimum functionality that is necessary for a control platform. This will result in a smaller footprint of DCRF. The modularization of control functionality achieved by the existing open controller approaches, as well as the configuration and startup of the software modules, can be mapped into the respective functions of the CORBA Component Model. Finally the OSACA reference architecture that specifies the software interfaces of control modules can be mapped into a reference architecture based on the Object Management Group Component Interface Definition Language (OMG CIDL).

The requirements for the infrastructure and the general-purpose components of DCRF were compiled. These requirements address on the one hand the data exchange between different real-time

© 2005 by CRC Press LLC

components and on the other the communication between hard real-time and less time-critical software components. Additionally, requirements for safety functions in DCRF were addressed.

Requirements were compiled for the following categories:

- Functional requirements,
- Latency requirements,
- Task Scheduling Jitter,
- Clock synchronization,
- Task interruption, and
- Software safety aspects.

The first part of the project was concluded once all information and data needed for designing the DCRF were collected. As a result of the investigations, the TAO–RTAI solution has been selected as the best combination to fulfill the requirements of DCRF. It allows a distribution and cross-platform deployment of components in a real-time environment. The benefits of existing open controller approaches have been identified and can be mapped into the CORBA-based development of DCRF.

Design, Implementation, and Validation of a DCRF

The second phase of the project, currently in progress, is the design, implementation, and validation of a DCRF. The first step for this implementation is porting of TAO to RTAI, done by the consortium and OCI. After this phase, the consortium will verify if the services of the TAO implementation satisfy the real-time approach. In this case, it will adapt the result to be the basis for the DCRF. One of the main aims of the DCRF is to have CNC components from different vendors interoperable with the DCRF framework, which means they have to be hardware independent or at least easily adaptable to the hardware of different control. To solve this problem, hardware abstractions have to be investigated and evaluated so that an exchange of components will be easy and feasible.

Moreover, it is mandatory for the real time components that their communication channels meet their time constraints (QoS). Therefore, suitable transport mechanisms have to be chosen. The lower level CORBA layer, which is called the "pluggable protocol framework" in TAO, has to be extended to meet the needs of DCRF.

Another parallel activity is the design and implementation of general-purpose components (for loading, configuration, and safety).

Design, Implementation, and Validation of Motion Control Base Components for an Open Numerical Control System

As of 2003, the detailed functionality of the components is another focus area. The aim here is to achieve a definition of a reference architecture for the motion control components of the open control systems by extending existing architectures (OSACA, OMAC, JOP) and new proposals. The goal is to provide standardized and published interface descriptions for components that are up to now part of monolithic control blocks and that will be extracted from there; this way, machine tool builders or end users will be able to integrate additional functionalities independent of control manufacturers. The components and their interfaces will be defined with formal methods like IDL or XML.

105.4 Foundations of the OCEAN Project, and Results

OSACA

The first goal of the OCEAN project is the development of DCRF based on Open Source Software, which provides a communication infrastructure for distributed real-time control applications. OCEAN draws considerably from the results and experience of the OSACA project.

© 2005 by CRC Press LLC

The OSACA system platform is composed of three main parts: reference architecture, configuration system, and communication system. The reference architecture specifies a data model for numerical controls. The configuration system coordinates the setup of control systems. The communication system handles data exchange.

In the OSACA reference architecture, five main functional units of numerical control have been specified: Motion Control, Motion Control Manager, Axis Control, Spindle Control, and Logic Control. The reference architecture that was developed in OSACA mainly deals with non-real-time control tasks. It was intended to be a specification for uniform interfaces between the NC kernel and the Human–Machine Interface (HMI).

The OCEAN project aims at the development of real-time capable control tasks. Therefore, data models for components within the NC kernel have to be defined and implemented. The development is split into two steps. In the first step, the basic components that are mandatory to operate an NC are designed and implemented, followed by the development of extension components that will enhance the functionality of numerical control. The base components are Motion Control Kernel Component, Kinematics Component, PLC-Server Component, and HMIServer Component. The benefits of the OSACA Motion Control, Axis Control, and Spindle Control units are taken into account for specifying the OCEAN Motion Control Kernel and HMI-Server Components. Furthermore, the OSACA Logic Control unit, which is very basic and only offers three data items, is taken into consideration for the OCEAN PLC-Server Component. The specification for the OCEAN Kinematics Component was developed from scratch. With respect to the Extension Components, all specifications were developed from scratch, except for the Multi-Channel Manager Component. This component can partly be based on the OSACA Motion Control Manager unit. The experiences from the OSACA configuration system are used for the development of the General-Purpose Components. In OCEAN, these are components for the configuration of distributed control systems, for supervision concerning safety, and for dynamically loading additional control components. For this purpose, the OSACA configuration system is extended by the CCM specification if applicable. The scope of the CCM and its impact in "resource management," "QoS," and usability has to be considered and adapted for the use in DCRF.

The OSACA communication system was completely replaced by RT CORBA. In this context, migration from OSACA to RT CORBA of the three different types of communication objects developed in OSACA (Variable Objects for data exchange, Process Objects for commands, and Event Objects for notifications about data updates) was required. This exchange of the communication systems also affects the development of the General-Purpose Components. For instance, the OSACA configuration system had to be further redeveloped to allow for the use of RT-CORBA.

LINUX

Linux is an operating system created by Linus Torvalds, at the University of Helsinki in Finland. The first version, 1.0, of the Linux Kernel was released in 1994. At present, Linux is developed under the GNU General Public License and its source code is freely available to everyone. This however, does not mean that Linux and its assorted distributions are free. Companies and developers may charge money for it as long as the source code remains available. Linux may be used for a wide variety of purposes including networking, software development, and as an end-user platform. Linux is often considered an excellent, low-cost alternative to other more expensive operating systems.

Due to the very nature of Linux's functionality and availability, it has become quite popular worldwide and a vast number of software programmers have taken Linux's source code and adapted it to meet their individual needs.

Linux Real-Time Extensions

For real-time extensions, a distinction between Soft Real-Time Extensions and Hard Real-Time Extensions can be made. Linux Real-Time Extensions can be defined as Hard if they guarantee deterministic worst-case latencies of interrupt servicing and scheduling. They can be defined as Soft if a fast

© 2005 by CRC Press LLC

response in terms of the Hard real-time requirements cannot be guaranteed. In the case of Numerical Control, a Hard Real-Time Extension that guarantees fast response is mandatory.

Available Implementations.
The two available implementations of real-time Linux are RTAI and RTLinux. RTAI and RTLinux are both patches (additions, but patch is the real technical term) to the standard Linux kernel. The multi-threaded real-time kernel runs standard Linux as the lowest priority thread that is always preemptible. This makes hard real-time functionality as well as most features of the non-real-time Linux kernel available to programmers. RTLinux is a small POSIX 1003.13/PSE51 compatible hard real-time operating system. RTAI is a variant of RTLinux that has gone off on its own path. It provides compatibility with POSIX 1003.1c and 1003.1b (Threads and Queues).

Some characteristics of RTL are:

- Majority of APIs are not portable.
- Dynamic thread creation is dangerous (uses kmalloc non-atomic).
- Support for Mutexes and Condition Variables.
- POSIX calls are part of the scheduler core.

Characteristics of RTAI:

- Modeled after standard LinuxThreads (by Xavier Leroy).
- Supports dynamic thread creation (from preallocated pool).
- Supports mutexes with priority inheritance.
- Supports condition variables.
- POSIX API provided by an optional module.
- Good basis for extending to meet the EL/IX specification.
- Supports user mode real-time tasks.
- Provided through a GPL License.

RTAI now has two separate approaches toward user space real-time: one extends the microkernel with system calls from the user space (via the trap mechanism); the other approach extends the Linux task API. The former is meant to work with ADEOS, as a completely Linux-independent real-time operating system, if desired. The latter can never work without Linux. The development in this issue is ongoing and not yet finished.

Based on the comparison, it can be judged that RTAI provides better RT support, meaning that:

- The modification required to install the patch on the Linux Kernel is smaller.
- It allows soft real time in user space along with hard real time in kernel space.
- It provides excellent performance in terms of low jitter and low latency.
- It provides better C++ support and a more complete feature set than RTLinux.
- RTAI has the better open source approach with lots of feedback from developers.

Furthermore, RTAI has evolved by gaining a good support for real-time access to system peripherals (e.g., real-time drivers for serial ports are now available).

RTAI now offers development of interrupt handlers in user mode and an enhanced scheduling policy.

License Agreements

The basic mechanism that stands at the basis of RTLinux is protected under U.S. Patent 5,995,745 and licensed without a fee to RTLinux users for commercial and noncommercial purposes. This means that RTLinux can be used royalty-free under two conditions:

- Under the terms of the GPL-Licence. It can be used and even modified, if it is used with any software that also runs under the terms of the GPL-License.
- Together with software that uses "Open RTLinux Execution Environment." In this case, any software can be run together with RTLinux even if the software is not open or not complying with the

© 2005 by CRC Press LLC

terms of GPL (e.g., LGPL software). "Open RTLinux Execution Environment" means a computer hardware system where the interrupt control hardware of processors and system boards is under the direct control of an unmodified Open RTLinux Software in binary form. A configuration done by using the options of a configuration tool is not considered a modification.

RTAI is a real-time extension that has partly been changed from LGPL conditions to GPL conditions. It is covered by the terms of Version 2 of the Open RTLinux Patent License, which says: "The Patented Process may be used, without any payment of a royalty."

CORBA

CORBA is a standard architecture for distributed object systems (Figure 105.3). It allows a distributed, heterogeneous collection of objects to interoperate. The definition of CORBA is managed by the Object Management Group (OMG). The OMG comprises over 700 companies and organizations, including almost all the major vendors and developers of distributed object technology, such as platform, database, and application vendors as well as software tool and corporate developers. An extensive introduction to Corba can be found in the Computer Software and Web Technologies section of this book.

Comparison of Available CORBA Implementations

For the comparison of available CORBA implementations, an Internet research was performed. In the scope of this research, open source ORBs as well as commercial solutions were investigated.

The following ORBs were included in the investigation:

- TAO, Distributed Object Group at Washington University, St. Louis, U.S.A.,
- ROFES, Aachen University of Technology, Germany,
- MICO, University of Frankfurt, Germany,
- ORBacus, IONA, Dublin, Ireland,
- ORBExpress, Object Interface Systems, Herndon, VA, U.S.A.,
- e*ORB, Vertel, Woodland Hills, CA, U.S.A.,
- ORBit, GNOME Project,
- omniORB2, AT&T Laboratories, Cambridge, U.K.
- ORBIX E2A, IONA, Dublin, Ireland,
- VisiBroker, Borland, Scotts Valley, CA, U.S.A., and
- JacORB, Software Engineering and Software Group, FU Berlin.

The research was based on the following criteria:

- Open Source availability,
- CORBA version implemented,
- real-time capability and implemented RT CORBA features,

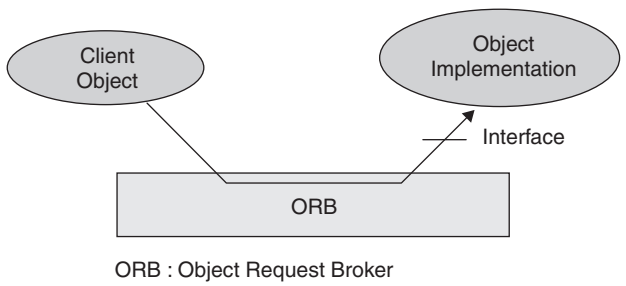

FIGURE 105.3 Basic Corba concept.

- available language bindings,
- implemented CORBA services,
- supported multithreading concept,
- supported protocols, and
- tested Linux and compiler support.

Except for the real-time version of VisiBroker and JacORB, all investigated ORBs have been ported into and tested on Linux platforms. All ORBs (except the Java-based JacORB) offer language bindings for C++. Real-time capability is provided by the Open Source ORBs TAO and ROFES. Further real-time versions of ORBExpress, e*ORB, and VisiBroker are available but only in commercial distributions. The range of CORBA services that is implemented for each ORB is quite different. The basic services like Naming, Event, and Trading are provided by almost all ORBs. Additional CORBA Services like Notification, Time, Scheduling, etc., vary among implementations. The largest range of implemented CORBA Services offer TAO and ORBit.

Interoperability between Different ORBs

The interoperability between different ORBs is an essential feature for the realization of distributed control systems using CORBA as middleware. The OMG specification covers the aspect of ORB interoperability since CORBA 2.0. This revision of the specification introduced a general ORB interoperability architecture, which is called General Inter-ORB Protocol (GIOP). GIOP is an abstract protocol that specifies the transfer syntax and a standard set of message formats to allow independently developed ORBs to communicate over any connection-oriented transport. The Internet Inter-ORB Protocol (IIOP) specifies how GIOP is implemented over TCP/IP (Figure 105.4).

ORB interoperability also requires standardized object reference formats. Object references are opaque to applications but they contain information that ORBs need in order to establish communications between clients and target objects. The standard object reference format, called the Interoperable Object reference (IOR), is flexible enough to store information for almost any inter-ORB protocol imaginable. An IOR identifies one or more supported protocols and contains information specific to that protocol. For IIOP, an IOR contains a host name, a TCP/IP port number, and an object key that identifies the target object at the given host name and port combination.

All investigated ORBs were implemented in conformance with the CORBA 2.0 specification. Therefore, all of them support IIOP, which is the basis for interoperability. Statements for successful interoperability test were found for the combination of the three ORBs: TAO, MICO, and JacORB.

To ensure and to test the interoperability between different ORBs, research projects have been launched for the development of test suits. One of them is the EC-funded project CORVAL2 (Enhanced Techniques for CORBA Validation; IST-1999-11131) and a second one is the open source projects COST (CORBA Open Source Testing). The main objective of these projects is to investigate new mechanisms and tools for validating the implementation of Object-Oriented technology. The resulting test suits can be applied by users and providers of CORBA technology to test products against the CORBA specifications, and hence to ensure product interoperability and application portability.

Investigation of the CCM

Introduction to the CCM

To provide higher-level reusable components, the OMG specifies a set of CORBA Object Services that define standard interfaces to access common distribution services, such as naming, trading, and event notification. By using CORBA and its Object Services, system developers can integrate and assemble large, complex distributed applications, and systems using features and services from different providers.

Unfortunately, the traditional CORBA object model, as defined by CORBA 2.4, has the following limitations.

1. *No standard way to deploy object implementations*. The earlier CORBA specification did not define a standard for deployment of object implementations in server processes. Deployment involves distributing object implementations, installing those implementations in their execution contexts, and activating the implementations in an ORB. Thus, system designers developed *ad hoc* strategies to instantiate all objects in a system. Moreover, since objects may depend on one another, the deployment and instantiation of objects in a large-scale distributed system are complicated and nonportable.
2. *Limited standard support for common CORBA server programming patterns*. The CORBA family of specifications provides a rich set of features to implement servers. For example, the CORBA 2.2 specification introduced *Portable Object Adapter* (POA), which is the ORB mechanism that forwards client requests to concrete object implementations. The POA specification provides standard APIs to register object implementations with the ORB, to deactivate those objects, and to activate object implementations on demand. The POA is flexible and provides numerous policies to configure its behavior. In many application domains, however, only a limited subset of these features is ever used repeatedly; yet, server developers face a steep learning curve to understand how to confugure POA policies *selectively* to obtain their desired behavior.
3. *Limited extension of object functionality*. In the traditional CORBA object model, objects can be extended only via inheritance. To support new interfaces, therefore, application developers must: (1) use CORBA´s Interface Definition Language (IDL) to define a new interface that inherits from all the required interfaces; (2) implement the new interface; and (3) deploy the new implementation across all their servers. Multiple inheritance in CORBA IDL is fragile, because overloading is not supported in CORBA; therefore, multiple inheritance has limited applicability. Moreover, applications may need to expose the same IDL interface multiple times to allow developers to either provide multiple implementations or multiple instances of the service through a single access point. Unfortunately, multiple inheritance cannot expose the same interface more than once, nor can it alone determine which interface should be exported to clients.
4. *Availability of* CORBA Object *Services not defined in advance*. The CORBA specification does not mandate which Object Services are available at runtime. Thus, object developers used *ad hoc* strategies to configure and activate these services when deploying a system.
5. *No standard object life cycle management.* Although the CORBA Object Service defines a Life Cycle Service, its use is not mandated. Therefore, clients often manage the life cycle of an object explicitly in *ad hoc* ways. Moreover, the developers of CORBA objects controlled through the life cycle service must define auxiliary interfaces to control the object life cycle. Defining these interfaces is tedious and should be automated when possible, but earlier CORBA specifications lacked the capabilities required to implement such automation.

In summary, the inadequacies, outlined above, of the CORBA specification, prior to and including version 2.4, often yield tightly coupled, *ad hoc* implementations of objects that are hard to design, reuse, deploy, maintain, and extend. The CCM extends the CORBA object model by defining features and services that enable application developers to implement, manage, configure, and deploy components that integrate commonly used CORBA services — such as transaction, security, persistent state, and event notification services — in a standard environment. In addition, the CCM standard allows greater software reuse for servers and provides greater flexibility for dynamic configuration of CORBA applications.

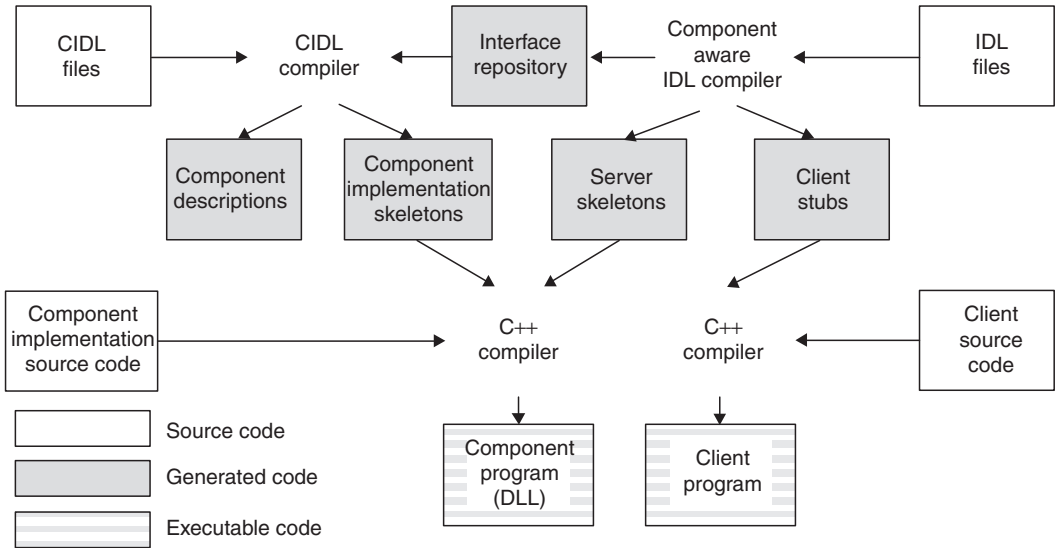

FIGURE 105.6 Tool chain using the Component Implementation Definition Language.

Figure 105.5 shows an example CCM component with IDL specification and Figure 105.6 shows the tool chain using the Component Implementation Definition Language.

Conclusion

The CORBA object model is increasingly gaining acceptance as the industry standard, cross-platform, cross-language distributed object computing model. The recent addition of the CCM integrates a successful component programming model from EJB, while maintaining the interoperability and language-neutrality of CORBA. The CCM programming model is thus suitable for leveraging proven technologies and existing services to develop the next -generation of highly scalable distributed applications. However, the CCM specification is large and complex. Therefore, ORB providers have only started implementing the specification recently. As with first-generation CORBA implementations several years ago, it is still hard to evaluate the quality and performance of CCM implementations. Moreover, the interoperability of components and containers from different providers is not yet well understood.

CCM providers are now implementing the complete specification, as well as support value-added enhancements to their implementations, just as operating system and ORB providers have done

© 2005 by CRC Press LLC

historically. In particular, containers provided by the CCM component model implementation provide QoS capabilities for CCM components, and can be extended to provide more services to components to relieve components from implementing these functionalities in an *ad hoc* way. These container QoS extensions provide services that can monitor and control certain aspects of components behaviors that crosscut different programming layers or require close interaction among components, containers, and operating systems. As CORBA and the CCM evolve, we expect that some of these enhancements will be incorporated into the CCM specification. CIAO will be the first implementation available with QoS RT-CCM enhancements and it is worth taking it into account for DCRF.

Selection of suitable ORB

For the development of DCRF, TAO is favored as ORB. This selection is based on the following arguments:

- TAO is available in open source,
- offers the majority of features defined in the RT CORBA 1.0 specification,
- comprises the main CORBA services, and
- a release including the CORBA Component Model is planned for 2003.

The only drawback of using TAO is its size, which should not be a problem in most cases, since a large amount of memory is needed to host a complete CNC.

105.5 OCEAN Consortium Members

As of 2003, the consortium involves:

1. **FIDIA S.p.A.**, coordinator: Manufacturer of Numerical Controls, High speed Milling Machines and CAM products (I);
2. **USTUTT**: The Numerical Controls Institute of the University of Stuttgart (D);
3. **RWTH**: The Machine Tool Institute of the Aachen University (D);
4. **KUL**: The Department of Mechanical Engineering of the Katholieke Universiteit Leuven (B);
5. **HOMAG**: Manufacturer of Numerical controls and Wood Working Machines (D);
6. **FATRONIK**: Research Institute for Machine Tool and Production Techniques (E);
7. **FAGOR**: Numerical Controls Manufacturer (E);
8. **OSAI**: Numerical Controls Manufacturer (I);
9. **GORATU**: Machine-tool (lathes, milling and High speed milling machine) Manufacturer, (E); and
10. **ITIA**: The Industrial Technologies and Automation Institute, of the Italian National Research Council (I).

106.6 The Future of HMS

106.1 Introduction

Holonic manufacturing systems (HMS) have their roots in using multiple interacting decision-makers in place of a single centralized decision-maker to solve complex manufacturing problems. In order to illustrate this, the inherently difficult task of shopfloor scheduling provides a good example of why a distributed approach is more promising than a centralized approach for computer control. The traditional approach to shopfloor scheduling uses a single, centralized scheduler. As Parunak (1993) notes, "scheduling and control take place sequentially" and are analogous to a large sequential computer program when this approach is used. If there are no disturbances on the shop floor (e.g., rush orders, missing tools or material, machine processing time variability, or failures), this approach is very effective and can generate solutions to the scheduling problem.

Real manufacturing systems, however, are not deterministic. In addition, they consist of physically distributed materials and resources that behave in a highly concurrent and dynamic manner. As a result, centralized schedules quickly become obsolete and must be either ignored or frequently updated, although this is not always possible if the schedule generation and dissemination times are large.

An alternative approach is to match the scheduling model more closely with the physical system. In other words, the problem can be decomposed such that decision-making is performed by many simple, autonomous, and cooperative entities. Rather than following a predetermined plan, the schedule emerges from the interaction of these intelligent entities. This approach leads to a scheduling system that is "decentralised rather than centralised, emergent rather than planned, and concurrent rather than sequential" (Parunak, 1996).

The disadvantages of this approach are that global optima cannot be guaranteed and predictions of the system's behavior can only be made at the aggregate level (Parunak, 1996). However, even with

© 2005 by CRC Press LLC

conventional approaches, global optima often cannot be achieved in practice and the detailed predictions provided by these systems are frequently invalidated by unanticipated events. Alternatively, distributed intelligent control provides the advantages of adaptability, ease of upgradeability and maintenance, and emergent behavior.

In the next section, we provide some background on distributed problem solving in the manufacturing domain. Next, we introduce the concept of HMS and provide a brief history of HMS research. We follow this with a more detailed description of holonic systems and focus on the various architectures proposed by researchers in HMS. Finally, we provide a brief summary of this work as well as our views on the future of HMS research.

106.2 Background

An early contribution in this area in the manufacturing domain was based on the negotiation metaphor that stemmed from the research of Davis and Smith (1983) on distributed sensor systems. Their distributed problem-solving approach requires the "co-operative solution of problems by a decentralised, loosely coupled collection of problem solvers" (Davis, 1983) and differs from distributed computing in that it is concerned with a "single task envisioned for the system;" the goal is to create an "environment for co-operative behaviour."

Parunak (1987) extended the concept of the contract net from the information domain to the manufacturing domain with the development of the Yet Another Manufacturing System (YAMS) software. This system uses Davis' and Smith's negotiation metaphor to achieve coordination of a network of distributed computing nodes. The YAMS system uses an "open system model" that allows for the addition and removal of problem solvers and separates knowledge from the control structure through information hiding.

Duffie and Prabhu (1994) have investigated this distributed approach with a "heterarchical," or nonhierarchical opportunistic scheduling approach for machine cell control. One characteristic of this approach that sets it apart from traditional hierarchical control structures is that part flow is achieved by part-oriented requests as opposed to machine-oriented requests. This requires the parts to be "intelligent enough to know when they are done at one machine and need another" (Duffie and Piper, 1986). Similar work in the area of bidding-based control of manufacturing cells has also been investigated by other researchers (e.g., Veeramani [1992]). Work in this area has served as a catalyst for research on extending concepts from the emerging field of Multi-Agent Systems (MAS) to the manufacturing domain. This next phase in the transition from FMS to HMS is discussed next.

MAS can be thought of as a "general software technology that was motivated by fundamental research questions" (Bussmann, 1998) such as how groups of software agents can work together to solve a common problem (Moulin and Chaib-draa, 1996). Huhns and Singh (1998) define agents as "active, persistent (software) components that perceive, reason, act, and communicate." This definition follows from the notion of a software object where the focus is on data abstraction, encapsulation, modularity, and inheritance (Booch, 1994).

A major advantage of agent-based software over conventional software is this autonomous nature of individual agents. As Parunak (1993) notes, agents "decide locally not only how to act (as subroutines do), and what actions to take (as objects do), but also when to initiate their own activity." This, in combination with the cooperative nature of agents in MAS, is particularly well suited to distributed intelligent control problems as noted previously.

Not surprisingly, there has already been considerable utilization of the agent concept in the manufacturing domain. In particular, autonomous agents or MAS are an attractive software engineering tool for the development of systems in which "data, control, expertise, or resources are distributed; agents provide a natural metaphor for delivering system functionality; or a number of legacy systems must be made to interwork" (Wooldridge and Jennings, 1999). Manufacturing applications are characteristically "modular, decentralised, changeable, ill-structured, and complex" (Parunak, 1999), and as a result present a host of problems that are well-suited to agent technology. Despite the traditional conservatism of the manufacturing domain, it is "one of the oldest and strongest areas of agent research" (Aparicio, 1999).

© 2005 by CRC Press LLC

Research into the application of MAS and distributed artificial intelligence in the manufacturing domain has been steadily growing over the last 10 years and has focused on all areas of the manufacturing enterprise ranging from product design to real-time control. For a comprehensive overview of agent-based systems in manufacturing, see Shen and Norrie (1999) and for MAS in concurrent design and manufacturing, Shen et al. (2000) can be consulted.

One motivation for the use of the agent model for the representation of manufacturing entities is that manufacturing entities, like agents, typically have well-defined state variables that are distinct from those of their environment (Parunak, 1999). As a result, a physical decomposition of the manufacturing system is obvious: agents are used to represent entities in the physical world, such as workers, machines, tools, fixtures, products, parts, features, operations, etc. Evidence from natural systems suggests that it may be more effective to assign agents to physical entities in the system (Weiss, 1999). In the manufacturing domain, critical information is usually organized by physical entities and the agents that represent these entities are the natural locus for maintaining the information. This approach naturally defines distinct sets of state variables that can be managed efficiently by individual agents with limited interactions; however, it requires a large number of resource-related agents. This leads to other problems such as communication overheads and complex agent management. A common example of this approach is the use of part and machine agents for manufacturing planning and scheduling (Duffie and Prabhu, 1994; Lin and Soldberg, 1992; Parunak, 1987).

An alternative approach to problem decomposition that has been used in the manufacturing domain is functional decomposition. With this approach, agents are used to encapsulate functionality such as order acquisition, planning, scheduling, material handling, transportation management, and product distribution, and have no explicit relationship with physical entities. This approach tends to exhibit high coupling (Booch, 1994), that is, the sharing of many state variables across different functions, which leads to problems of consistency and unintended interactions. Examples of this approach include the use of agents to encapsulate special functionality, such as facilitator agents (Cutkosky et al., 1993), broker agents (Peng et al., 1998), and mediator agents (Maturana and Norrie, 1996). A second set of examples is provided by systems such as ARCHON (Cockburn and Jennings, 1996) and EXPORT (Monceyron and Barthes, 1992), which utilize agents to resolve problems in the integration of legacy systems.

As noted previously, MAS can be thought of as a general software technology; manufacturing, however, is fundamentally concerned with "ironware" (physical equipment and products). As a result, when these two worlds merge, it becomes useful to start thinking about a type of agent different from those that populate classic agent-based systems. In particular, it becomes useful to think about "physical agents" that possess both classical software agent capabilities as well as the ability to interface with physical equipment on the shop floor. In the next section, we provide an overview of the international collaborative effort to develop systems of these unique manufacturing-specific agents.

106.3 Holonic Concepts

The concepts of HMS can be considered as constituting a distributed intelligent control paradigm for manufacturing. Unlike MAS, which is a broader software approach that can be also used for distributed intelligent control, an HMS is, by definition, a manufacturing-specific approach to distributed intelligent control.

Suda (1989) first introduced the concept of HMS in the 1990s. This work was motivated by the need to address these shortcomings as well as by new pressures faced by manufacturers in the 1990s such as increasingly stringent customer requirements for high-quality, customizable, low-cost products that can be delivered quickly, as well as the increasing levels of system complexity due to the distributed, concurrent, and stochastic nature of manufacturing systems.

The research in distributed control described in the previous section led many to the realization that an "autonomous, distributed and co-operative" (Valckenaers and van Brussel, 1994) approach was required to address these issues. This new control software and hardware approach appeared to hold the most promise of realizing manufacturing systems that are both flexible (capable of reconfiguration) and responsive (capable of recovering from disturbances). However, past experiences with "green field" approaches like Flexible

© 2005 by CRC Press LLC

Manufacturing Systems (FMS) left a bad taste in the mouths of many manufacturers. Clearly, an incremental approach was required if new techniques of flexible automation were to be accepted by industry.

HMS is one of the Intelligent Manufacturing Systems (IMS) program's six major projects resulting from a 2-yr feasibility study started in February 1992 (Christensen, 1994). In very general terms, holonics can be thought of as a marriage between a general philosophy (of living organisms and social organizations) and an emerging software approach (distributed artificial intelligence) that is intended to ultimately lead to a better understanding of how next-generation manufacturing systems should be designed. The objective of the HMS Consortium is to "attain in manufacturing the benefits that holonic organisation provides to living organisms and societies, e.g., stability in the face of disturbances, adaptability and flexibility in the face of change, and efficient use of available resources" (HMS, 2003).

The term "holon" was coined by Arthur Koestler (Koestler, 1967). He observed a dichotomy of wholeness and partness in living organisms and social organizations, and summarized this with the statement: "wholes and parts in the absolute sense do not exist anywhere." To understand these systems, Koestler used the "Janus Effect" as a metaphor for this dichotomy of wholeness and partness observed in many such systems: that is, "like the Roman god Janus, members of a hierarchy have two faces looking in opposite directions." In other words, these members can be thought of as self-contained wholes looking toward the subordinate level and/or dependent parts looking upward. To explain this concept, Koestler suggested a new term to describe the members of these systems: "holon," from the Greek *holos* meaning "whole" and the suffix *on* implying particle as in "proton" or "neutron."

In order to achieve the benefits of Koestler's holonic organizations, HMS "consist of autonomous, self-reliant manufacturing units, called holons" (Bussmann, 1998) that cooperate to achieve the overall manufacturing system objectives. A holon is defined by the Holonic Manufacturing Systems Consortium (HMS, 2003) as "an autonomous and co-operative building block of a manufacturing system for transforming, transporting, storing and/or validating information and physical objects."

Another other important characteristic of holons that is particularly relevant to the manufacturing domain is that they consist of an information processing part and often a physical processing part. This distinction really sets HMS apart from the mainstream MAS community, although another organization formed in 1996, the Foundation for Intelligent Physical Agents (FIPA, 2003), also recognized this use of agent technology quite early. FIPA however, did not pursue the notion of *physical agents* closely until recently (Ulieru, 2001).

Another important holonic concept that is also relevant to the manufacturing domain is the notion of functional decomposition. Simon's (1996) observation that "complex systems evolve from simple systems much more rapidly if there are stable intermediate forms than if there are not" is at the heart of this. In other words, the complexity of manufacturing systems can be dealt with by decomposing the system into smaller parts. A consequence of this is the idea that holons can contain other holons (i.e., they are recursive). In addition, problem solving is achieved by holarchies, or groups of autonomous and cooperative basic holons and/or recursive holons that are themselves holarchies.

As noted previously, HMS began in 1992 as a feasibility study. At the time, it was felt that an international effort would be required if manufacturing systems based on the concepts described above were to be developed in a reasonable period of time. It was not clear, however, whether a collaborative effort among competitive industries and across various cultures would work in practice (Valckenaers and Van Brussel, 1994). Despite these early fears, the results of this feasibility study were very promising (Kriz, 1995), leading to the launch of the full-scale program in 1995.

During this first phase of the HMS Project (1995–2000), work was conducted around three main areas: generic technologies, benchmarking, and organization (e.g., project management, technology transfer, dissemination, and exploitation). In order to provide a clear focus for the project, this work was organized into the seven work packages summarized below (Gruver et al., 2003):

- Systems Architecture and Engineering (WP1): Generation of reference models, information models, standards, and support tools for holons, holonic systems, and the holonic systems engineering process.
- Systems Operation (WP2): Generic operational aspects of HMS such as communication, negotiation, and coordination, planning, resource allocation, fault management, and reconfiguration.

© 2005 by CRC Press LLC

- Holonic Resource Management (WP3): Development of strategies, techniques, and architectures for resource management in HMS.
- Holonic Manufacturing Unit (WP4): Machining, finishing, inspection, and tooling.
- Holonic Fixturing (WP5): Fixturing in the machining and assembly process.
- Holonic Handling Systems (WP6): Robots, end-effectors, fixtures, feeders, mobile handling systems, and sensors.
- Holomobiles (WP7): Mobile systems for transport, maintenance, and supervision.

As can be seen from these work package descriptions, this first phase of the HMS project focused on the development of a generic holonic systems technology (WP1–WP3) as well as the demonstration of this approach in specific application areas (WP4–WP7).

A significant contribution was made during the first phase of the HMS project by van Brussel's group at Katholieke Universiteit Leuven. Van Brussel et al. (1998) proposed a reference architecture for HMS called PROSA that specifies four main holon types: Product, Resource, Order, and StAff. The generic nature of this architecture has resulted in it serving as the foundation for many of the proposed holonic architectures that followed during the first and second phases of the HMS project (Langer, 1999), (Suessmann et al., 2002; Weichhart et al., 2002; Monch et al., 2003). PROSA will be discussed in further detail in the next section.

Another significant advance during this phase of the project involved the progress toward the definition of standards for holonic systems that were primarily based on the International Electrotechnical Commission (IEC) 61499 function block standard (IEC, 2000). For example, Fletcher et al. (2000) describe a suitable architecture for holonic systems that uses a layered framework of IEC 61499 function blocks called a holonic kernel. In order to enable holonic cooperation and autonomy, this kernel consists of four specialized services (each implemented by an IEC 61499 service interface function block): a Function Block Manager, a Coordination Manager, a Cooperation Domain Interface, and a Data/Knowledge Base Interface (this will be described in more detail in the next section).

The primary motivation for the use of the function block model was its suitability for event-driven control. As Marik and Pechoucek (2001) noted, the scan-based approach to control used by traditional programmable logic controllers "does not enable the required flexibility in scheduling of events, especially in the case of hard real-time control." Alternatively, by explicitly representing events, the function block model focuses on process abstraction and synchronization; this makes this approach particularly suitable for control of an environment that is concurrent, asynchronous, and distributed.

However, the work during this phase of the HMS Consortium showed that this model does have some limitations in its current form. For example, as pointed out by Christensen (1994), the model must support mechanisms for dynamic reconfiguration if the agility requirements of FMS are to be met. In addition, although the function block is particularly suited for low-level, real-time process/machine control and lends itself well to various hardware implementations such as (Fletcher et al., 2001), it is not well suited for higher-level reasoning (Brennan and Norrie, 2001).

As a result, it was recognized that the best approach is to encapsulate the function block solution into a higher-level software when and where it is required to enable more sophisticated reasoning and a richer knowledge representation than function blocks alone. These resulting components have been referred to as "holonic agents" (Marik and Pechoucek, 2001) because of their integration of a holonic part (for hard real-time) and software agent part (responsible for higher-level, soft real-time or non-real-time intelligent decision-making). This concept is illustrated in Figure 106.1, which shows a multilayer architecture consisting of four temporally decomposed layers of agents (i.e., the ovals in Figure 106.1) and devices: execution control (EC), control execution (CE), execution (E), and hardware (Brennan and Norrie, 2002). As one moves down the layers, time scales become shorter and real-time constraints change from soft to hard real time; also, the degree of agency decreases in higher-level agents are more sophisticated but slower, while lower-level agents are fast and light-weight.

Having explored holonic systems technologies since 1995, the HMS Consortium entered its second phase in 2001, focusing on the integration and application of these technologies. In order to provide for the entire scope of the manufacturing enterprise, the Consortium took the conventional view of manufacturing

© 2005 by CRC Press LLC

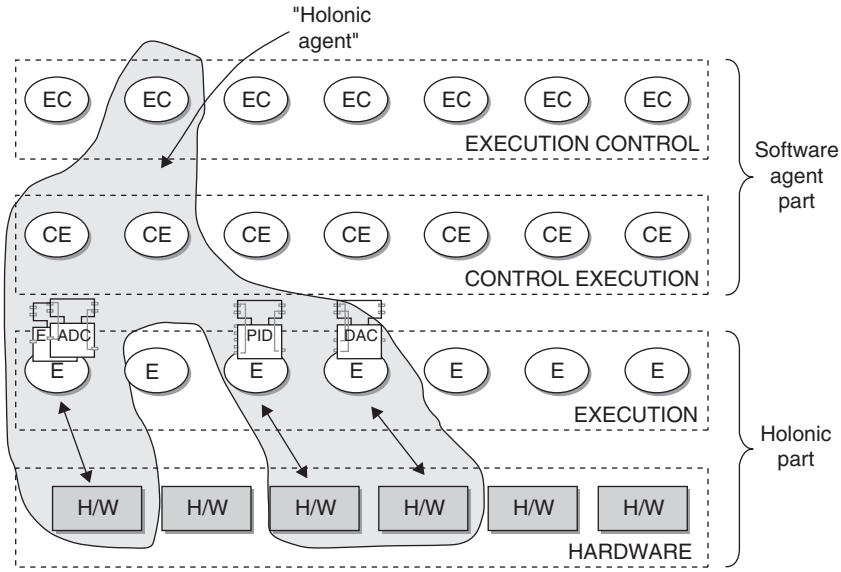

FIGURE 106.1 Software agents and holons.

planning and control systems as being a hierarchy of decision levels that range from long-term, strategic decisions at the highest level to short-term, detailed execution and control at the lowest level. As a result, the focus of HMS is now on three fundamental levels of the manufacturing enterprise (Gruver et al., 2003):

- Holonic Production Execution Systems: The factory and supply chain level.
- Holonic Production Sites and Physical Equipment: The work cell level (which consists of a number of holonic control devices).
- Holonic Control Devices: The physical, real-time control level.

This decomposition can be thought of as a simplification of the widely accepted National Bureau of Standards (NBS) (Jones and McLean, 1986) five-level model and the International Standards Organisation (ISO) (ISO, 1986) six-level model. In addition, the three HMS levels now have a close parallel with the recently proposed FIPA "Holonic Enterprise" model (Ulieru, 2001). Figure 106.2 provides an overview of these models.

In the next section, we look at holonics in more detail. In particular, we focus on the main architectures proposed to implement the holonic concepts described above in the manufacturing domain.

106.4 Holonic Architectures

It was noted previously that an important distinguishing characteristic of holons is that they consist of an information processing part and often a physical processing part. This is reflected in Bussmann's (1998) basic architecture of a holon illustrated in Figure 106.3.

Given this basic building block, the HMS community next looked at how holons could be implemented to solve basic manufacturing problems. As noted previously, Van Brussel et al. (1998) proposed a reference architecture to address this issue, which consists of four fundamental holon types:

- Resource Holon: The resource holon is an abstraction of the production processes (factory, shop, machine tools, conveyors, robots, and other intelligent devices) in a manufacturing system that provides production capacity and functionality to other holons.
- Product Holon: The product holon contains process and product knowledge in order to ensure that products are made correctly and in sufficient quantity. As a result, the product holon is

© 2005 by CRC Press LLC

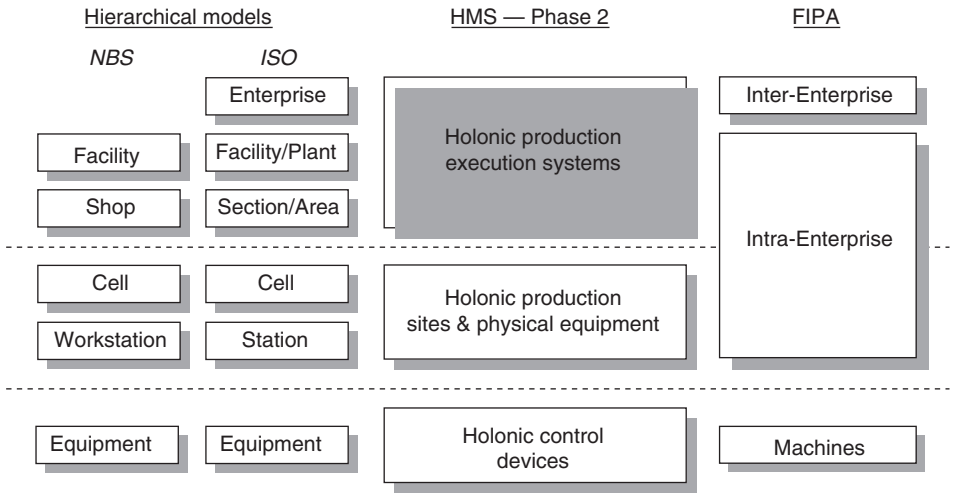

FIGURE 106.2 HMS, FIPA, and the hierarchical models of the manufacturing enterprise.

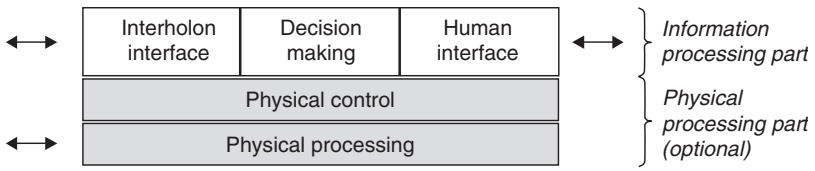

FIGURE 106.3 Architecture of a basic holon (from Bussmann, 1998).

responsible for the functionalities that are traditionally covered by product design, process planning, and quality assurance.

- Order Holon: The order holon manages the set of physical products being produced. As a result, it is concerned with logistical information such as customer orders and make-to-stock orders.
- Staff Holon: The staff holon is an optional, centralized element of the PROSA architecture that is used to assist the basic holons (Resource, Product, and Order) in performing their tasks. For example, the staff holon may play the role of a mediator as in the Metamorph Architecture of Maturana and Norrie (1996).

The basic building blocks of the PROSA architecture are illustrated in Figure 106.4, where each of the three main types of holons are intended to be responsible for manufacturing control. The staff holon can be combined with these basic holons to provide expert knowledge for longer-term, strategic decision-making, fault-diagnosis, maintenance, and to facilitate the incorporation of legacy systems.

Another important property of holons, not illustrated in Figure 106.4, is that they can contain other holons (i.e., they are recursive). Problem solving is achieved by holarchies, groups of autonomous, and co-operative basic holons and/or recursive holons that are themselves holarchies. In order to achieve this form of cooperation, the notion of a "Cooperation Domain" (CD) was introduced in holonic systems, which, as Fletcher et al. (2000) observed, "is considered a logical space in which holons communicate and operate, that provides the context where holons may locate, contact, and

© 2005 by CRC Press LLC

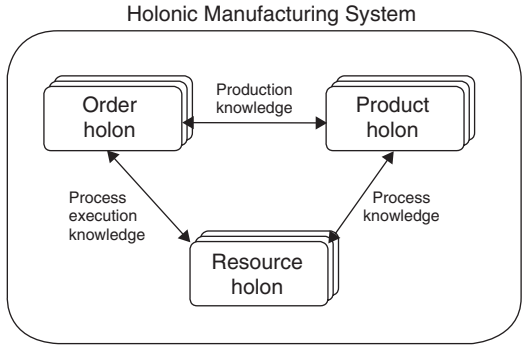

FIGURE 106.4 The PROSA architecture (from Van Brussel et al., 1998).

interact with each other." Within this framework, two types of cooperation occur among holons (Fletcher et al., 2000):

- Simple cooperation: A holon is committed to answer queries from another holon, even if the response is noncooperative.
- Complex cooperation: Holons achieve a joint goal (e.g., agreeing upon a mutual plan of executing tasks for solving a distributed problem).

This second form of cooperation is based on the concept of cooperation domains, and requires an integration of the physical device level with the higher reasoning/deliberative level of the manufacturing system. For example, Christensen (2003) has proposed that the architecture of a holonic manufacturing system is split into two distinct levels: Low-Level Control (LLC) and High-Level Control (HLC).

LLC refers to normal, nonholonic control and automation functions where response times range from 10 μsec to 100 msec (Christensen, 2003). At this level, the IEC 61499 standard for the use of function blocks in distributed automation is particularly relevant (IEC, 2000; Lewis, 2001). As a result, the LLC architecture shown in Figure 106.5 addresses the functions associated with real-time control.

Unlike the LLC, the HLC sits more firmly in the IT world of software agents and, as such, is concerned with higher-level reasoning. More specifically, the HLC architecture, shown in Figure 106.6, "addresses the functions associated with the domain of inter-holon cooperation, including negotiation and coordination of mutually agreed tasks and mutual action to recover from operational faults" (Christensen, 2003). Response times in this domain are much slower (100 msec to 10 sec), and rather than the control-oriented function block, the main entity is the agent as described by the FIPA architecture standard for software agent systems (FIPA, 2003).

As can be seen in Figure 106.6, each holon is composed of three basic building blocks, which together form the "holonic kernel" (Fletcher et al., 2000): Cooperation Domain Interface (CDI), Coordination Manager (CM), and Function Block Manager (FBM). The CDI provides an interface from holons to one or more cooperation domains to transfer knowledge relating to tasks and ontologies. It also serves as "yellow pages," allowing services to be found and offered. The CM controls interactions within the holon and among holons. For example, the CM is responsible for task decomposition, planning, conflict resolution, and the aggregation of results. It is also responsible for maintaining knowledge bases in the holon's local repository. Finally, the FBM serves as the interface to the LLC layer. It is responsible for the management of function block configurations upon a resource (i.e., physical device). For example, the FBM manages the creation, configuration, running, and deletion of function block applications.

Figures 106.5 and 106.6 illustrate the internal structure of holons at the LLC and HLC levels, and also how these holons interface with the cooperation domain. When combined, the LLC and HLC architectures provide the link between the information and physical worlds that is unique to holonic systems. For example, higher-level reasoning tasks such as planning, scheduling, fault monitoring, and fault recovery

© 2005 by CRC Press LLC

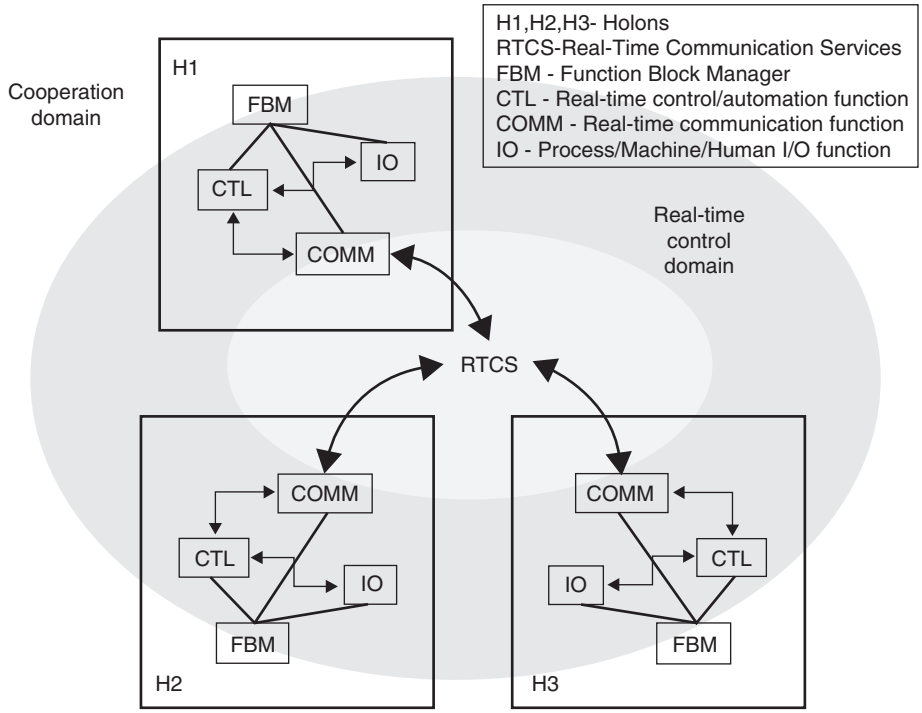

FIGURE 106.5 LLC architecture (from Christensen, 2003).

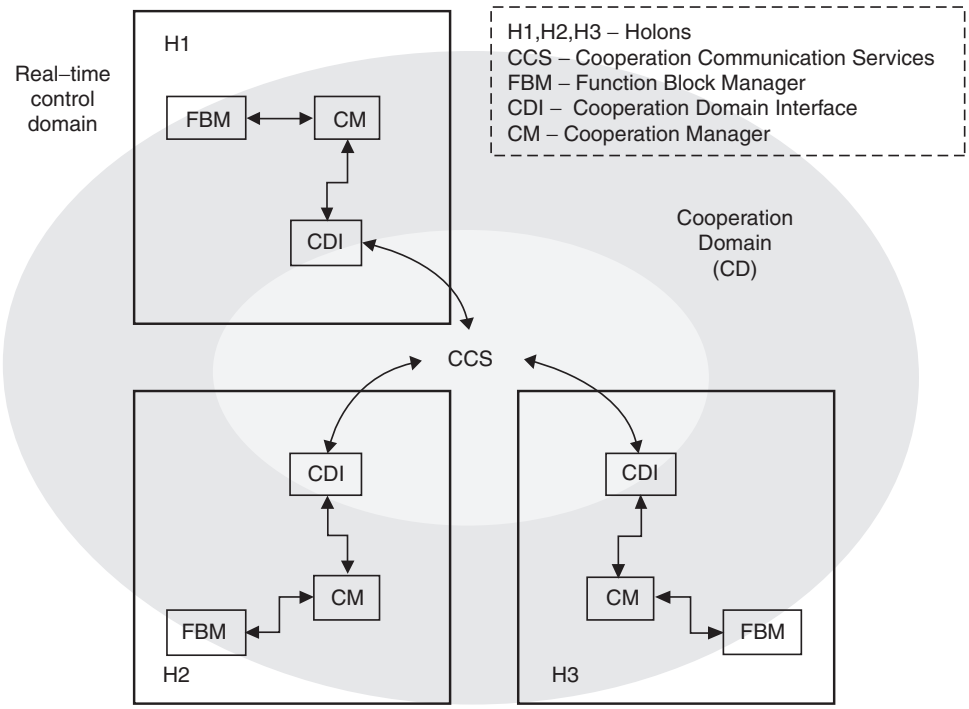

FIGURE 106.6 HLC architecture (from Christensen, 2003).

© 2005 by CRC Press LLC

can be accomplished by task decomposition and virtual clustering at the HLC level. Plans can be then realized by the physical machinery at the LLC level. Neligwa and Fletcher (2003) provide an example of this combined holonic architecture as illustrated in Figure 106.7.

Without an effective interface between the HLC and LLC levels, however, agents and machines will continue to exist and operate largely apart as they do today. The concept of a real-time interface between the soft world of agents and the physical world of machinery is tied closely to some fundamental ideas in holonic systems and holonic manufacturing systems. Holonic systems are essentially adaptive agent–machine systems. The real-time control interface problem is therefore a concern for those wishing to apply holonic concepts to manufacturing and other areas. Not surprisingly, the HMS Consortium (HMS, 2003) has a work group devoted to Holonic Control Devices (HCD). Although approaches developed by this group would be applicable to a larger area than manufacturing, an even wider application focus would be desirable. Figure 106.8 provides an overview of the interface architecture proposed by the Holonic Control Devices (HCD) group of the HMS Consortium (Brennan et al., 2003).

The Deliberative Layer is twofold: (i) application domain-specific functionality and (ii) generic functionality. The former functionality corresponds to a set of user-defined functions that are made available to the agent/holon instances inside the HCD throughout function calls. The latter functionality corresponds to a set of generic decision-making components that act as the nervous system of the HCD instance for decision-making. As illustrated in Figure 106.8, there are four generic decision-making modules:

- Planner: The planner component carries out the construction of control-action steps for the HCD instance. It also negotiates with other HCD instances, which can be local or remote, via an agent communication language (e.g., FIPA, KQML).
- Process Model: The process model, which carries out a local model simulation (which can be a mathematical expression that quantifies performance metrics) of input data to quantify the current control step performance, thereby evaluates present execution states or forecasting near-future states.
- Execution Control: The execution control component coordinates the execution of control action steps, thereby carrying out the HCD plans, which are built and committed by the planner during the

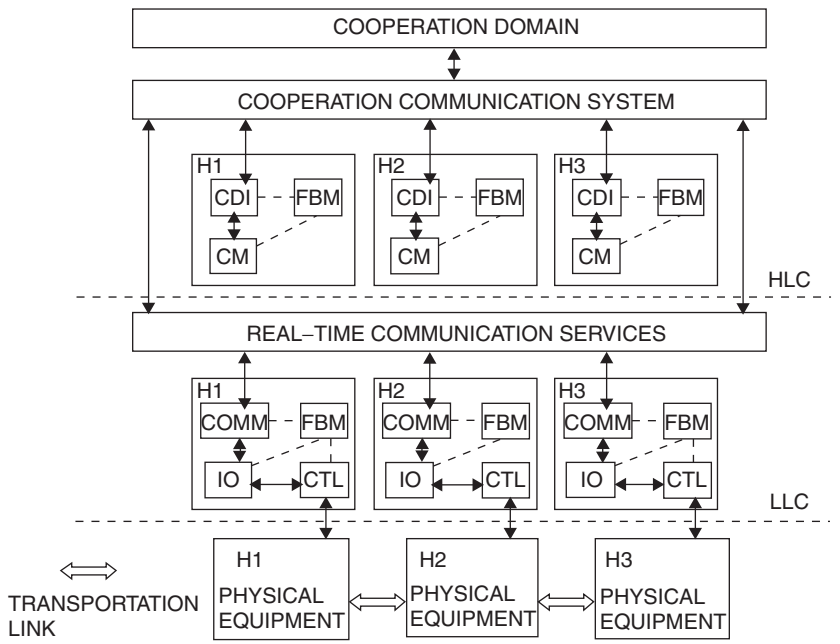

FIGURE 106.7 Integration of the HLC and LLC architectures (from Neligwa and Fletcher, 2003).

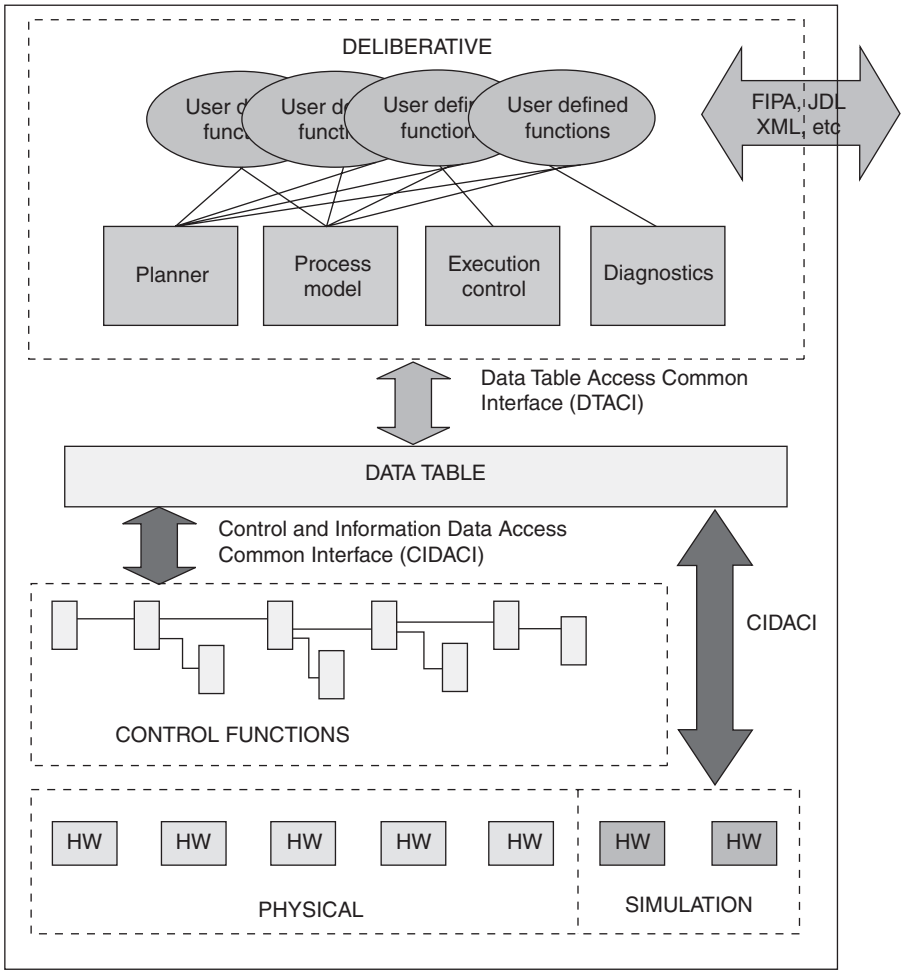

FIGURE 106.8 An interface architecture for holonic control devices.

inter-HCD instance negotiation. This is a further refinement of the planner's functionality, which results in the higher-level goals being translated into a form that can be used at the control level.

- Diagnostics: The diagnostics component carries out a local self-assessment activity to verify the correct operation of hardware attached to the HCD and/or HCD instances.

The *Deliberative Layer* communicates with other layers throughout the device's data table via a Data Table Access Common Interface (DTACI). The *Data Table Layer* is the state data repository for the HCD instances. The *Control Functions Layer* is the user-defined application logic that controls the activities of the physical hardware or process that is attached to the HCD. Although Figure 106.8 shows IEC 61131-3 function blocks, any of the IEC 61131-3 languages for programmable logic controllers (i.e., IL, ST, LD, SFC, or LD) could be used to specify the control logic. In addition, distributed intelligent devices at the physical layer can also be supported at this layer by the IEC 61499 model.

106.5 Holonic Systems and Information Technology

In this chapter, we have provided an overview of the evolution in manufacturing systems control from distributed decision-making to holonic systems. A common thread that runs throughout this work is the close link between distributed artificial intelligence and multiagent systems and holonic systems.

© 2005 by CRC Press LLC

Like HMS, multiagent manufacturing systems also consist of cooperative and autonomous manufacturing units, but unlike HMS, MAS can be considered as embedding a "general software technology that was motivated by fundamental research questions" (Bussmann, 1998). Research in MAS, however, has played a key role in the development of HMS (e.g., Bussman's agent-oriented architecture for a holon as shown in Figure 106.3).

As a result, various cooperation, communication, and organizational techniques from the MAS literature (e.g., Weiss, 1999) can be used to implement autonomous, cooperative, and recursive agents ("holons"). For example, holarchies can be implemented using federation architecture approaches such as facilitators, brokers, or mediators (e.g., Maturana and Norrie, 1996). The resulting software agent may be considered a holon, or it may be considered the information processing part of a holon as illustrated in Figure 106.3.

As shown in Figures 106.7 and 106.8, the implementation of the "holon" is dependent on the role the holon plays and its position in the manufacturing hierarchy. In other words, it is the stance that is taken toward the manufacturing systems control problem that will influence whether agents, holons, or function blocks are used. More specifically, HMS can be considered a general paradigm for distributed intelligent manufacturing control, whereas MAS and function blocks are regarded as software technologies that can be used to implement HMS.

106.6 The Future of HMS

The focus of the current phase of the HMS project is on the integration and application of holonic concepts. This is a particularly important direction, since, to this date, the majority of the developments in HMS have been primarily of an exploratory nature with only a few proven industrial implementations (McFarlane and Bussman, 2003). If HMS are to gain wider industrial acceptance, evidence will have to be shown that holonic manufacturing systems are economically viable and that they do indeed perform well in the presence of disturbances.

One notable industrial implementation is DaimlerChrysler's holonic control implementation for engine assembly (Bussman and Sieverding, 2001). This particular implementation of a holonic system has now been in operation for 3 years and has demonstrated that many of the claimed technical advantages are achievable using a holonic systems approach. Unfortunately, it is difficult to weigh the potential economic advantages of this approach (e.g., as a result of increased flexibility) against the up-front cost associated with the implementation of this technology. This illustrates the need to not only demonstrate the technological advantages of holonic systems but also the economic benefits.

Despite this concern, there is interest in the holonic systems community for extending the scope for the holonic approach. Rather than just the relatively narrow focus on manufacturing systems control during the first phase of the HMS project, there is now considerable activity in applying holonic concepts to a variety of nonmanufacturing domains. For example, Maturana et al. (2003) have recently applied holonic and agent-based techniques to the design of reconfigurable ship-based chilled-water systems. Fleetwood et al. (2003) have been investigating the integration of the holonic system architecture with the evolving hydrogen infrastructure for fueling hydrogen to fuel cell-powered vehicles. A considerable amount of interest has also been shown recently in the application of holonic systems concepts to supply chain management (e.g., Weichhart et al., 2003).

As the HMS Consortium (HMS, 2003) draws to a close in 2004, the momentum is building for applications to a variety of industrial problems. As McFarlane and Bussman (2003) observed, a number of open issues must still be in the areas of holonic control system design and implementation; however, promise of this approach appears to be strong enough to warrant further work in these areas in the years to come.

107.1 Introduction

Both the complexity of manufacturing environments as well as the complexity of tasks to be solved are growing continuously. In many manufacturing scenarios, traditional centralized and hierarchical approaches applied to production control, planning and scheduling, supply chain management, and manufacturing and business solutions in general are not adequate and can fail because of the insufficient means to cope with the high degree of complexity and practical requirements for *generality* and *reconfigurability*.

These issues naturally lead to a development of new manufacturing architectures and solutions based on the consideration of highly distributed, autonomous, and efficiently cooperating units integrated by the plug-and-play approach. This trend of application of multi-agent systems (MAS) techniques is clearly visible at all levels of manufacturing and businesses. On the lowest, real-time level, where these units are

© 2005 by CRC Press LLC

tightly linked with the physical manufacturing hardware, we refere to them as *holons* or *holonic agents* [1]. Intelligent agents are also used in solving production planning and scheduling tasks both on the workshop and factory levels. More generic visions of intensive cooperation among enterprises connected via communication network have led to the ideas of *virtual enterprises*:

A virtual enterprise is a temporary alliance of enterprises that come together to share skills or core competencies and resources in order to better respond to business opportunities, and whose cooperation is supported by computer networks [2].

The philosophical background of all these highly distributed solutions is the same: the community of autonomous, intelligent, and goal-oriented units efficiently cooperating and coordinating their behavior in order to reach the global level goals. The decision-making knowledge stored and exploited locally in the agents/holons invokes the global behavior of the system that is not deterministic, but rather emergent — such a behavior cannot be precisely predicted at the design time of the community. The experimental testing of the global behavior with the physical manufacturing/control environment being involved is not only extremely expensive, but nonrealistic as well. The only possible solution is the simulation, both of the controlled process of the manufacturing facility as well as the simulation of the interagent interactions.

107.2 Technology Overview

The architecture of an agent usually consists of the *agent's body* and the *agent's wrapper*. We can also say that the body, the functional core of an agent, is encapsulated by the wrapper to create an agent [3]. The wrapper accounts for the interagent communication and real-time reactivity. The body is an agent's reasoning component, responsible for carrying out the main functionality of the agent. It is usually not aware of the other members of the community, their capabilities, duties, etc. This is the wrapper, which is responsible for communicating with the other agents, for collecting information about the intents, goals, capabilities, load, reliability, etc., of the other units in the agents' community.

From the implementation point of view, there are two types of agents: (i) *custom-tailored agents*, which are implemented in order to provide a specific service to the community (e.g., service brokering) and (ii) *integrated agents*, which encapsulate a preexisting, "inherited," or "legacy" piece of software/hardware by the agent's wrapper into the appropriate agent structure. In this case, the wrapper provides a standardized communication interface enabling to plug the legacy system into the corresponding agent community. From the outside, such a wrapped software system cannot be distinguished from the *custom-tailored agents* as it communicates in a standard way with the others and understands the predefined language used for the interagent communication (e.g., Agent Communication Language — ACL defined by Foundation for Intelligent Physical Agents [FIPA]). These *agentification processes* provide an elegant mechanism for *system integration* — a technique supporting the *technology migration* from the centralized systems toward the distributed agent-based architectures.

We distinguish three different concepts of agency that we need to explain in more detail.

Mobile Agents

Mobile agents are generally pieces of code traveling freely inside a certain communication network (usually inside the Internet). Such agents, being usually developed and studied in the area of computer science, are stand-alone, executable software modules, which are being sent to different host computers/servers to carry out a specific computational tasks (usually upon the locally stored data). They are expected to report back the results of the computation process. The mobile agents can travel across the network, can be cloned or destroyed by their own decision when fulfilling their specific task, etc.

MAS

MAS can be described as goal-oriented communities of cooperative/self-interested agents in a certain interaction environment. They have been developed within the domain of the distributed artificial intelligence

© 2005 by CRC Press LLC

and they explore the principles of artificial intelligence for reasoning, communication, and cooperation. The important attribute of each agent is its *autonomy* — the agent resides on a computer platform where it autonomously carries out a particular task/functionality. The agent owns only a part of the global information about the goals of the community that is sufficient for its local decision-making and behavior. However, in some situations, for example, when the agent is not capable of fulfilling the requested operation alone, the agent is capable of *cooperation* with other agents (asking them for help) usually via message sending. The agents asked for cooperation are still autonomous in their decisions, that is, can either agree on cooperation or can even refuse to cooperate (e.g., due to lack of their own resources). Another important attribute of MAS is the *plug-and-play* approach — the agents, which can be grouped into different types of communities (such as teams, coalitions, platforms, etc., see Section 107.3), can freely join and leave the communities. Usually, the community offers a yellow-pages-like mechanism that is used by agents to offer their services to the other agents as well as to find out suitable agents for possible cooperation. This allows to dynamically change the overall capabilities and goals of the MAS (according to user requests) by adding new agents with desired functionalities.

The cooperation among the agents supported by their *social behavior* is the dominant feature of the activities of the agents in the community. The term social behavior means that the agents are able to communicate, to understand the goals, states, capabilities, etc., of the others and to respect the general rules and constraints of behavior valid for each of the community members. Communication (exchange of information usually in the form of messages) plays the crucial and decisive role in the agents' communities with social behavior of either a cooperative or competitive nature.

Holons

Holons are agents dedicated to real-time manufacturing tasks [4]. These are tightly physically coupled, really "hard-wired" with the manufacturing hardware (devices, machines, workshop cells), thus with a low degree of freedom in their mutual communication. The holons operate in the "hard" real time, and their patterns of behavior are strictly preprogrammed. This means that their reactions in certain situations are predictable and emergent behavior is not highly appreciated (usually not allowed). The Holonic Manufacturing Systems (HMS) are designed mainly to enable a fast and efficient system *reconfiguration* in the case of any machine failure. One of the pioneering features of holonic systems is a complete separation of the data flow from the control instructions. The communication principles, supporting the holons' interoperability, are already standardized (the IEC 61499 standard; see Section 107.6).

107.3 Cooperation and Coordination Models

As we have already mentioned, communication among the agents is an important enabler of their social behavior. The agents usually explore specific communication language with standardized types of messages. The set of messages is chosen so that it represents the most typical communicative acts, often called *performatives* (according to the speech act theory of Searle [5]), used by agents in a particular domain. Examples of such performatives can be `request` used by an agent to request the other one to perform a particular operation, `agree` used to confirm the willingness to cooperate, or, for example `refuse` to deny to perform requested action. Along with the performative, the message bears the information about the sender and receiver, the content of the message, and the identification of the language used for the message's content. Additional attributes can be included in the message, for example, the reference to the appropriate knowledge ontology describing semantics of the message (see Section 107.5) or the brief description of the negotiation strategy used (the structure of replies expected).

The communication among the agents is usually not just a random exchange of messages, but the message flow is managed by a set of standard *communication protocols*. These protocols range from a simple "question–reply," via "subscribe–inform" through to more complex negotiation protocols like "Contract-Net-Protocol" (CNP), different versions of auctions (Dutch, sealed, Vickery, etc.). The communication protocols and communication traffic in general can be represented graphically by means of interaction

© 2005 by CRC Press LLC

diagrams. Figure 107.1 shows the *Request* and *Contract-net* protocols from FIPA specifications captured in AUML — Agent-based extensions to the standard UML.

The more knowledge is available locally, which means it is "owned" by individual agents, the smaller the communication traffic needed to achieve cooperative social behavior. One of the crucial questions is how to store and use the knowledge locally. For this purpose, different *acquaintance models* are located in the wrappers of individual agents. These are used to organize, maintain, and explore knowledge about the other agents (about their addresses, capabilities, load, reliability, etc.). This kind of knowledge, which strongly supports collaboration activities among the agents, is called *social knowledge* [3]. These models can be used to organize both the long-term as well as temporary or semipermanent knowledge/data concerning cooperation partners. To keep the temporary and semipermanent knowledge fresh, several *knowledge maintenance techniques* have been developed, namely (i) *periodic knowledge revisions* — the knowledge is updated periodically by regular "question–answer" processes, (ii) *subscription-based update* — the knowledge update is preordered by a specific subscription mechanism. The field is strongly influenced and motivated by Rao and Georgeff's BDI (Beliefs-Desires-Intentions) model [11] used to express and model agents' beliefs, desires and intentions, and other generic aspects of MAS.

The MAS research community provides various techniques and components for creating the architecture of an agent community. The crucial categories of agents, according to their intra- and inter-community functionalities (e.g., resource agents, order or customer agents, and information agents) have been identified. Services have been defined for specific categories of agents (e.g., white pages, yellow pages, brokerage, etc). In some of the architectures, the agents do not communicate directly among themselves. They send messages via facilitators, which play the role of communication interfaces among collaborating agents [6]. Other architectures are based on utilization of matchmakers, which proactively try to find the best possible collaborator, brokers that act on behalf of the agent [7], or mediators that coordinate the agents by suggesting and promoting new cooperation patterns among them [8]. Increasing attention has recently been paid to the concept of the meta-agent, which independently observes the interagent communication and suggests possible operational improvements [9].

The techniques for organizing long-term *alliances* and short-term *coalitions* as well as techniques for planning of their activities (*team action planning*) have been developed recently [10]. These algorithms can help to solve certain types of tasks more efficiently and to allocate the load among the agents in an

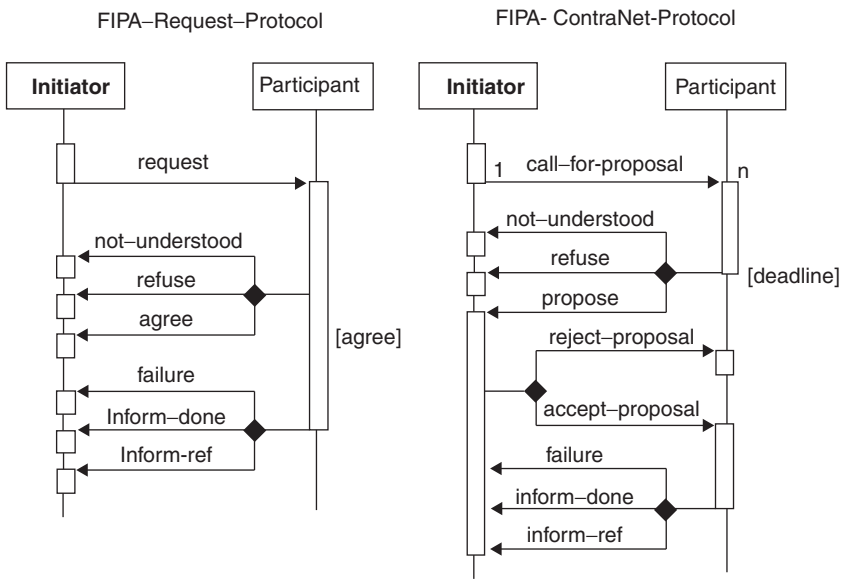

FIGURE 107.1 FIPA's *Request* and *Contract-net* communication protocols.

© 2005 by CRC Press LLC

optimal way. They can be explored with an advantage for automated creation and dissolving of virtual organizations as well as for an optimal load distribution among the individual bodies in a virtual organization. Alliance and coalition formation techniques can be linked with methodologies and techniques for administration and maintenance of *private, semiprivate*, and *public knowledge*. This seems to be an important issue to tackle, especially in virtual organizations of temporary nature where units competing in one business project are also contracted to cooperate in the other one. It is also possible to classify and measure the necessary leakage of private/semiprivate knowledge to reflect this fact in the future contracts.

107.4 Agents Interoperability Standardization — FIPA

The FIPA is a nonprofit association registered in Geneva, Switzerland, founded in December 1995. The main goal of FIPA is to maximize interoperability across agent-based applications, services, and equipment. This is done through FIPA specifications.

FIPA provides specifications of basic agent technologies that can be integrated by agent systems developers to make complex systems with a high degree of interoperability. FIPA specifies the set of interfaces, which the agent uses for interaction with various components in the agent's environment, that is, humans, other agents, nonagent software, and the physical world. It focuses on specifying *external communication among agents* rather than the internal processing of the communication at the receiver.

The FIPA Abstract Architecture defines a high-level organizational model for agent communication and core support for it. It is neutral with respect to any particular network protocol for message transport or any service implementation. This abstract architecture cannot be directly implemented; it should be viewed as a basis or specification framework for the development of particular architectural specifications.

The FIPA Abstract Architecture contains agent system specifications in the form of both descriptive and formal models. It covers three important areas: (i) *agent communication,* (ii) *agent management,* and (iii) *agent message transport*.

Agent Communication and Agent Communication Language

FIPA provides standards for agent communication languages. The messages exchanged among the agents must comply with a FIPA-ACL specification. FIPA-ACL is based on speech act theory [5] and resembles Knowledge Query Manipulation Language (KQML). Each message is labeled by a *performative*, denoting a corresponding *communicative act* (see previous section), such as `inform` or `request`. Along with the performative, each message contains information about its sender and receiver, the content of the message, a content language specification, and an ontology identifier. Other important attributes of an message are the information about the conversation protocol that applies to the current message (e.g., FIPA-Request) and the *conversation ID* that uniquely identifies to which "conversation thread" this message belongs (since there can be more conversations between two agents following the same protocol at the same time).

The core of the FIPA ACL message is its content, which is encoded in language denoted in the *language* slot of the message. FIPA offers a Semantic Language (*FIPA-SL*) as a general-purpose knowledge representation formalism for different agent domains. This formalism maps each agent message type (performative) to an SL formula that defines constraints (called feasibility conditions) that the sender has to satisfy, and to another formula that defines the rational effect of the corresponding action. Nevertheless, any other existing or user-defined language can be used as a content language of FIPA messages. One of the most popular languages used today to express the message syntax is the XML.

Bellow is an example of a FIPA message, where the agent "the-sender" requests the agent "the-receiver" to deliver a specific box to a specific location, using the XML content language and the FIPA-Request conversation protocol.

```
(request
  :sender (agent-identifier :name the-sender)
  :receiver (set (agent-identifier :name the-receiver))
  :content
```

© 2005 by CRC Press LLC

```
        <deliver item="box017" locX="12" locY="19" />
    :protocol fipa-request
    :language XML
    :conversation-id order567
)
```

Agent Management

The FIPA Agent Management Specification provides a specification of how the members of the multi-agent community shall be registered, organized, and managed. According to the FIPA philosophy, the agents are grouped into high-level organizational structures called a*gent platforms* (APs). Members of each platform are usually geographically "close" — for example, they may be run on one computer or be located in a local area network. Each platform must provide its agents with the following two mandatory services: the Agent Management System (AMS) and the Directory Facilitator (DF).

The AMS administers a list of agents registered with the platform. This component implements the creation and deletion of the running agents and provides the agents with a "white-page-list" type of service, for example, a list of all agents accommodated on the given agent platform and their addresses. Unlike the AMS, the DF supplies the community with a "yellow-page-list" type of service. Agents register their services with the DF and can query the DF to find out what services are offered by other agents, or to find all agents that provide a particular service. Thus, agents can find the addresses of others that can assist in accomplishing the desired goals.

Message Transport Service

The Message Transport Service (MTS) is a third mandatory component (besides AMS and DF) that the agent platform has to offer to the agents. The MTS is provided by so-called Agent Communication Channel (ACC), which is responsible for the physical transportation of messages among agents local to a single AP as well as among agents hosted by different APs. For the former case, FIPA does not mandate to use a specific communication protocol or interface — different protocols are being used today in agent platform implementations, such as the TCP/IP sockets, the UDP protocol, or, particularly in JAVA implementations, the JAVA Remote Method Invocation (RMI). In the latter case, the FIPA defines a *message transport protocol* (MTP) that ensures the interoperability between agents from different agent platforms. For this purpose, the ACC must implement the MTP for at least one of the following communication protocols specified by FIPA: the IIOP (Internet Inter-Orb Protocol), WAP, or HTTP.

107.5 Ontologies

Ontologies play a significant role not only in the interagent communication, where the content of messages exchanged among agents must conform to some ontology in order to be understood, but also in knowledge capturing, sharing, and reuse. One of the main reasons why ontologies are being used is the *semantic interoperability* enabling among others:

- to share knowledge — by sharing the understanding of the structure of information exchanged among software agents and people,
- to reuse knowledge — ontology can be reused for other systems operating on a similar domain, and
- to make assumptions about a domain explicit — for example, for easier communication.

Basically, ontology can be referred to as a vocabulary providing the agents with the semantics of symbols, terms, or keywords used in messages [12]. Thus, if an agent sends a message to another agent using particular ontology, it can be sure that the other agent (of course, if it shares the same ontology) will understand the message.

© 2005 by CRC Press LLC

Ontologies for MAS

Two examples can be selected to illustrate multi-agent-oriented ontological efforts in the area of manufacturing. The first one, FIPA Ontology Service Recommendation, is a part of a set of practical recommendations on how to implement agents in a standardized way. The other one, Process Specification Language (PSL) project [13], tries to develop general ontology for representing manufacturing processes. Its aim is to serve as interlingua for translating between process ontologies. The transformation between ontologies for translation using PSL is expected to be defined by humans.

The former approach seems to be much more general and applicable. FIPA uses Open Knowledge Base Connectivity, (OKBC) [14], as a base for expressing ontologies. OKBC is an API for accessing and modifying multiple, heterogeneous knowledge bases. Its knowledge model defines a meta-ontology for expressing ontologies in an object-oriented frame-based manner. OKBC can be mapped to the object-oriented languages, so that classes in programming languages can be built on the underlying ontology and be used for exchanging information. Semantics of OKBC constructs is defined in KIF as a description of what the constructs intuitively mean. However, no reasoning engine that would enable to use this information for, for example, ontology integration, is provided. Moreover, it could be difficult to provide a reasoning support for some of the constructs.

Ontologies in FIPA proposals and related ontologies for practical applications [15] are motivated mainly by the need to have something that would work immediately, because currently more attention is paid to the functional behavior of agents. There is nothing wrong with this approach, if we want to have a working solution in a short time where we do not care about the possibility of reasoning about the ontologies and further interoperability. However, the need for reasoning about ontologies can easily arise, for example, when requiring interoperability in open multiagent systems, that is, systems where new agents with possibly other ontologies can join the community.

107.6 HMS

Over the past 10 years, researches attempted to apply the agent technology to various manufacturing areas such as supply chain management, manufacturing planning, scheduling, and execution control. This effort resulted in the development of a new concept, the *HMS*, based on the ideas of *holons* presented by Koestler [17] and strongly influenced by the requirements of industrial control.

Holons are autonomous, cooperative units that can be considered as elementary building blocks of manufacturing systems with decentralized control [16]. They can be organized in hierarchical or heterarchical structures. Holons, especially those for real-time control, are usually directly linked to the physical hardware of the manufacturing facility and are able to physically influence the real world (e.g., they may be linked to a device, tool or other manufacturing unit, or to a transportation belt or a storage manipulator).

Holons for real-time control are expected to provide reactive behavior rather than being capable of deliberative behavior based on complex "mental states" and strongly proactive strategies. They are expected mainly to react to changes in the manufacturing environment (e.g., when a device failure or a change in the global plan occurs). Under "stable circumstances," during routine operation, they are not required to change the environment proactively. The reason for the prevalence of reactive behavior of real-time control holons is that each of them is linked to a physical manufacturing facility/environment, changes to which are not very simple, cheap, or desirable in a comparatively "stable" manufacturing facility. The physical linkage to physical equipment seems to be a strong limiting factor of the holons' freedom in decision-making.

The more generic holonic ideas and considerations have led to the vision of a *holonic factory* [18]. Here, all the operations (starting from product ordering, planning, scheduling, and manufacturing, to invoicing the customer) are based entirely on holonic principles. A holonic factory contains a group of principal system components (holons) that represent physical manufacturing entities such as machines or products as well as virtual entities like orders or invoices. The holons work autonomously and cooperate together in order to achieve the global goals of the factory. Thus, the factory can be managed toward global goals by

© 2005 by CRC Press LLC

the activities of individual autonomous holons operating locally. The community of researchers trying to implement the vision of the holonic factory is well organized around the international HMS consortium.

The vision of the holonic factory covers several levels of information processing for manufacturing. We can distinguish at least three separate levels, namely,

- *real-time control*, which is tightly linked with the physical manufacturing equipment;
- *production planning and scheduling*, both on the workshop and on the factory level; and
- *supply chain management*, integrating a particular plant with external entities (suppliers, customers, cooperators, sales network, etc.).

At the lowest RT-control level, the main characteristics of holons is their linkage to the physical manufacturing devices — these holons read data from sensors and send control signals to actuators. Within the HMS activities, the standard IEC-61499 known as *function blocks* has been developed for these RT-control purposes. It is based on function blocks part of the well-known IEC-1131-3 standard for languages in Programmable Logical Controllers (PLCs). The major advantage is the separation between the data flow and the event flow among various function blocks. Multiple function blocks can be logically grouped together, across multiple devices into an application, to perform some process control.

Since the IEC-61499 fits well these RT-control purposes, it does not address the higher level aspects of holons acting as cooperative entities capable of communication, negotiation, and high-level decision making. It is obvious that this is the field where the techniques of multi-agent systems have to be applied. Thus, a general architecture combining function-bocks with agents was presented in [1]. As shown in Figure 107.2, a software agent and function block control application (connected to the physical layer) are encapsulated into a single structure.

In such a holon equipped with a higher-level software component, three communication channels should be considered:

- *Intraholon* communication between the function block part and the software agent component.
- *Interholon* communication that is aimed at communication among the agent-based parts of multiple holons — FIPA standards are used more and more often for this purpose.
- A *direct* communication channel between function block parts of neighboring holons. If we are prepared to break the autonomy of an independent holon, then this communication is standardized by IEC 61499 already; otherwise, a new type of real-time coordination technology is needed to ensure real-time coordination.

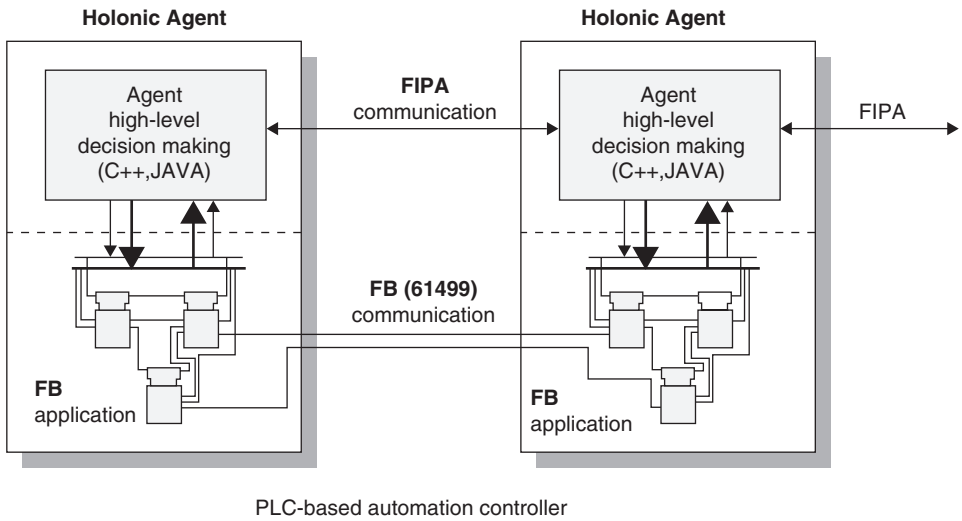

FIGURE 107.2 Holonic agent: combination of function block application and software agent.

© 2005 by CRC Press LLC

As a matter of fact, the holons defined in this way behave — on the level of interholon communication — like standard software agents. They can communicate widely among themselves, carry out complex negotiations, cooperate, develop manufacturing scenarios, etc. We can call them holonic agents (or agentified holons), as they consist of both a holonic part connected with the physical layer of the manufacturing system (operating in hard real time) and a software agent for higher-level, soft real-time or non-real-time intelligent decision making. It has already been mentioned that the interholon communication is usually standardized by the FIPA approach, and direct communication could be achieved by IEC standards (not necessarily IEC 61499). Let us stress that the FIPA standards are not applicable for the low-level real-time control purposes as they do not take account of the real-time control aspects.

The attention of system developers is currently directed mainly at the intraholon communication, which is usually both application- and company-specific and is usually connected with the solution of the "migration problem" (the problem of exploring the classical real-time control hardware for holonic control). McFarlane et al. [19] introduced a blackboard system for accomplishing the intra-holon communication, while others [20] proposed using a special management service interface function block.

It is expected that the communication among holonic agents will be standardized for many reasons. One reason is that these holonic agents should be involved in global communities of company agents, where they can directly participate in supply chain management negotiations or contribute to virtual enterprise simulation games, etc. The FIPA communication standards are considered preferable for implementing the inter-holon communication. To develop these standards, the HMS community must declare messages, define their semantics, and develop the appropriate *knowledge ontologies* (see Section 107.5). This seems to be quite a demanding task, as manufacturing, material-handling, production planning, and supply chain management requirements differ significantly between different industries and between different types of production.

From a wider perspective, for the FIPA standards to be applicable to holonic manufacturing, they should take account of the preexistence and coexistence of other standards. In manufacturing industry, there is STEP (Standard for the Exchange of Product Model Data), which is a comprehensive ISO standard (ISO 10303) that is used for representation and exchange of engineering product data and specifies the EXPRESS language for product data representation in any kind of industry. Integration of these widely accepted concepts with the HMS and FIPA effort seems to be of high importance. On the level of physical interoperability, there are various standards, such as the TCP/IP and UDP protocols, Common Request Broker Architecture (CORBA), Distributed Common Object Model (DCOM), and others. Similarly, the use of higher-level cooperation standards in the area of multi-agent systems such as KQML, FIPA, and JINI is inevitable for dynamic, flexible, and reconfigurable manufacturing enterprises.

107.7 Agent Platforms

A complex nature of the agents (high-level decision-making units capable of mutual collaboration) requires using a high-level programming language such as C++ or JAVA for their implementation. As mentioned in the previous section, for manufacturing purposes the software agents' parts of holonic agents have to be able to interact with the low-level control layer. In the majority of current holonic testbed implementations, the low-level holonic control (connected to the physical layer) is usually carried out by IEC 1131-3 (mainly ladder logic) or IEC 61499 function block programs that run on industrial PLC-based automation controllers. However, the software agent parts, implemented in C++ or JAVA, are running separately on a standard PC and communicate, for example, via a *blackboard system* (part of the data storage area in a controller allocated for each holonic agent and shared by the agent- and holonic-subsystem of the holonic agent).

It is obvious that for real industrial deployment, particularly where a high degree of robustness is required, the use of PC(s) for running agent-components of holonic agents is not safe and is also not possibly feasible for certain types of control systems. The only acceptable solution is to *run holonic agents as wholes directly within PLC-based controllers*. One controller can host one or more holonic agents, but not all of them — they have to be distributed in reasonable groups over several controllers and allowed to communicate with each other either within a single controller or among different controllers.

© 2005 by CRC Press LLC

The major issue of such a solution is to extend the current architecture of a PLC in such a way that it is able to run software agents written in a high-level programming language in parallel with the low-level control code and also provide the interface for interactions between these two layers. The programming language in which the software agents should be implemented can either be C++ or JAVA. However, there are many reasons to prefer the JAVA language to be the target one. One of its advantages is the portability of JAVA programs, which the user develops independent of hardware platforms or operating systems — the same application can run either on a PC with Microsoft Windows or Unix/Linux or on a small device like Personal Digital Assistant (PDA) or a mobile phone with Windows CE, Symbian, or other operating systems with JAVA support. Another reason to choose JAVA is that currently there are a large number of JAVA-based agent development tools available, either as commercial products or open-source projects, that simplify the development of agent systems. Moreover, some of them are fully compliant with the FIPA specifications, which insures the desired interoperability.

Agent Development Tools Characteristics

Basically, the agent development tool, often called an *agent platform*, provides the user with a set of JAVA libraries for specification of user agent classes with specific attributes and behaviors. A kind of a *run-time environment* that is provided by the agent platform is then used to actually run the agent application. This run-time environment, implemented in JAVA as well, particularly ensures transport of messages among agents, registration, and deregistration of agents in the community (white pages services) and also registration and lookup for services provided by agents themselves (yellow pages services). Some other optional tools can also be a part of the agent platform runtime, for instance, a graphical viewer of messages sent among agents, etc.

The implementation of JAVA-based agents in the automation controllers obviously requires such an agent platform runtime to be embedded into the controller architecture. Since it is used as a background for the *real-time* holonic agents, there are specific requirements on the properties of the agent platform, such as speed, memory footprint, reliability, etc. The evaluation of available JAVA agent platforms, presented in the following paragraphs, has been conducted [21] in order to find out to what extent they fulfill these criteria and therefore which ones are best suitable for the purposes of manufacturing control.

FIPA Compliancy

Compliance with the FIPA standards has been recognized as a crucial property ensuring the interoperability of holonic agents not only at the lowest real-time control level (allowing, e.g., communication of different kinds of holonic agents hosted by PLC controllers from different vendors) but also the interoperability between holonic agents and other agents at higher levels of information processing within the company, for example, data-mining agents, ERP agents, supply chain management agents, and so on.

The FIPA specification of the message transport protocol (see the Section Message transport service) defines how the messages should be delivered among agents within the same agent community and particularly between different communities. For the latter case, the protocol based on IIOP or HTTP ensures the full interoperability between different agent platform implementations. It means that the agent running, for example, on the JADE agent platform can easily communicate with the agent hosted by the FIPA-OS platform, etc.

Costs and Maintainability of the Source Code

From the cost point of view, the agent platforms that are currently available can basically be divided into two categories: free and commercial ones. Majority of the free agent platforms are distributed under a kind of an open source license (e.g., GNU Lesser General Public License), which means that you are provided with the source codes and allowed to modify them. This is an important characteristic since the integration of the agent platform into the PLC-based controllers certainly requires some modifications to be made, for example, due to different versions of JAVA virtual machine supported by the controller, the specifics of the TCP/IP communication support, or other possible issues and limitations.

© 2005 by CRC Press LLC

On the other hand, in the case of commercial products the cost in order of thousands USD per each installation, for example, can considerably increase the total cost of the agent-based control solution where a large number of PLC controllers, PCs, and possibly other devices running agents are expected to be deployed. Moreover, the source codes are not available, so that all modifications of the platform that need to be made in order to port it to another device has to be committed to the company developing the agent platform.

Memory Requirements

An issue that has to be taken into account is usually a limited memory available for user applications on the controller. Within the RAM memory of the controller, which can, for example, be about 4 to 8 MB, the agent platform run-time environment, the agents themselves and also the low-level control code (ladder logic or function blocks) have to fit inside. There are also smaller PLC-like devices that can have only 256 KB of memory available, which would be a strong limitation factor for integrating the run-time part of the agent platform. Fortunately, the agent platform developers, especially in the telecommunication area, are seriously interested in deploying agents on small devices like mobile phones or PDAs, that is, on devices with similar memory limitations. Due to this fact, for some of the agent platforms, their lightweight versions have been developed, usually implemented in Java2 Micro Edition (CLDC/MIDP) [22]. It has been documented [23] that the memory footprint of such an agent platform runtime can be less than 100KB, that is, small enough to fit well within the memory capacity limits of majority of small mobile devices and thus the PLC-based automation controllers as well.

Message Sending Speed

The last factor considered in this evaluation is the speed of the message sending between the agents. It has already been argued that the holonic agents are expected to be used for real-time control applications where a fast reaction can be a vital characteristic. In Figure 107.2 (Chapter 6), a direct communication channel between RT control subsystems of neighboring holons is conceded but it obviously breaks the autonomy of holonic agents. If we are not willing to accept such a violation, communication at the agent level is the only allowable way of interaction among holonic agents. Thus, the agent platform runtime, carrying out such interactions, should be fast enough to ensure reasonable message delivery times (i.e., in the order of milliseconds or tens of milliseconds).

We have conducted a series of tests to compare the message-sending speed of different agent platforms. Detailed information about the benchmarking testbed configuration and the speed measuring results can be found in the subsequent section.

Agent Platforms Overview

Table 107.1 gives an overview of majority of currently available agent development tools with respect to the properties discussed in previous paragraphs. A security attribute has been added as a property of the agent platform ensuring secure communication (usually via SSL), authorization, authentication, permissions, etc. The ✓ sign indicates that an agent platform has a particular property; meanwhile, the × sign indicates that such a property is missing. If a ? sign is used, there is no reference to such a property in available sources and it can be assumed that the platform does not have it.

The Java Agent Services (JAS) have also been included in Table 107.1. However, this project is aimed at the development of the standard JAVA APIs (under the `javax.agent` namespace), that is, a set of classes and interfaces for the development of your own FIPA-compliant agent-based systems. From this perspective, JAS cannot be considered as a classical agent platform, since it does not provide any run-time environment that could be used to run your agents (either on a PC or possibly on an automation controller).

The JINI technology [24] has not been considered in this evaluation either. Similar to JAS, JINI is a set of APIs and network protocols (based on JAVA Remote Method Invocation) that can help you to build and deploy distributed systems. It is based on the idea of services providing useful functions on the network and the lookup service that helps clients to locate these services. Although JINI provides a solid framework for various agent implementations (see, e.g., [25]), it cannot itself be regarded as an agent platform.

Message-Sending Speed Benchmarks

It has been discussed earlier that a speed at which the messages are exchanged among agents can be a crucial factor in agent-based real-time manufacturing applications. Thus, we have put selected agent platforms through a series of tests where the message delivery times have been observed under different conditions.

In each test, the so-called average round-trip time (avgRTT) is measured. This is the time period needed for a pair of agents (let say A and B) to send a message (from A to B) and receive a reply (from B to A). We use a JAVA `System.currentTimeMillis()` method, which returns the current time as the number of milliseconds since midnight, January 1, 1970. The round-trip time is computed by the A-agent when a reply from B is received as a difference between the receive time and the send time. An issue is that a millisecond precision cannot be mostly reached; the time grain is mostly 10 or 15 msec (depending on the hardware configuration and the operating system). However, it can easily be solved by repeating a message exchange several times (1000 times in our testing) and computing the average from all the trials.

As can be seen in Table 107.2, three different numbers of agent pairs have been considered: 1 agent pair (A–B) with 1000 messages exchanged, ten agent pairs (A1–B1, A2–B2, …, A10–B10) with 100 messages exchanged within each pair, and finally 100 agent pairs (A1–B1, A2–B2, …, A100–B100) with ten messages per pair. Moreover, for each of these configurations, two different ways of executing the tests are applied. In the serial test, the A agent from each pair sends one message to its B counterpart and when a reply is received, the round-trip time for this trial is computed. It is repeated in the same manner N-times (N is 1000/100/10 according to number of agents) and after the Nth round-trip is finished, the average response time is computed from all the trials. The parallel test differs in such a way that the A agent from each pair sends all N messages to B at once and then waits until all N replies from B are received. In both the cases, when all the agent pairs are finished, from their results the total average round-trip time is computed.

As the agent-based systems are distributed in their nature, all the agent platforms provide the possibility to distribute agents on several computers (hosts) as well as run agents on several agent platforms (or parts of the same platform) within one computer. Thus, for each platform, three different configurations have been considered: (i) all agents running on one host within one agent platform, (ii) agents running on one host but within two agent platforms (i.e., within two Java Virtual Machines — JVM), and (iii) agents distributed on two hosts. The distribution in the last two cases was obviously done by separation of the A–B agent pairs.

The overall benchmark results are presented in Table 107.2. Recall that the results for serial tests are in milliseconds (msec) while for parallel testing, seconds (sec) have been used. Different protocols used by agent platforms for the interplatform communication are also mentioned: Java RMI for JADE and FIPA-OS, TCP/IP for ZEUS, and UDP for JACK. To give some technical details, two Pentium II processor-based computers running on 600 MHz (256 MB memory) with Windows 2000 and Java2 SDK v1.4.1_01 were used. Some of the tests, especially in the case of 100 agents, were not successfully completed mainly because of communication errors or errors connected with the creation of agents. These cases (particularly for FIPA-OS and ZEUS platforms) are marked by a × symbol.

Platforms — Conclusion

On the basis of the results of this study, the *JADE* agent platform seems to be the most suitable open-source candidate for the development tool and the run-time environment for agent-based manufacturing solutions. In comparison with its main competitor, *FIPA-OS*, the JADE platform offers approximately twice the speed in message sending and, above all, a much more stable environment, especially in the case of larger number of agents deployed.

Among the commercial agent platforms, to date, only *JACK* can offer full FIPA compliancy and also cross-platform interoperability through a special plug-in — JACK agents can send messages, for example, to JADE or FIPA-OS agents (and vice versa) via the FIPA message transport protocol based on HTTP. In the intraplatform communication, based on the UDP protocol, JACK (unlike other platforms) keeps

pace with JADE in case of one host and even surpasses it in other cases, being approximately 2–3 times faster. Considering the full implementation of the Belief–Desire–Intention (BDI) model, JACK can be regarded as a good alternative to both the open-source JADE and FIPA-OS platforms.

107.8 Role of Agent-Based Simulation

The process of developing and implementing a holonic system relies on several phases and widely explores the simulation principles. The simulation process and its fast development using efficient simulation tools represent the key tasks for any implementation of a real-life holonic/agent-based system. The following stages of the design process based on simulation can be gathered like this:

1. *Identification of holons/agents*: The design of each holonic system starts from a thorough analysis of:

   (a) The system to be controlled or manufacturing facility to be deployed.
   (b) The control/manufacturing requirements, constraints, and hardware/software available.

   The result of this analysis is the first specification of *holon/agent classes* (types) to be introduced. This specification is based on the application and its ontology knowledge. The obvious design principle is that each device, or each segment of the transportation path or each workcell is represented by a holon.
2. *Implementation/Instantiation* of holon classes from the holon/agent type-library. The holon/agent-type library is either developed (step 1) or reused (if already available). Particular holons/agents

© 2005 by CRC Press LLC

are created as instances of the holonic definitions in the holon/agent-type library. Furthermore, the implementation of communication links among these holon/agent instances is established within the framework of initialization from these generic holon/agent classes (for instance, holons are given the names of their partners for cooperation).

3. *Simulation*: The behavior of a holonic system is not deterministic, but rather emergent — the decision-making knowledge stored locally in the agents/holons invokes the global behavior of the system in a way that cannot be precisely predicted. Yet, the direct experimental testing of the global behavior with the physical manufacturing/control environment being involved is not only extremely expensive, but nonrealistic as well. Simulation is the only way out. For this purpose, it is necessary to have:
   (a) A suitable tool used to model and simulate the physical processes in the manufacturing facility. Standard simulation tools like, for example, Arena, Grasp, Silk, or Matlab can be used for these purposes.
   (b) A suitable agent run-time environment for modeling the interactions of holonic agent parts. On the basis of the results of agent platforms comparison (Section. 107.7), the JADE platform as open source or JACK as a commercial tool can be recommended.
   (c) A good simulation environment to model the real-time parts of multiple holons. There are function block emulation tools from Rockwell Automation (Holobloc [26]) and the modified 4-control platform from Softing [27]. Yet, these tools do not adequately generate and handle real-time control problems. A more sophisticated real-time solution would be to use embedded firmware systems like JBED, with its time-based scheduler, to run JAVA objects (which simulate function blocks) and manage events in a realistic manner.
   (d) Human–Machine Interfaces (HMI) for all the phases of the system design and simulation.
4. *Implementation of the target control/manufacturing system*: In this stage, the target holonic control or manufacturing system is reimplemented into the (real-time) running code. This implementation usually relies on ladder logic, structured text, or function blocks at the lowest level of control. However, some parts of the targeted manufacturing systems (such as resource or operation planning subsystems) are often reused as in the phase 3. For example, in the eXPlanTech production planning MAS [28], there was 70% of the real code reused from the simulation prototype. Therefore, the choice of the multi-agent platform in the phases 3 and 4 is critical (it has been advised to operate with one platform only).

107.9 Conclusions

Why does the agent technology seem to be so important for the area of manufacturing? What are the reasons and advantages of applying them? What do they really bring? Let us try to summarize the current experience shared by both the holonic and multiagent communities. The main advantages can be summed up as follows:

1. *Robustness and flexibility of the control/diagnostic systems*:
   (a) Robustness is achieved mainly due to the fact that there is *no central element*, no centralized decision making. Any loss of any subsystem cannot cause a fatal failure of any other subsystem.
   (b) The agent technology enables to handle the problems of *production technology failures* in a very efficient way. Optimal reconfiguration of the available equipment (which remains in operation) can be carried out in a very fast way. Thus, sustainable continuation of the production task or operation or safety stopping of the manufacturing process can be achieved. (Similarly, accomplishment of the life-critical part of a mission — after an important part of the equipment has been destroyed — can be achieved in the military environment).
   (c) *Changes in the production facility* (adding a machine, deleting a transportation path, etc.) can be handled on the fly, without any need to reprogram the software system as a whole. Just a couple of messages are exchanged, and the agents are aware of the change and behave accordingly.

© 2005 by CRC Press LLC

(d) *Changes in production plan or schedule* can be handled easily, without the need for stopping the process or bringing it back to some of the initial states. The changes in the production plan or schedule can be handled in parallel to solving the tasks connected with changes in the facility equipment and/or failures.

2. The *plug-and-play approach* is strongly supported. This enables to change/add/delete the hardware equipment as well as software modules on the fly. The migration process from the old to the new technology can be carried out smoothly, on a permanent basis, without any need to stop the operation. This also makes the system maintenance costs significantly cheaper.
3. Control and diagnostics are carried out as *near to the physical processes* as possible; control and diagnostic subsystems can cooperate on the lowest level (and in a much faster way). Control and diagnostics can be really fully integrated. This fact improves the behavior of control/diagnostic systems in the hard real-time control/diagnostic tasks. Moreover, it is possible to change the principles of behavior centrally, just by changes in the rules or policies known to each of the agents.
4. *The same agent-based philosophy can be used on different levels*, in different subsystems of the manufacturing facility and company. The same agent-oriented principles and techniques can be, for example, applied on the hard real-time level (holonic control), soft real-time control, strategic decision making for control tasks, for integrated diagnostics or diagnostics running as a separate process aside of control, for production planning and scheduling, for higher-level decision making on the company level, for supply-chain management, as well as for the purposes of virtual enterprises (viewed as coalitions of cooperating companies). Despite the same communication standards and negotiation scenarios being used across all the tasks mentioned above, a very high efficiency resulting from automatic communication and negotiation between units on different levels and located in different subsystems can be obtained.

Besides the advantages of the agent-based solutions, several disadvantages can also be easily identified:

1. The *investments* needed to implement the agents-based manufacturing system *are higher*. Unfortunately, the available flexibility, which is the payoff for these expenses, is usually so enormous that the manufacturing process can leverage just a very small portion of it.
2. As there is no central control element present (in an ideal agent-based factory), in the society of mutually communicating agents, unpredictable, *emergent behavior* can be expected. This causes several obstacles for the agent-based solutions to be easily accepted by the company management. The only way out seems to be a very thorough *simulation of the agent-community behavior*. From the authors' own experience, the simulation detects just a limited number of patterns of emergent behavior. The "dangerous" patterns can be avoided by introducing appropriate policies across the system. Thus, the system simulation helps to understand the patterns of emergent behavior and their nature and to find protective measures, if necessary.
3. The current control systems offered by all the important vendors support the centralized control solutions only. The *migration toward autonomous, independent controllers*, communicating asynchronously (when needed) among themselves in the peer-to-peer way, seems to be the necessary technology enabler for a wider application of the agent-based solutions. Rockwell Automation, as a pioneering company in solving the migration process, is currently extending the classical PLC controller architecture to enable to run JAVA agents as well as a JAVA-based agent run-time environment directly within existing PLCs in parallel with the classical real-time scan-based control. Thus, the concept of holonic agents presented in Section 107.6 shifts from mainly academic considerations to the actual implementation.
4. Nearly the entire community *of control engineers has been educated to design*, run, and maintain strictly *centralized solutions*. This is quite a serious obstacle, as the engineers with the "classical" centralization-oriented approach (stressed in the last three decades under the CIM label) are really not ready and able to support the agent-based solutions. Much more educational efforts will be needed to overcome this serious hurdle.

© 2005 by CRC Press LLC

5. Not all the tasks can be solved by the agent-based approach (the estimates talk about 30% of the control tasks and 60% of the diagnostic tasks to be suitable for application of the agent-based techniques). But certain areas with a higher degree of applicability of the agent-based technology have been identified already (see below). In general, *applying the agent-based technology in inappropriate tasks can lead to frustration*.

The areas suitable for application of the agent-based techniques are as follows:

1. *Transportation of material/material handling*. The transportation paths (conveyors, pipelines, AGVs, etc.) and their sensing and switching elements (diverters, crossings, storages, valves, tag readers, pressure sensors, etc.) can be easily represented by agents; their mutual communication can be defined and organized in a quite natural way. Interesting pioneering testbeds have been built. They document the viability and efficiency of this approach in the given category of tasks.
2. *Intelligent control of highly distributed systems*, namely in the *chemical industry* and in the area of *utility distribution* control (electrical energy, gas, waste water treatment, etc.). Many decisions can be made locally, in a very fast way; the communication among the autonomous unit is carried out only if really needed.
3. *Flexible manufacturing in automotive industry*. For this industry (aimed at mass production of individually customized products), very variable customization requirements, changes in the plans and schedules, changes in technology, as well as equipment failures seem to be quite obvious features of everyday operation. All these requirements and emergency situations can be easily handled by the agent technology.
4. *Complex military systems* (like aircraft and their groups, ships, army troops in the battlefield) can be *modeled and managed as groups of agents*. For instance, very high flexibility of the technical equipment on board a ship enables to accomplish at least a part of its mission if certain subsystems are destroyed or permanently out of operation.

The research in the field of agent-based control and diagnostic systems for manufacturing has been concentrated namely around the HMS consortium within the frame of the international initiative Intelligent Manufacturing Systems. Currently, there can be recognized several leading academic and industrial centers active in this field and bringing important results.

Let us mention the following academic sites: University of Cambridge, Center for Distributed Automation and Control (CDAC), Cambridge, U.K.; University of Calgary, Department of Mechanical Engineering, Canada; Katholieke University of Leuwen, Department of PMA, Belgium; Vienna University of Technology, INFA Institute, Vienna, Austria; University of Hannover, IPA, Hannover, Germany; Czech Technical University, Gerstner Lab, Prague, Czech Republic.

Among the industrial leaders in agent-based control and diagnostics, following companies should be mentioned: Rockwell Automation, Milwaukee, WI; Rockwell Scientific comp., Thousand Oaks, CA; Daimler-Chrysler, Central Research Institute, Stuttgart, Germany; Toshiba + Fanuc, Japan; ProFactor, Steyr, Austria; SoftIng, Munich, Germany; CertiCon, a.s., Prague, Czech Republic; CSIRO, Melbourne, Australia.

The agent-based technology for manufacturing is developing in a very fast way. This development trend strictly follows the current trend in MAS research in the field of Artificial Intelligence as well as all the recommendations of the FIPA standardization consortium. But a long way remains in front of us: it is necessary, for example, (i) to change the way of thinking of industrial designers and engineers of control systems, (ii) to document the reliability and manageability of the emergent behavior of the agent-based systems (for this purpose, much more robust simulation tools should be developed), (iii) to support the migration processes from the centralized to agent-based control, which concern both the hardware and software, (iv) to solve the technical problems of interoperability, communication, and negotiation among the agents, and (v) to work toward widely acceptable ontology structures and languages.

108.1 Motivation and Introduction

The evolution during the last few years in the field of production sciences and production practice has induced major changes. Many companies have found that formerly successful actions, methods, and strategies — which were based on the paradigm of a stable production environment with predictable processes and a minimum of external disturbances — were no longer suitable to produce good results [KühM00]. This challenge to production science and practice is mainly driven by a turbulent industrial environment, which is characterized by an aggressive economic competition on a global scale, more educated and demanding customers, and a rapid pace of change in process technology. The overall reaction can be outlined by:

- an increasing frequency in the introduction of new products;
- smaller lot sizes and a rising amount of variants;
- changes in parts of existing products;
- large fluctuations in product demand and mix;
- changes in governmental regulations (e.g., safety and environment); and
- changes in process technology [KoUa99].

Consequently, the markets are characterized by an individualization of the customers' wishes. To be able to cope with these wishes — and by this, simultaneously, to be able to cope with the competitors — enterprises answer with increasingly more (customer) specific products and services. The number of variants that have to be produced in the corresponding plants are also increasing. This dynamics concerning the alteration of processes is accompanied by a decreasing possibility to plan the production program and the amount of sold products [Förs99].

Summarizing, it has to be stated that one basic thinking model is replaced by another one, which partially overthrows rules and regularity or even leads to contradictions. The point is a basic paradigm

© 2005 by CRC Press LLC

change toward highly flexible and reconfigurable production systems, which are able to reflect the new balance among economy, technology, and society.

Unfortunately, due to an insufficient technological infrastructure, implementations of such concepts in industrial plants were for a long time unworkable until relatively recently. Nowadays, with rapidly declining computer hardware cost, a viable infrastructure is in place [RePM01]. Furthermore, the latest developments in information technology and science support the required reconfigurability and flexibility of modern production systems and simultaneously allow for a dislocation and decentralization of production to open production networks. Under the catchwords "Extended Enterprise," "eProduction," and "B2B," such open production networks come more and more into the focus of production sciences and production practice [Klm02]. As the corresponding "enabling technologies" for information and communication in such production systems, the Internet with connections down to single field devices, the Extensible Markup Language (XML) as integrating technology, and so-called active technologies such as Java and .Net increasingly come into the focus of vendors and end users of automation systems [Klm02, Pesc02]. Against the background of Java's platform independence — which is displayed in the "write once, run anywhere" concept of this language — and Java's advantages as an object-oriented high-level language, (Java based) mobile software agents seem to be worth taking a deeper look inside. Mobile software agents are a relatively new concept to realize distributed (software) systems. Distributed systems — also referred to as distributed control systems or decentralized intelligent automation technology — are a number of autonomous, subnet-connected processors and repositories that communicate with each other to achieve a common goal. By means of communication via the network, the respective distributed processes autonomously coordinate their activities and exchange information [Ensl78]. While traditional distributed systems are based on stationary software programs, exchanging their data via a network, mobile agents are designed as software entities that autonomously migrate from one node in the network to the next one. This means that the algorithms are going to be mobile, not only the data which have to be calculated [McOS98, MiHM99].

Particularly, the above-mentioned technologies are the basis for the PABADIS (Plant Automation based on Distributed Systems, an IMS project under reference IST-1999-60016) project, which aims at providing a flexible plant automation solution based on the use of information technologies as mentioned above and described in several other chapters of this book (see [Spec03] for more details).

108.2 PABADIS Architecture for Reconfigurable Manufacturing Systems

General Overview

In this chapter, a control system is described, which enforces the use of distributed intelligence and therefore enables flexibility in plant, product, and device management. Agents are responsible for scheduling and resource allocation of their respective products and manufacturing steps. Most important is that the agents are able to use less complex algorithms than those used in centralized systems and can react much more flexibly than those.

The above-mentioned reconfigurability can be seen in two ways: first, in a horizontal way and second, in a vertical way. Reconfigurability in a horizontal way refers to the plug-and-play capabilities of the used hardware and means the possibility to simply plug in new production equipment, and use it without major changes within the production system. By an appropriate network technology, simple mechanisms are provided that enable machines to plug together to form an impromptu community — a community put together without any planning, installation, or human intervention. Each machine provides services that other entities in the community may use. These machines provide their own interfaces, which ensures reliability and compatibility. Such mechanisms already do exist for the embedded systems market; it is one objective of PABADIS to make this technology also applicable in factory automation.

In a vertical way, a dynamic architecture means that especially the scheduling of the produced articles has to be very dynamic. This allows to react on urgent jobs, failures of machinery, and other possible disturbances,

© 2005 by CRC Press LLC

which are due to the turbulence of the production's environment. Scheduling within a company means to consider the office level with its ERP system as well as the field level where programmable logic controllers and machine controls are located. In fact, the aim is to dissolve the MES layer and divide its functionality into a centralized part that can be attached to the ERP system and a decentralized part that can be implemented by partially mobile software agents; hence, the baseline vision of the project is that every work piece has an agent "attached to it" carrying the necessary product information and moving through the plant along with the work piece. This requires the introduction of an information-oriented "alter ego" for each product. Software agents are a suitable approach for this as it is very difficult to design a conventional network that adjusts well to either changing usage patterns over short time scales or to evolving needs and circumstances over the long haul. In contrast, a mobile agent-based system can be reconfigured on the fly, in response to new situations or demands, and with or without human intervention [MiHM99].

The transition from restrictive and rigid communication and information in central production systems to flexible and reconfigurable information streams in reconfigurable, decentralized units is outlined in Figure 108.1.

From the communication point of view, this approach both necessitates and supports the current trend in industrial automation to flatten the network hierarchy and to use IP-based networks down to the control level [DieS00]. It can be stated that in the near future, industrial automation will change significantly in all three aspects of hardware, software, and communication systems. At the communication level, Ethernet more and more pervades the shop floor and platform organizations such as the IAONA e.V. (Industrial Automation Open Network Alliance) foster this trend and smooth Ethernet's way down into the plant. With respect to the software, first applications of Java™ and .Net™ in industrial control can be found, and first products already do exist. For these technologies, PC platforms are needed. Fortunately, from a hardware point of view, industrial PCs (iPCs) have been conquering industrial plants for some time, and, generally speaking, there are no major challenges to cope with in the first step.

The following sections are dedicated to first, an overview of the architecture, second, the Multi-Agent System (MAS), third, the corresponding Agency, and fourth, the connection to the machinery by a generic interface layer, the so-called Cooperative Manufacturing Unit (CMU).

Overview of Architecture and Processes

Contrary to the conventional centralized job control approach, the Multiagent Architecture described in this chapter focuses on job control using autonomous production units. The objective is to dissolve the Manufacturing Execution System (MES) layer and divide its functionality into a centralized part that can be attached to the Enterprise Resource Planning (ERP) system and a decentralized part that can be implemented by (partially) mobile software agents. This effectively comes down to reducing the hierarchy described in Figure 108.1 into two layers.

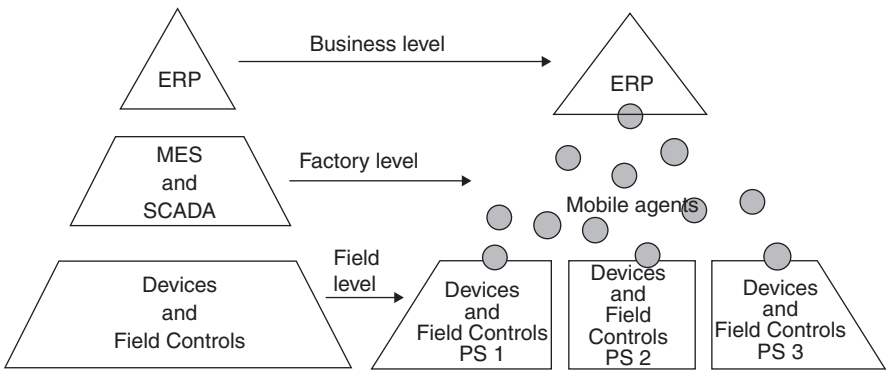

FIGURE 108.1 Transition of information and communication from rigid to reconfigurable systems [Klm02].

© 2005 by CRC Press LLC

As outlined above, the baseline vision of the architecture is that every work piece has a mobile agent "assigned to it," carrying the necessary product information and moving through the plant along with the work piece. In fact, every production system needs two main inputs: the actual physical work piece and information. If we consider a single piece production system, most of this information is tightly connected to the individual product, such as

- production sequence and schedule;
- machine-related production data;
- status of the processing; and
- general administrative information about the order.

In addition, there is information associated with the entire production system, such as

- overall resource use;
- overall production schedule;
- machine status information; and
- quality control information.

The overall production scheduling and resource planning data should, of course, be consistent with the product-specific data sets; hence, they can be compiled or deduced from each other. Traditionally, these data are generated by the ERP system in a strictly centralized manner. Detailed planning, adjustments to the overall scheduling, and job control are subsequently done by the MES. With a view to the information distribution sketched above, it seems reasonable to largely remove the detailed planning and job control functionality from the ERP and distribute it on the level below among the "products" that can independently keep track of their processing needs and status. As mentioned above, this requires the introduction of an information-oriented "alter ego" for each product, the so-called *Product Agent* (PA). Figure 108.2 gives an overview of the corresponding architecture.

The production means are modeled as abstract entities with a generic interface between PABADIS and the actual production equipment. Such an entity is called CMU. It provides available functions to the manufacturing process. This definition is deliberately abstract and makes no assumptions about the physical realization. In fact, we can distinguish two different types of CMUs:

- *Manufacturing CMUs* are used for the physical processing of products and involve some kind of manipulation of the work pieces, for example, welding machines.

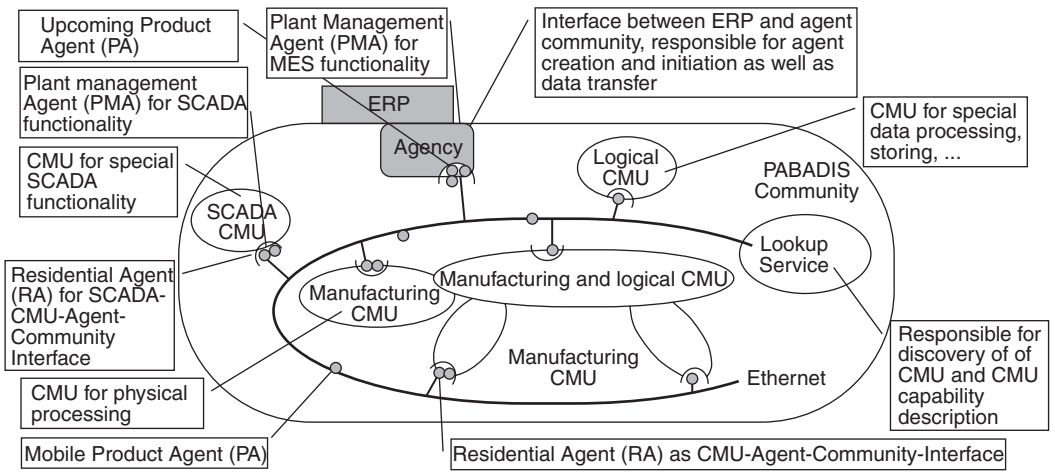

FIGURE 108.2 Agent-based architecture for job control in turbulent industrial environments.

© 2005 by CRC Press LLC

- *Logical CMUs* provide computational services and are consulted by the agents for special tasks like complex scheduling algorithms, database search, or similar things.

A detailed description of the CMU concept can be seen in a further section.

The manufacturing process according to the PABADIS idea starts with the generation of a conventional manufacturing order by the ERP system to process a product. This order comprises the sequence of required processing steps together with the appropriate parameters for product processing. The manufacturing order is passed to the *Agency*, where it is translated into one or several work orders. A mobile Product Agent will be responsible for each work order, which is generated and initialized at the *Agent Fabricator* as part of the Agency and joins the MAS.

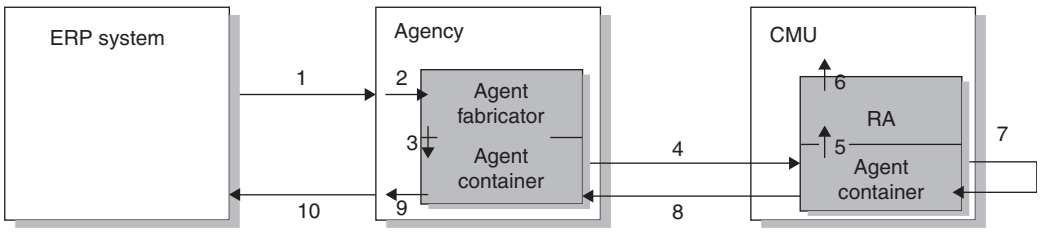
Step by step, the PA executes its production plan in the course of which it always follows the same basic procedure: it consults a *Lookup Service*, which is available in the network to find a CMU (see Figure 108.2) that can provide the needed manufacturing service. The Lookup Service acts as a central service broker and informs the PA about the access path and the abilities of possibly useable CMUs. Subsequently, the PA contacts the CMU and asks for additional information that is necessary to decide which service provider should be chosen. Based on these data, the agent selects the CMU that it considers optimal.

Throughout the manufacturing process, the PA guides the work piece. It ensures the processing of the work piece by the CMU in an appropriate way in cooperation with the *Residential Agent* of each CMU.

Upon completion, the PA returns to the Agency to deliver all product-dependent information that was collected during processing at the respective CMUs to the data collector and terminates. The Agency then generates a report to the ERP system using the data the PA collected on its way through the production (if so desired by the ERP system in the production order). The whole product processing flow is depicted in Figure 108.3.

One main characteristic of this system is the correlation of work piece and product data by Product Agents. Nevertheless, the association between PA, product data, and work pieces is not only a 1:1:1 association. Of course, a set of unique products with the same product information and therefore a set of work pieces can be handled by one PA. The only prerequisite is the necessity of control over the work pieces and their production. If the work pieces belonging to one PA are always transported together, for example, on the same pallet, this control is ensured. Hence, the PABADIS architecture can be used in a broader context than mentioned here.

In this context, let us have a look at the system behavior resulting from the occurrence of a manufacturing order with a lot size of χ products. If η products can be transported on/in a common transport unit (pallet/container), the *Agency* needs to create $\lceil \chi/\eta \rceil$ PAs guiding $\lceil \chi/\eta \rceil$ transportation units with a maximum amount of $\lceil \chi/\eta \rceil$ times η products. The total amount of transported products is equal to or



1. Manufacturing order from ERP to Agency
2. Distribution of the manufacturing order to one or more Product Agents (PAs)
3. PA initialization and start
4. Migration to a Cooperative Manufacturing Unit (CMU)
5. PA contacts Residential Agent (RA) at the respective CMU
6. Access from the RA to the machine functions
7. PA migration to the next CMU
8. PA migration back to the Agency
9. Aggregation of the product data from each PA
10. Manufacturing report to the ERP system

FIGURE 108.3 Product processing steps in a PABADIS system.

© 2005 by CRC Press LLC

less than $\lceil \chi/\eta \rceil$ times η products, due to the fact that at least one transport unit needs not necessarily to be full. These PAs (or PA sets) can behave as described above.

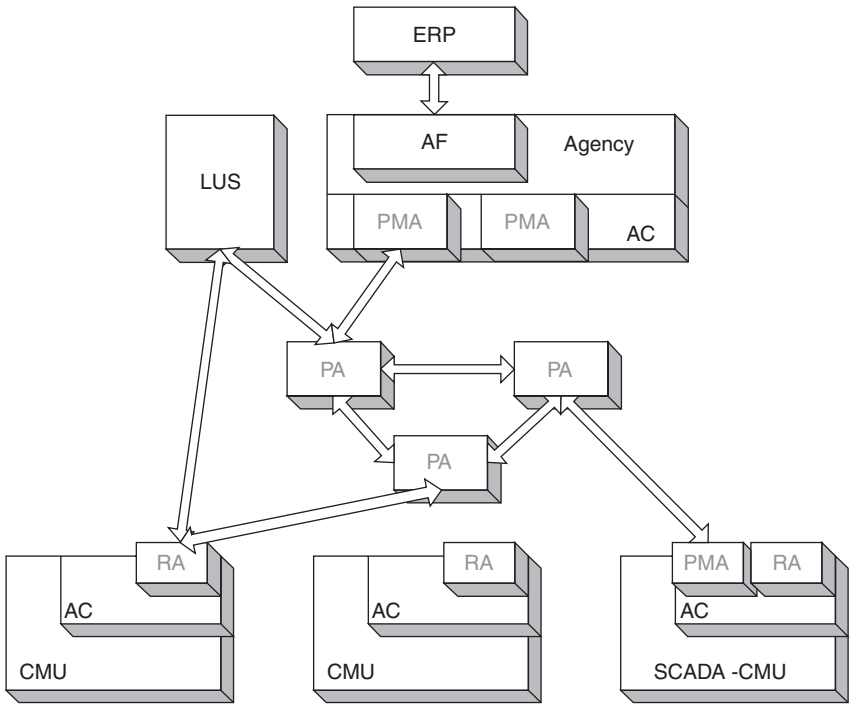
In addition to the PAs, *Plant Management Agents* are created by the Agency to fulfill specific control or supervision tasks that are not related to individual products as, for example, maintenance- and quality-related tasks.

The MAS

The MAS has been designed with respect to decentralized control in plant automation and distributed intelligence. In the context at hand, it is a set of independently acting intelligent software entities that are working autonomously and communicate with each other in order to perform their own respective tasks. An important achievement of this combination of independent process execution and agent communication is the realization of two objectives of the plant automation control system:

- product manufacturing control and
- an efficient machine usage.

As shown in Figures 108.2 and 108.4, there are three types of agents defined in a PABADIS agent community: PAs, Residential Agents (RAs), and Plant Management Agents (PMAs). According to the general objectives of job control in a manufacturing plant, the PA community implements the main job control tasks by performing the relevant work orders decentralized, independently, and by their own "intelligence."



AC	Agent Container	PA	Product Agent
AF	Automation Function	PMA	Plant Management Agent
CMU	Cooperative Manufacturing Unit	RA	Residential Agent
ERP	Enterprise Resource Planning	SCADA	Supervisory Control and Data Acquisition
LUS	Lookup Service		

FIGURE 108.4 MAS and the respective communication relations.

© 2005 by CRC Press LLC

This independent order execution includes the necessary communication with the appropriate entities of the whole system. Against this background, it is important to note that all PAs work in concurrence with other agents (either other PAs or PMAs) and perform the "egoistic" target of producing their respective work order.

An RA provides the functionality of a CMU to the PABADIS system and its entities. Contrary to PAs, RAs do not communicate with each other via the network. If at all, they communicate locally on a shared device. This is due to the fact that there might be the necessity for negotiations between RAs — providing parallel accessible functions of a CMU and the respective RAs providing alternative functions that always depend on the parallel functions provided by the other RAs residing on the same machine. This prohibited communication between RAs over the network is a principal difference between the PABADIS concept and many other agent-based manufacturing concepts like the Holonic Manufacturing Systems (HMS) (see [FGCD00]). All "intelligence" of the PABADIS system is concentrated in PAs, while in HMS, the intelligent modules are "machine"-dependent.

The duty of a PMA is to provide an interface between the MAS and the ERP system. It also takes part in the communication between a SCADA system and the MAS, but the main reason for introducing PMAs in the PABADIS concept is the necessity of having special units for MES functions that cannot be implemented by PAs or RAs, which means MES functions independent of a definite work piece and a definite CMU.

The following three subsections shall provide a deeper insight into the reason and structure of the above-mentioned types of agents.

The PA

The community of PAs is seen as a key component of the PABADIS MAS, because it provides the main "intelligence" of the system. As mentioned above, the main task of a PA is to perform a work order provided by the Agency. Due to this objective, a life cycle of a PA can be described by the following steps:

Initialization

During this step, a PA receives a work order, setup variables, recognizes its place in the community, and prepares a work order to be analyzed.

Work order parsing

As the name suggests, work order parsing means that a PA parses a work order in order to construct an execution plan. To do this, the PA analyzes all branches of the work order, which are represented in a graph view, and creates a string array with a sequence of actions, which will be used by the PA for resource allocation.

Scheduling

Scheduling means that a PA reserves resources for its tasks, representing the processing steps. In order to do this, it communicates with the RAs of the needed CMUs. Depending on the depth of the scheduling (provided by the Agency with a work order), a PA can allocate all resources in advance, for a first set of tasks, or only for the very next task (step-by-step scheduling). At the end of this step, a PA knows where it wants to migrate to in order to perform the next task of the work order.

Migration

During this step, a PA migrates to a CMU, checks its location, and waits for an execution slot. A PA initiates a migration, but does not control the process itself — this is done by the agent containers of the concerned CMUs (current location of an agent and destination CMU).

Task performing

As long as a special manufacturing step is performed at the respective CMU, the PA just waits for the end of this execution process. The CMU's RA, correspondingly, informs the waiting PA about the results of the workpiece processing; hence a PA is just a passive element during a task's performance. For critical situations, the possibility is foreseen to interrupt the task-performing process.

Termination

As the final step, after finishing its work order processing, the termination of a PA is foreseen. Termination either occurs when the work order is finished or, due to disturbances in the system or other failures, cannot

© 2005 by CRC Press LLC

be finished. In both cases, a PA starts a termination procedure: it migrates to the Agency, creates a report to the Agency/ERP, and terminates itself. This means that a PA removes all its files from the system and, accordingly, cannot be restarted; only a creation of a new agent using the old PA's report is possible.

During all these steps, a PA bases its behavior on the work order provided by the Agency and the status of the available CMUs. Correspondingly, if it should become necessary to react on a sudden change within a work order — for example, the customer decides *during* the manufacturing process that he would prefer a blue car instead of the ordered yellow one — by a change of the respective work order the job can be changed "on the fly." This work order is an XML file that is accessible via an XML parser; this XML -parser converts XML data into a view that is understandable for an agent as well.

From a logical point of view, a PA consists of several modules that execute specific parts of the agent functionality.

PAServiceModule — provides the main functionality of the PA, including initialization, agent logic, calculation, and termination. This module includes the starting method of the PA and does most of the functionality related to the work order.

PAMigrationModule — a specific module for the PA, which implements the mobility of the PA, including pre- and postmigration methods. The Migration Module is closely connected to the agent platform. In fact, it is based on the methods provided by the agent platform. In order to make the whole system more flexible, the usage of the mechanisms of the used agent platform is hidden.

PACommunicationModule — this module includes all mechanisms that are used by a PA for communicating with other components of the system, such as an RA, a PMA, and other PAs. Communications are represented by a set of interfaces that a PA uses in order to organize the communication.

PADataModule — all agent data and methods for data manipulation are contained within the data module. This module includes an XML parser, which is used for work order interpretation. All other data related to a PA, such as history data, status data, and other MES data, are also represented by the data module.

The RA

As stated above, the RA is an interface between the agent community and the CMU community. The main functionality of an RA is to provide a set of interfaces and methods in order to provide a communication mechanism between two different entities. Logically, an RA is a part of the MAS and a CMU. In contrast to PAs, an RA does not have intelligence in the sense of task decisions based on its own calculations. Nevertheless, this does not mean that an RA cannot control processes. Specifically, an RA can be an active element in communications or negotiations. All decisions of an RA are based on inputs from other components of the PABADIS system (CMU and PA), but mostly an RA just reacts to the events that occur in the system.

Logically, an RA consists of the same set of modules as a PA does, except for the migration module. However, the functionality of these modules is slightly different:

RAServiceModule — In contrast to the PA concept, this module is an additional component, which does not have logical importance. The main method is still implemented in this module, but there is no life cycle for the RA to be implemented. A corresponding event handler is also implemented here because an RA most of the time just reacts on certain events.

RACommunicationModule — the most important part of an RA. It contains all logic of this agent type and is some kind of analog to the PA's service module. Specifically, the functionality of the agent is implemented there.

RADataModule — all agent data and methods for data manipulation are realized in the data module. This module deals with a CMU's XML parser. All other data related to an RA, such as history data, status data, and other MES data, are represented by the data module, but stored in the Common Feature Module (CFM), which is part of the CMU (see The CMU concept). The RA uses this database to perform its tasks.

The PMA

The purpose of a PMA is to provide work piece-independent MES functions. Some of these functions cannot be implemented completely without human control. Hence, PMAs become necessary that are responsible for requesting appropriate information from the system needed by, for example, ERP or SCADA

© 2005 by CRC Press LLC

system and for giving the responses back to the operators, who initialized these requests. The "human control," nevertheless, is optional and might sometimes be replaced by an automatically initialized request.

Logically, a PMA can be seen as a combination of a PA and an RA. On the one hand, a PMA is a stationary agent that is located in the Agency. On the other, a PMA is created in order to perform a special work order that is based on an ERP-based manufacturing order. As mentioned above, a PMA is responsible for several tasks, which will be listed in the following in more detail:

Some *special MES functions* need a direct communication between the ERP and the Agent Community. In this case, the PMA is a permanent and stationary agent residing at the Agency, which behaves like an arbitrary RA. Furthermore, this PMA type is stable and will never be removed from the system. Otherwise the system would lose some of the MES functionality provided by the appropriate PMA. For this reason, an agent life cycle like that of a PA can be stated.

For *temporary functions*. In this case, the ERP orders the Agency to perform specific tasks; the Agent Fabricator creates a PMA, which executes an appropriate sequence of actions related to the given order. As a result, the PMA sends the report back to the ERP system and terminates in the Agency. Hence, it shows an agent life cycle like a PA, but is stationary.

A third type of PMAs is the *mobile PMA for special tasks*. It is absolutely equal to a PA with the exception of the work order definition. In contrast to a PA, the work order of this PMA type is to execute some special tasks, mostly to collect appropriate information as, for example, particular quality data. Hence, the PMA does not have a work order of the type "make a product," but logically the aforementioned tasks of the mobile PMA are conceptually equal to the PAs work orders.

The Agency

The Agency is a program that interfaces the ERP level with the MAS. The Agency processes ERP demands, creates agents, and transmits process and status information about production operations between ERP and agent community in both directions. Therefore, the ERP system produces a manufacturing order, which has to be decomposed by the Agency into elementary work orders to allow parallel processing. For each work order, a specific PA is generated.

In case products are made with concurrent operations like assembly, disassembly, scrap, and recycling, the Agency creates as many PAs as necessary and combines the different issues. Against this background, the Agency provides PAs with the execution plan of the whole work order, so that synchronization and coordination can be managed by the agents themselves. This plan may have the form of a Gantt chart as shown in Figure 108.5.

At completion of the elementary order (work order), the PA reports to the Agency and is then terminated; after completion of the entire manufacturing order, the Agency finally sends a report to the ERP system. This report accounts for the whole manufacturing process and has to be archived to enable traceability.

As mentioned before, the elaboration of work orders occurs consecutively to a manufacturing order issued by the ERP system. Manufacturing orders start a production process with all data from product and process databases. For flexibility reasons, in PABADIS the allocation of resources is no longer an operation planned beforehand, but is now an on-line and dynamic operation performed by PAs and CMUs.

Before presenting the structure of the Agency, first it shall be explained how work orders are generated. A manufacturing order can be decomposed into elementary work orders following different ways. Figure 108.6 shows a simple example.

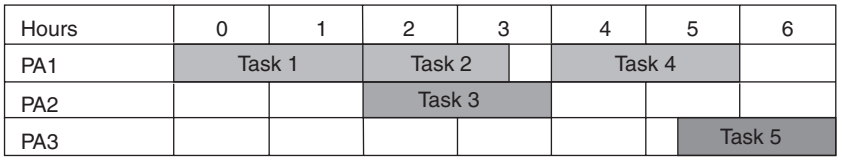


FIGURE 108.5 Example of a manufacturing order.

© 2005 by CRC Press LLC

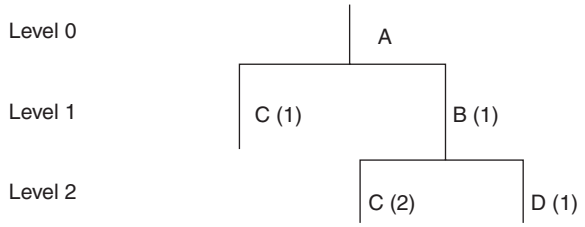

FIGURE 108.6 Example of a bill of material.

In this example, the end product A is made up of C plus B, and B in turn is made up of two Cs plus D.

Level code allows for building the structure of the product by providing the tree decomposition or parent/child relationships. As a first assumption, it shall be supposed that all endings of the tree (here C and D) are purchased parts, components, or raw materials that are available in the inventory at the start of the manufacturing order. This means that the ERP system has correctly released all previous orders (buying, supply, or production orders) and that the stocks are sufficient.

In this example, we then have two possibilities of defining work orders (WOs) (Figure 108.7):

- One WO: this WO consists in making product B with C and D, and then making product A with B and C.
- Two WOs: in this case, we define one WO for product B, and one WO for product A.

One of these alternatives is predefined in the manufacturing order or — to prevent complex situations that could arise depending on the nature of manufacturing processes involved — the second one is chosen automatically, which means one WO per manufactured product. In a general case, there are distinguished products or parts in two categories: Manufactured (M) or Purchased (P). More details can be seen in [Spec03]

With each work order, a routing is associated (from a routing file, accessed by ERP) and a sequence of tasks (processing steps) necessary to achieve the work order. This routing has to be expressed as a list of services, and each service will be matched with CMU functions. Routings are associated to products by means of a correspondence table (part and service correspondence table).

Figure 108.8 shows the technical composition of the Agency. Modules are differentiated between static and dynamic elements.

Static elements:

- Interface to ERP: This module in fact represents the communication link with ERP on the Agency side. It is limited to the access methods regarding the Agency database.
- MOManager, IRManager, PSObserver have exactly the same behavior: each time a new request is delivered, the corresponding module creates a specific PMA, gets its report, and finally deletes it.
- Agentfabricator is a module that offers agent creation methods and, thus, in the narrow sense is the entity that produces the agents.
- AgencyRA is the Agency Residential Agent, created at the start of the Agency.

Dynamic elements:

PMAs are dynamically created in the Agency: an MOPMA for a Manufacturing Order, an IRPMA for an Information Request, and a PSPMA for a Plant Structure request. In addition, an MOPMA will create the PAs that will be in charge of the Work Orders.

1. An MOPMA is created with a list of WOs:
   - in turn it creates a PA for each WO;
   - it maintains a PA reference table (unique agent identifiers), a WO table, and a WO report table;
   - when MO is completed, MOPMA is deleted by MOManager; and
   - in addition, MOPMA disposes of agent management methods (from AgentManager) for the control of the PAs.

2. IRPMA sends requests to CMUs and waits for the reports.
3. PSPMA sends a request to the Look Up Service (LUS) and waits for the report.

The CMU Concept

In the agent-based architecture at hand, manufacturing operations as such (drilling, welding, handling, etc.) and the corresponding automation functions are represented by autonomous units, the so-called CMU. Each CMU contains an agent run-time environment and an RA as an interface between PA and the corresponding automation function. To enable a broad applicability of the described architecture, some basic requirements have to be met:

- Different control systems must be allowed to be integrated into the concept. This means that the CMU architecture has to be independent of the used control hardware.
- A broad spectrum of different, partially unknown automation functions shall be covered and allow the usage of the whole architecture in various manufacturing branches.
- At runtime, the real-time capabilities of the automation functions of the manufacturing system must not be influenced by chance. To achieve this, a strict separation of the automation functions' control and the agents' tasks has to be guaranteed. In this context, it is important to note that the agents are slower for several magnitudes than conventional controls and with regard to job control normally do not require real-time in a narrow sense.
- Changes in an automation function should not require any changes in the agent-based architecture at hand. The description and the evaluation process of any automation function shoud be independent of the implementation and the used hardware, only under consideration of the manipulation (or the possibility to manipulate) the work piece at hand.

The requirements mentioned above are best met by the loose coupling of two components independent from each other; these are on the one hand the PABADIS software environment (as described in this chapter) and on the other the run-time environment with the automation function (Figure 108.9).

In principle, a CMU consists of an RA, a universal supporting component for all PAs and PMAs — the so-called Common Feature Module — and the automation function as representative of the processing of the work piece. Each automation function is definitely related to one RA; thus, the RA is in charge of "his" automation function. Nevertheless, a fix relation between hardware and automation function is not necessarily given.

Between RA and automation function, the generic interface Residential Agent Function Interface (RAFI) is located for control and data exchange reasons. This interface is completely defined, but an implementation

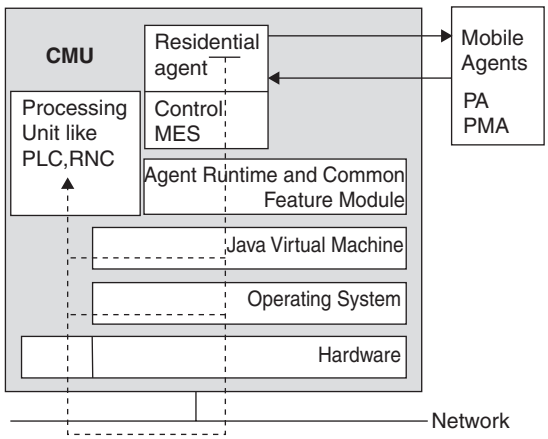

FIGURE 108.9 CMU hardware/software-structure.

© 2005 by CRC Press LLC

is not prescribed. In this way, different manners of coupling the PABADIS software architecture to the automation function are possible; a Java-based Programmable Logic Controller (PLC), for example, under the same hardware could run a second Java Virtual Machine (Java linked CMU), or an already existing control system can be used, which is coupled via the communication network (COM-linked CMU). Several other variants between these two extremes can be realized. *The following subchapters give an overview of the main-components of the CMU concept. A more detailed description of the CMU concept can also be found in [B1DeK102].*

The Residential Agent Function Interface

Residential Agent Function Interface (RAFI) offers a universal view on a CMU's automation function and its connection (also universal) to the MAS (Figure 108.10).

At the moment, although not necessary, it seems most appropriate to implement the agents and the other parts of the PABADIS architecture in the Java programming language. The access to the data of the automation function should be realized in the corresponding language of the control system used. Since the RAFI methods are specified in Java and are also called in Java, within the RAFI also the translation from Java into the target language is performed (Java Native Interface).

As Java is independent of the respective automation function, only one RAFI implementation per control system (e.g., PLC type) is necessary, which has to be developed by the producer of the respective control system.

The Function Control Module

The Function Control Module (FCM) offers the generic access path to the automation function, whereas the real-time environment of the automation function and the MAS are decoupled from each other.

Transitions from one state to the other are triggered by the automation function as well as by the RA. To avoid couplings and additional synchronizations, the state machine (Figure 108.11) is defined such that each time only one of these two components determines the access. If a transition is performed, the other (passive) component is informed.

This distribution of competencies as well as the mutual information result in definite messages between RA and automation function; thus, the FCM state machine can be differentiated into two independent state machines and the respective messages during implementation. This property enables the required flexibility when coupling the MAS to existing control systems. Hence, the FCM can also be seen as a communication protocol between RA and automation function.

Parameter Interface and Information Request Interface

Before an automation function can be started to process a certain manufacturing step, normally several parameters have to be set. The function-specific parameter sets are described within the CD (Capability

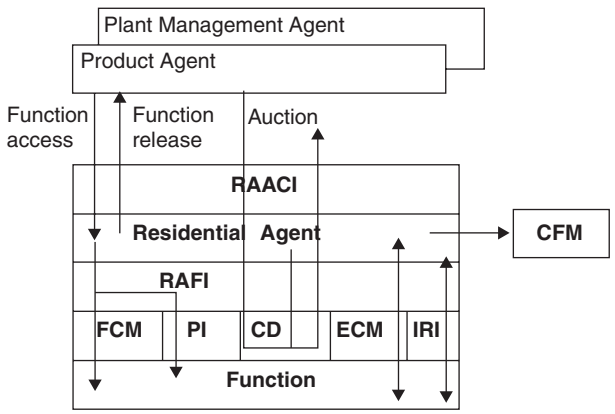

FIGURE 108.10 Access path to the function.

© 2005 by CRC Press LLC

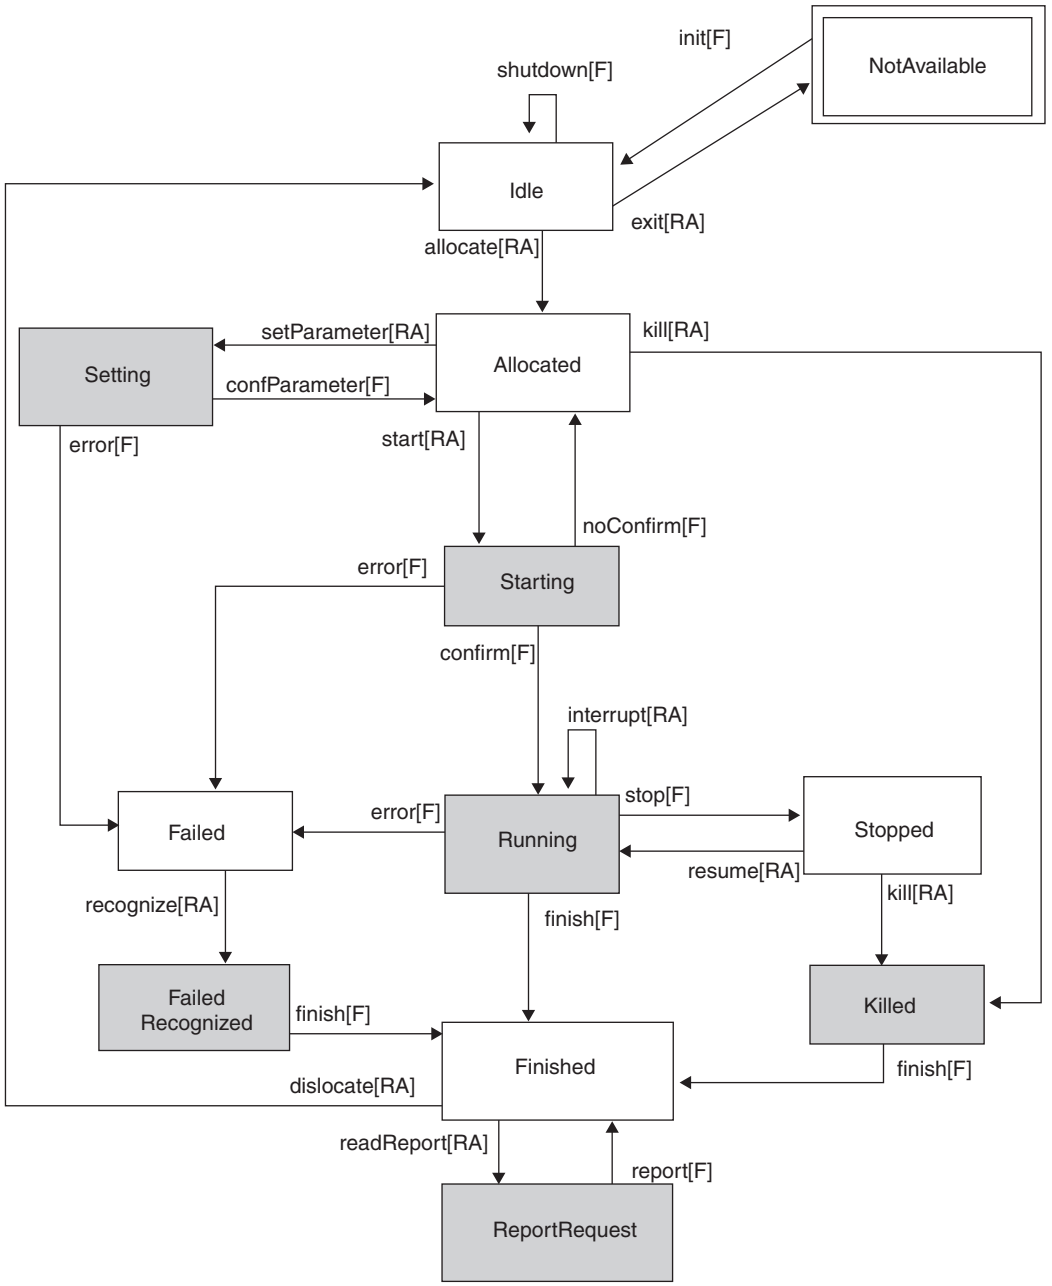

FIGURE 108.11 Function Control Machine.

Description, see below), and the PA contains the special manufacturing step-relevant parameter values. The setting of these parameters occurs via a generic interface, the Parameter Interface (PI), which is embedded into the FCM. As can be seen from the state machine (Figure 108.11), setting of parameter values is only possible in the state "allocated" with the message "setParameter." By means of a call, the data of a parameter set are transmitted; within the PI, it will be confirmed whether all mandatory parameters are set by the PA and whether all parameters that shall be set by the PA are extant. When arrays of parameters are set, these are also verified; if in the course of verification no mistakes are detected, the set of parameters is passed to the automation function.

© 2005 by CRC Press LLC

As during or after the processing of an automation function, possibly a PMA needs data from this automation function, the reading of the data of any automation function is possible via the Information Request Interface (IRI). Nevertheless, data that are read at a certain point of time, depending on the automation function, are not always consistent over time. For this reason, additionally so-called reports are defined, which can only be read after an automation function has finished. The handling of reports within the IRI occurs analogously to the parameter sets within the PI. Reading of reports is controlled via the FCM and is only possible in the state "finished" — otherwise, an error message is produced.

The Event Control Module

The Event Control Module (ECM) serves for the asynchronous information exchange between the automation function and the RA. To be able to support different control platforms, similar to the FCM concept, a state machine is defined, which loosely couples the two systems to each other. To have a bidirectional asynchronous course of events, two instances for the state machine exist. The events, which are supported by the automation function, and their parameters are defined within the CD; the processing of the parameter data occurs in a manner similar to PI and IRI and, thus, are not explained in more detail at this point.

The Capability Description

The Capability Description (CD) is an XML-based description [REC00], which, in a clear, standardized form contains the complete description of all data objects needed for the application of a CMU in MAS. Against this background, a data structure was defined and translated into a set of XML-Schema [REC01a, b]; hence, a CD instance is an XML file based on these schemes. Each data object contains a clear identification (<xxx.ID>) and an extensive description (<xxx.Description>) as well as several other elements, depending on the respective object. Per CMU, there exists exactly one CD that has to be built by the developer of the respective automation function. During the definition phase of the CD former works in the area "description of control components within a network" as the FDCML [ISO03] and methods for process description as the PSL [PSL03] were evaluated and considered.

The CD data structure consists of five main elements, see Figure 108.12 below, under which the respective data elements in a tree structure are positioned. <Identity> contains information for the definite identification of the respective CMU (e.g., name, version). <System Data> contains data with respect to the used technology and system topology. Further objects — which are independent from the state of the automation function — are summarized under the term <data management>. These contain information about events concerning the CMU, reports that the CMU has to deliver, and product-independent data that the CMU is able to offer. In contrast, <function support> contains information with direct relation to the automation function. Here, information that refers to tools, consumables, and the necessary supervisory control, which are required for the respective CMU's execution of its automation function, is available.

This structure is resolved in very much more detail [Spec03], but will not be further described in this context.

108.3 Benefits of the Agent-Based Architecture for Job Control in Turbulent Industrial Environments

The economic relevance and the corresponding benefits for the end user of the proposed agent-based architecture can be seen in three main fields: the improved application of industrial production systems by enhancing the system flexibility, the simplification of system design by introducing new system design strategies, and the refinement of the supply chain management by increasing system clarity and system openness.

The *enhancement of flexibility* of a plant by a PABADIS system is based on two main effects. The distribution of MES functions and the use of mobile product agents, which are correlated to the work pieces, ensure an improvement of vertical flexibility. New products can be easily integrated into the production plan. This also applies to products that were unknown at the moment of plant design. The use of a suitable plug-and-play system (which is not described in more detail in this chapter) enables a horizontal flexibility. New machines can be integrated and used in the system without any changes in the configuration

© 2005 by CRC Press LLC

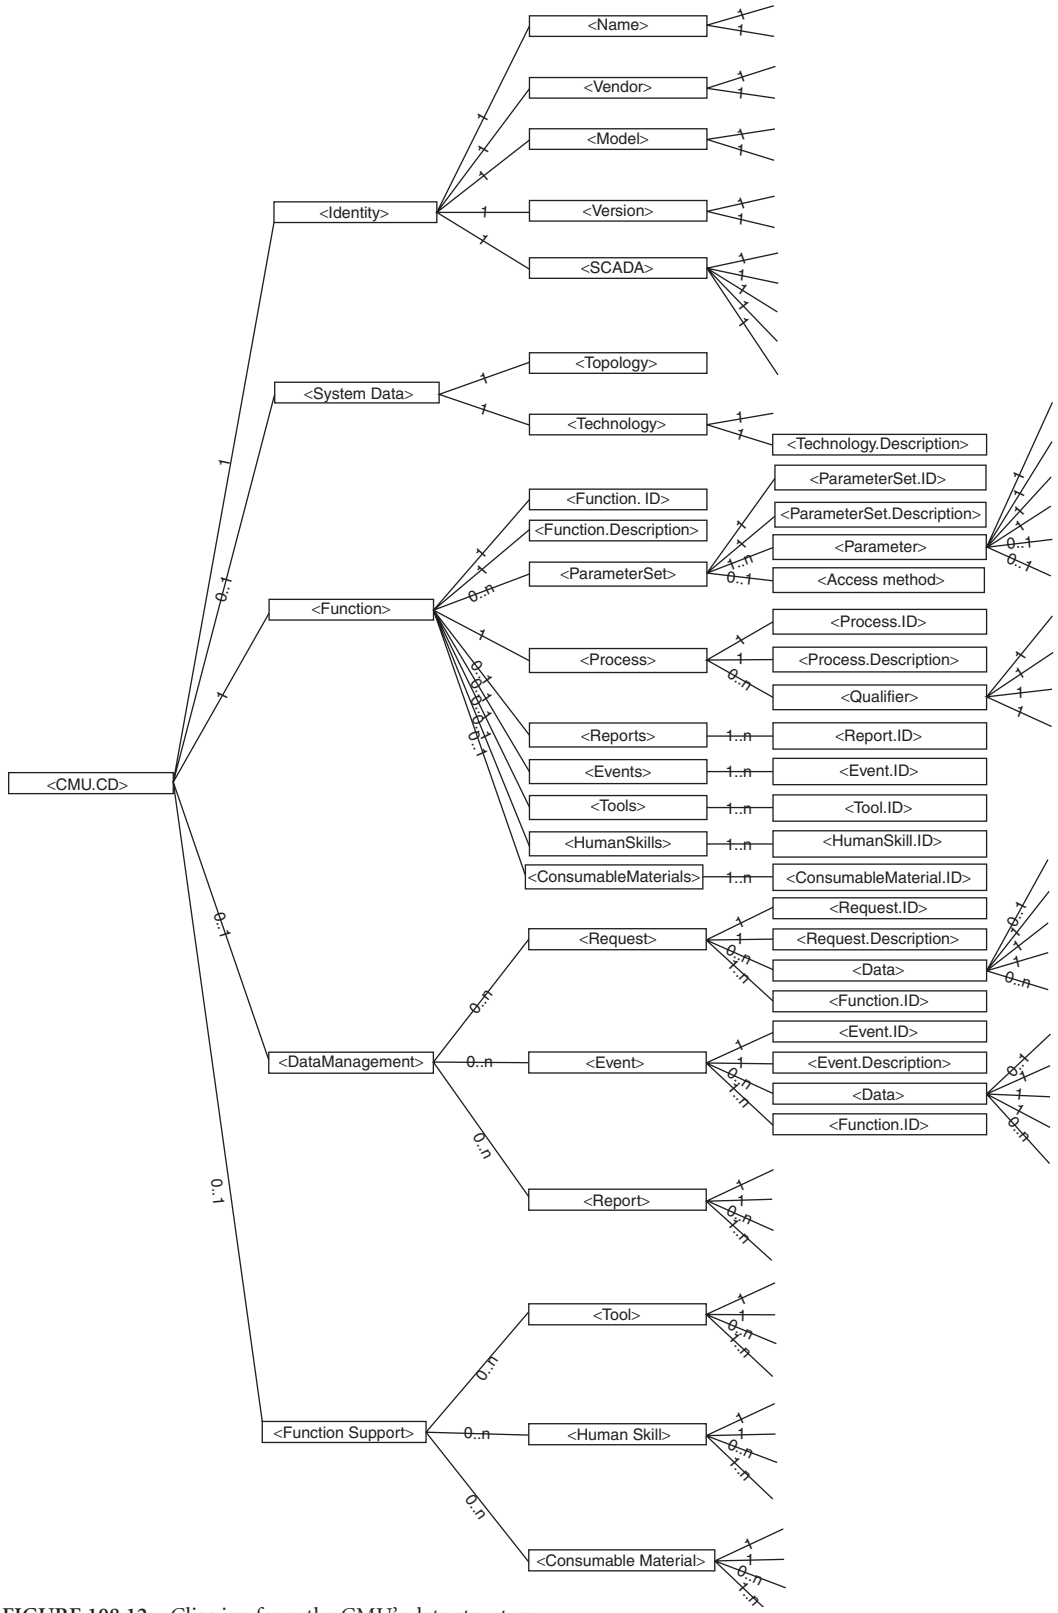

FIGURE 108.12 Clipping from the CMU's data structure.

© 2005 by CRC Press LLC

of other machines. Moreover, a system redesign is easily possible. Further horizontal flexibility arises from the use of Product Agents. These agents react spontaneously to a system change (by the introduction of new machines as well as by failure of existing machines). In both cases, a rescheduling and a new resource allocation might be initiated.

The *system design* is normally based on a system design method that uses a design specification and a design tool. The use of a PABADIS system for plant design enables the plant designer to reduce the complexity of the machine control design by reducing the control to production process control. In contrast to this, in a conventional control system communication with ERP and MES as well as logistical behavior are implemented. In a plant as described here, these functions are implemented by the pregiven and preimplemented RA of the machine containing CMU. Thereby, the reuse of software is also improved. The plug-and-play technology enables an immediate availability of the systems/ CMUs joining the CMU community. The HTTP-server of each CMU, required for the plug-and-play system, can also be used for system redesign by control program uploading or, more generally speaking, for Web Integrated Manufacturing and Web-Based Management.

The *supply chain management is improved* by the use of mobile PAs correlated to work pieces. Data mining with respect to the product-dependent data as well as the machine-dependent data becomes much more easy since direct data acquisition based on a PMA is an essential part of the described system structure. As a consequence, product tracing becomes possible. In addition, the direct relation between product data and the PA can be used for the improvement of the supply chain management. Particularly, it is conceivable to extend the system to the whole logistical supply chain: this means that the agents (PAs) may move from one company to another company of the supply chain.

Finally, it can be stated that the proposed PABADIS concept makes it possible to retrofit a conventional controlled plant, while maintaining the majority of investments already made. These investments can be saved by integrating existing ERP, SCADA, and control systems with slight changes. This prevents the PABADIS system from a main drawback in the field of practical application by enabling a soft change from centralized to decentralized plant control.

108.4 Summary and Conclusions

In this chapter, an agent-based architecture for job control in turbulent industrial environments was presented. It was shown that the presented structure could be applied to nearly all product processing systems, but it is most fitted for small and medium lot sizes and works very well even for lot size one. Correspondingly, the architecture presented is a technical solution to several of the concepts, which, under the term "Mass Customization" try to manage a synthesis of two competing management systems: mass production systems versus those that provide products and services individually. The mass customization paradigm is based on flexibility and quick responsiveness in developing, producing, marketing, and delivering products that can satisfy as wide a range of customers as possible without substantially increasing costs. [Knol01].

The practical use and, of course, the success of a new control structure within plant automation requires a strategy to integrate existing solutions. Otherwise, investments already made cannot be preserved and existing knowledge is lost. The integration of existing control structures into a system as described in this chapter depends on the level of these structures in the control pyramid shown in Figure 108.1.

The integration of existing ERP systems is uncomplicated. An ERP system is connected to the MAS via the Agency. Here, manufacturing orders and data depending on these orders as well as general plant relevant data are exchanged. To integrate an arbitrary ERP system, the interface between Agency and ERP was also designed (although not part of this chapter). This interface is based on an XML service module so that the only requirement for the ERP system is an XML interface, which may be given in advance or needs to be designed, based, for example, on SQL database queries.

At the field control level, the integration of existing solutions is assured by the use of the generic CMU interfaces (see The CMU Concept). Hence, the corresponding controls need not be changed, only adapted. The type of integration also depends on the hardware and software environment of the respective control's device.

© 2005 by CRC Press LLC

As mentioned, one main advantage of the described structure is the distribution and decentralization of MES functions with the aim to be able to concentrate more on the special requirements of the single product. Here, mobile as well as stationary agents are used to fulfill the corresponding jobs, whereas each MES functionality can be translated into corresponding agent functions. The integration of existing MES systems, which are based on a centralized system view, is thus not reasonable.

The integration of SCADA systems is possible by the introduction of a so-called SCADA-CMU. In this case, the existing systems are extended in the same way as a normal CMU, with the SCADA functions used in the sense of a service. If the SCADA functions act as a client, the SCADA system is extended by a residential PMA, acting as an interface to the agent system. Hence, any conventional SCADA system can be integrated if these extensions are suitable.

As an upshot, the authors would like to state that the technical possibility exists and the economic reason dictates the use of office information technologies also in plant environments. In conjunction with intelligent job control architectures like PABADIS, this offers chances to production science and practice, which will eventually provide the end user with the flexibility needed to compete and will finally open new markets and jobs for component suppliers and plant erectors.

109.1 Introduction

From CIM to Heter-archical Control and Production Management

New revolutionary manufacturing concepts and emerging technologies, which take advantage of the newest mechatronics, information, and communication technologies and paradigms, and address many of the fundamental problems described above, have been researched and developed since the last decade of the 20th century (see, e.g., [9, 39], and the references therein).

© 2005 by CRC Press LLC

The process of globalization has forced the development and operation of traditional manufacturing systems to evolve into inherently multidisciplinary tasks. Manufacturing paradigms, such as mass customization, instigated rapid changes in economic, technical, and organizational manufacturing environments. Considering all this, the manufacturing system of the 21st century [22] constitutes a complicated mixture of people, software systems, processes, and equipment (hardware). The management and control of such complex systems is, as a consequence, a multidisciplinary task based on knowledge of manufacturing strategies, planning, operations, and the integration of communication, information, and control functions, and this across the entire enterprise[8,27,43,45].

The Computer Integrated Manufacturing (CIM) concept has been promoted as a solution that can somehow deal with all the above-addressed challenges, for example, providing more flexibility in product spectrum and processes, improving the agility of the production system, better response, and integration of hardware and software components [1,28]. Nevertheless, this centralized and sequential manufacturing planning, scheduling, and control mechanism is increasingly being found to be insufficient in flexibility and agility when responding to changing production styles and highly dynamic variations in product requirements. Moreover, its construction always entails the risk of huge investment, long development schedules, and the generation of very rigid systems due to increased size and centralization. For this reason, before the CIM vision even made its way into practice [31], the original approach changed from a basically centralized model to a decentralized one.

One promising architecture, in this respect, is to have a conglomerate of distributed, autonomous, intelligent, fault-tolerant, reusable manufacturing units, which operate as a set of cooperating entities. Each entity is capable of dynamically interacting with the others to achieve both local and global manufacturing objectives, from the physical/machine control level on the shop floor to the higher levels of factory management systems [12,18]. Due to the tremendous amount of interaction between the different components and the variety of performed functions, the control of such manufacturing systems is currently based on a hierarchical and distributed structure, that is, heter-archical structure, as shown in Figure 109.1 [18,35].

Collaborative Factory Automation. A Result of the Integration of Emerging Technologies and Paradigms: Agent Technology, Holonic Control Systems, and Mechatronics

In the context of today's markets, many industrial companies are looking for a flexible, network-shaped, but sometimes temporally restricted, virtual cooperation of decentral and distributed production competencies. This decentralization originates within a single company (spread over several different production sites) or through the association of several different companies within a single supply chain (virtual enterprise). Collaborative automation approaches are required for such scenarios, that is, a shared but remote supervision is necessary. Autonomous automation units with local supervision functionality installed in each production site interact or cooperate, providing a global (networkwide) supervision (control, monitoring, diagnosis, HMI, maintenance).

A software agent approach seems well suited in relation to the control and supervision of each mechatronics component in an intelligent manufacturing system. Agent-based software systems are becoming a key control software technology for manufacturing control systems. A multiagent-based software platform can offer distributed intelligent control functions with communication, cooperation, and synchronization capabilities, and also provide for the behavior specifications of the mechatronics components and the production specifications to be fulfilled by the manufacturing system (see [2–7,11,15,25,26, 36]).

This trend is accompanied by the fact that modular design of machines and processes, combined with the aggressive augmentation of IT-SW technologies, has pushed automation architectures from a central concentrated system, to a Collaborative Automation, requiring new services via Ethernet TCP/IP, to synchronize distributed applications, new engineering tools, distributed web HMI, and integrate mechatronics specifications.

The answer from Schneider Electric IA to these requirements is a new industrial collaborative automation architecture. It is a global application consisting of several applications deployed as differ-

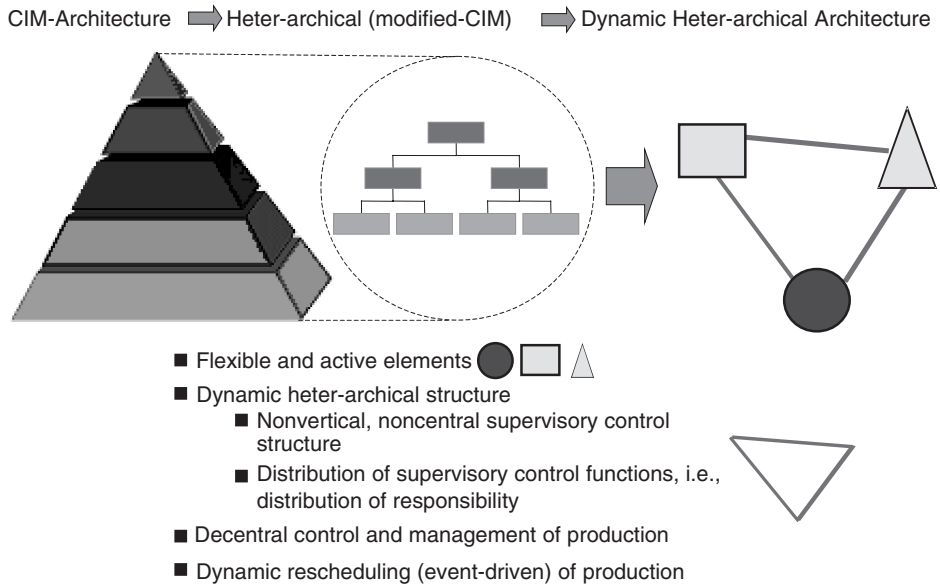

FIGURE 109.1 Heter-archical control and management of production.

ent control units. The interconnection of the control units is ensured using Modbus TCP. An Ethernet TCP/IP application layer controls messaging between devices and assures automatic data refreshing in web browsers. High-performance data sharing for PLC synchronization via Ethernet is now available thanks to Global Data services, providing for automatic and powerful multicast exchanges and improving determinism.

In this chapter, the underlying principles on which the "collaborative factory automation" concept is based (see Figure 109.2) are described. Following this description, this chapter proposes an approach that supports the design and the implementation of a collaborative control platform for industrial manufacturing automation systems based on a multiagent architecture with functions closely related to real-time "shop-floor distributed control and dynamic scheduling." The system has embedded knowledge about the layout and current behavior of mechatronics components that allows it to perform real-time decision-making processes and to run in a synchronized manner with the real production world. It is well suited to accommodating heterogeneous hardware and software components in both their manufacturing control and information systems, in integrating existing/legacy systems, and in adapting new production plans and/or schedules to changing environments (Dynamic System Reconfiguration).

109.2 From Holonic Manufacturing Systems and Agent Technology to Collaborative Factory Automation

The Technical Challenge of Holonic Manufacturing Systems and its Relation to Collaborative Automation

Approximately 35 years ago, Arthur Koestler proposed the word "Holon" [17] to describe the hybrid nature of "wholes/parts." It is an amalgamation from the Greek word "holo = whole," and the suffix "on," which suggests a particle or part, as in "electron, neutron, or proton." Hence, Holon, meaning "whole and part." Holons are self-contained wholes to their subordinated parts but are simultaneously dependent parts themselves when viewed from another angle. Transferring Koestler's model of evolution and life to the shop floor means the installation of intelligent components (hardware and software) and a lateral

© 2005 by CRC Press LLC

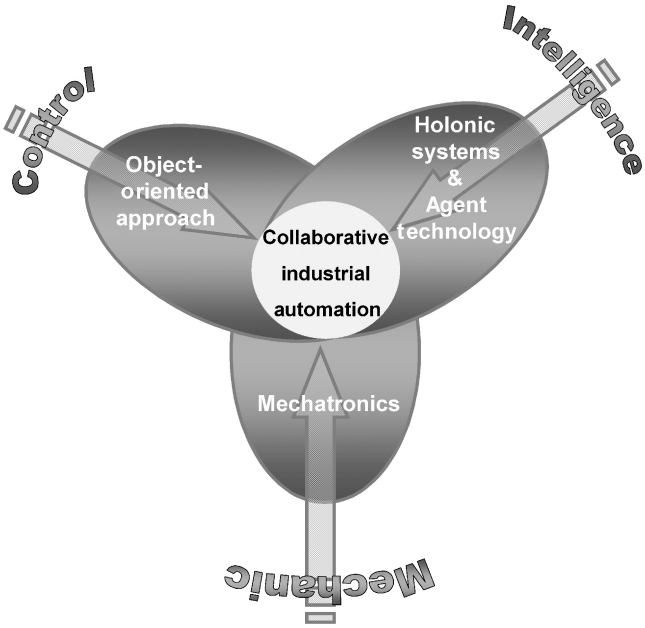

FIGURE 109.2 Collaborative industrial automation paradigm.

means of communication between the production entities and individual machines (viewed as Holons) to enable autonomous decisions to be made within a predefined decision range.

Collaborative Control Units/Holons are responsible for interfacing the system with humans, other Holons for the information system, and peripherals, such as sensors and actuators.

The system entails:

- Multiagent-based Automation Software Technology (physical agent collaborative control component).
- Real-time control functions that implement and supervise the required sequences of operations as well as detecting and diagnosing malfunctions.
- Physical interfaces between the control functions and the sensors and actuators of the physical processing equipment.

The range of applications for collaborative manufacturing automation transcends the traditional views of restricting autonomous operations to machines, manufacturing cells, or other geographically distributed units and/or humans. In fact, a Collaborative Automation Unit can be purely informational (e.g., a process plan or diagnosis module) or may consist of physical objects that are endowed with additional information processing capabilities (e.g., machines with an informational shell or intelligent wrapper), as shown in Figure 109.3.

To summarize, an Intelligent Control System, the humans, and the physical processing system can all constitute separate "Collaborative Automation Units," or be a "Collaborative Automation Unit" in itself.

Multiagent-based Automation Software Technology

The components of a system based on "collaborative principles" naturally suggests a distributed software implementation with autonomously executing cooperative entities as modules, that is, Collaborative Automation Units. Two well-known software engineering technologies are well suited to implement an abstraction of a problem [40]: Multi-Agent Systems (MAS) because of their distributed nature and Object-Oriented Software Engineering, given its recursive structure.

© 2005 by CRC Press LLC

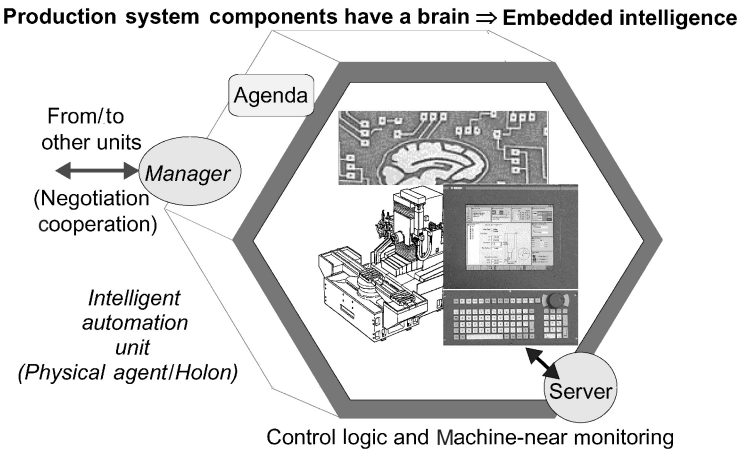

FIGURE 109.3 Collaborative Automation Unit.

The agent technology and the MAS paradigms have been considered over more than a decade as an important approach for developing and implementing the software components of intelligent manufacturing systems. Researchers and practitioners alike have been applying agent technology to manufacturing systems planning, scheduling, execution control, materials handling, and new manufacturing paradigms (see [36] and references therein).

A brief analysis of the reported results shows that the following deficiencies have not yet been solved [16]:

- An agreed definition: Agents built by different teams have different capabilities.
- Duplication of effort: There has been little or no reuse of agent architectures, designs, or components.
- An inability to satisfy industrial strength requirements: Agents must integrate with existing hardware, software, and computer infrastructure, that is, integration of legacy systems.

Agent and Collaborative Automation Units

An agent-based representation of a manufacturing system organization at the physical machine level allows for the conception of an intelligent control component being part of the physical transformation, the transportation, and the storage resources. In fact, each manufacturing resource, including work-pieces and tools, is mapped into an agent, which abstracts all those parameters of the resource needed for the control and supervision of the physical processing equipment. Moreover, the communication- and information-processing capabilities that are endowed in the agent-based control software of the manufacturing resources, transforms it into a self-reconfiguring, intelligent element, that is, a Collaborative Automation Unit. The result is a distributed intelligent control system associated with the lowest layer of a manufacturing holarchy (as depicted in Figure 109.4), with the following main functions:

- Interunit communication allowing the intelligent manufacturing resource to negotiate and coordinate the execution of manufacturing plans (sequences of manufacturing operations) and recovery from abnormal operations.
- Real-time supervisory control functions, that is, control, monitoring, as well as detection and diagnosis of malfunctions.
- Physical interfaces between the control software and the sensor/actuator interface of the physical manufacturing resources.

In the following, this multiagent-based control system is called a "Collaborative Automation System."

© 2005 by CRC Press LLC

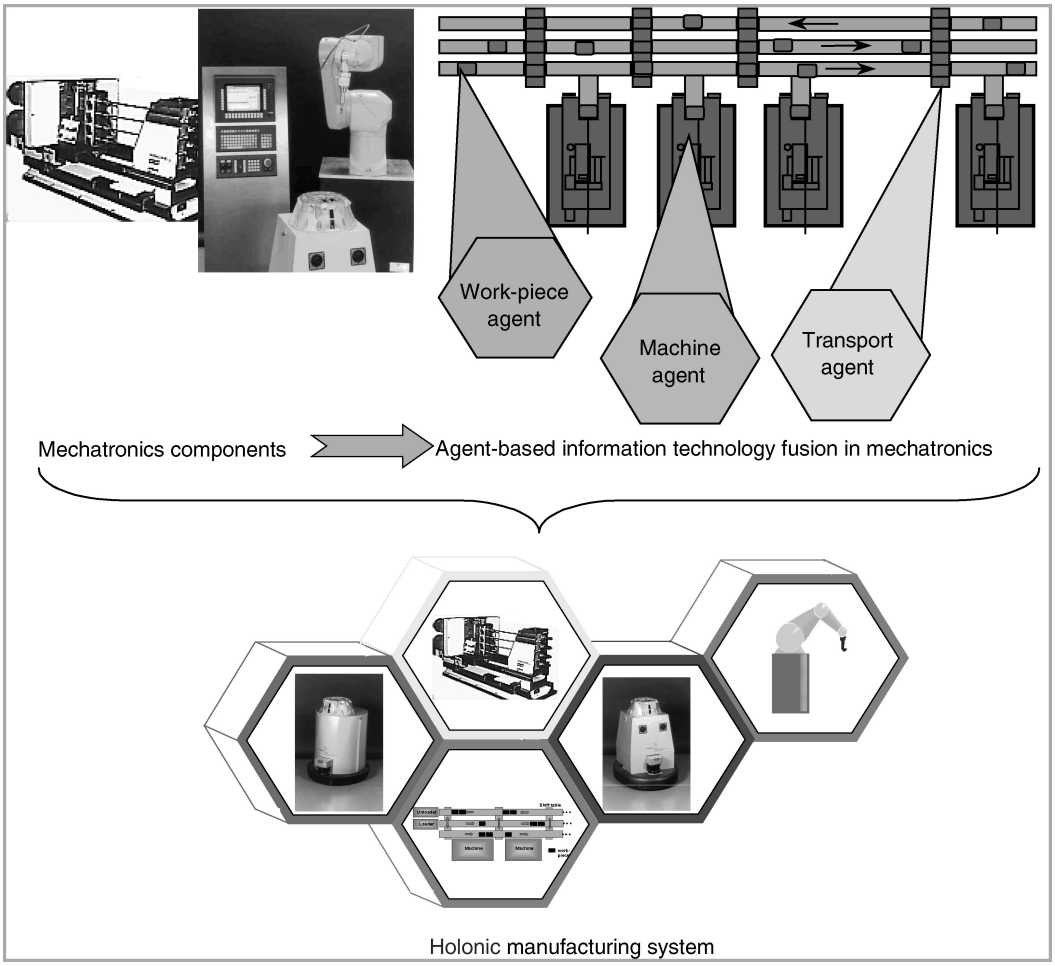

FIGURE 109.4 Principle of an agent-based Collaborative Automation System.

109.3 A Collaborative (Agent-Based) Factory Automation Platform

Motivation and General Characteristics

The application of new strategies and technologies to attain an agile production, standardized machines, flexible material flow systems, and hardware redundancy (e.g., each processing operation is provided by multiple processing units) generates a new set of problems with their corresponding requirements for the control and management of operations:

- Either all possible error cases and/or abnormal states/situations are preprogrammed or more intelligence is distributed to the hardware components.
- The basic components of the manufacturing system are composed of mechatronical components (mechanic plus electrical units), which must be treated as a unique element.
- The components become autonomous and have more "responsibility."

Taking into account the above factors, and based on our previous research results and the prototypes and agent framework specifications presented in [6,13,41], this work summarizes the main characteris-

© 2005 by CRC Press LLC

tics of the heterogeneous agent-oriented collaborative control system *FactoryBroker*™ that has been developed and implemented by Schneider Electric GmbH (Industrial Automation), in cooperation with DaimlerChrysler AG, Research and Technology, Berlin, Germany.

FactoryBroker has been developed as an automation tool to support the implementation, at industrial level, of the "Collaborative Manufacturing Automation System" paradigm. It is particularly relevant in an industrial process control system to control widely distributed, heterogeneous (i.e., different hardware manufacturers) devices in environments that are prone to disruptions [37] and where stiff real-time constraints must be met to achieve safe system operation. The system embodies the idea of the "agile manufacturing" paradigm, where "reprogrammable, reconfigurable, continuously changeable production systems, are integrated into an information intensive manufacturing system, making the lot size of an order irrelevant" [22].

Design Specifications

The "collaborative (agent-based) components" of FactoryBroker are basically formed on a functional modularization of a shop floor. It is complemented by all the essential attributes that are necessary in a holarchy: cooperation, autonomy, intelligence, and transparency.

The following two key constraints have been applied to the design of this Collaborative Control System, which reduce the problems stated above:

- The interfaces of the agents are specified in such a way that different (heterogeneous) agents may cooperate with each other. This supports the interoperability of the Collaborative Control System with other MAS-platforms.
- Agents are used to model the intelligent software part of Collaborative Automation Units, which are software and hardware entities. The scope of responsibility of the designed agents is then derived from the physical system — machines have machine agents, transport systems have transport agents, and work-pieces have work-piece agents.

This differs from functionally derived agents (e.g., prescheduling agent, evaluation agent, simulation agents, etc., as in [2]).

To reduce the effort, existing platforms were used in the design and prototype phase. However, limitations are encountered when the agents have to be embedded into PLC and CNC systems.

The key aspect for applications at the shop floor level is indeed the integration with existing machine control systems, that is, legacy systems [10,33]. As depicted in Figure 109.5, this includes embedding into conventional control equipment (e.g., Programmable Logic Controllers [PLC] and Computer Numerical Control [CNC]), the use of specific operating systems at the shop floor (e.g., Windows NT), and interfacing with established communication interfaces (e.g., DCOM, Ethernet).

Summarizing, a FactoryBroker-Agent is:

- Intelligent software, which has a defined set of goals related to production specifications:
  - to Harmonize overall transport,
  - to Reduce down-time: optimizing load of machines, and
  - to allow different types and degrees of flexibility, that is, allowing variants in work-pieces.
- Intelligent software, which extends existing platforms
  - IEC 61131 function blocks for PLCs, and
  - Windows NT.
- Intelligent software, which is acting autonomously and communicating interactively with other components, using different communication methods
  - COM/DCOM [32] and
  - TCP/IP (XWAY- Schneider Electric protocol).

Architecture and Communication Interface

The architecture of FactoryBroker provides a framework for an unambiguous specification of the structure and relationships between the functional units of the system. During the design phase, this distributed

© 2005 by CRC Press LLC

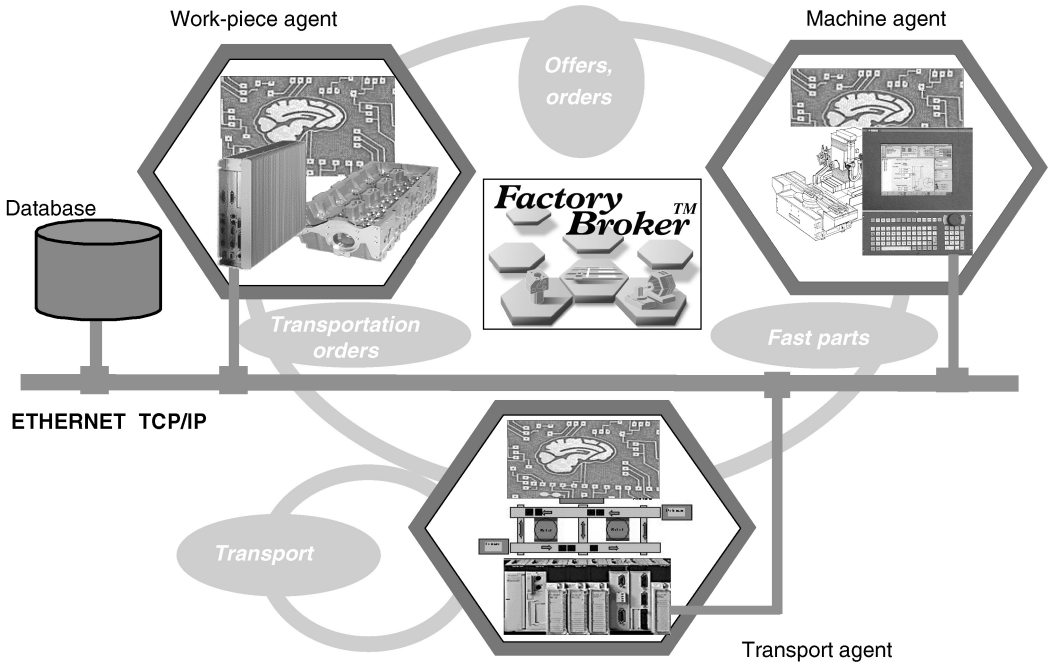

FIGURE 109.5 Collaborative Automation Architecture, FactoryBroker principle.

control system passed through several incremental steps of simplification. The starting point was a mobile agent platform based on JAVA with a simplified agent architecture, that is, the capabilities for mobile agents had been removed. Corresponding to the static arrangement of the production system, the system was redesigned with static, nonmobile agents, as shown in Figure 109.6.

The derived architecture is characterized by:

- A communication framework as a Windows NT-Service that provides standardized agent-orientated interfaces, a user-defined level of fault-detection, and no blocking mechanism of internal functions if communication fails (this was reached by specific implemented additions to Windows NT).
- Encapsulation of the agent type-specific algorithm (COM DLL).
- Definition of critical (wait for a response) and noncritical (continuing after timeout if no response is received) transactions.

The Collaborative Control System depicted in Figure 109.7 covers both conventional real-time machine control and multi-agent-based control of production. These control components are assigned to the distributed manufacturing components in a 1-to-1 relationship:

1. Each machine is controlled by a CNC and PLC, both implemented on an Industrial PC (IPC). Each CNC includes a machine agent that acts as an "Operator" of the machine.
2. Each shift table of a transport system is controlled by a PLC that includes a transport agent that is able to choose transport jobs.
3. Each work-piece is identified by a unique name in the system. A work-piece agent manages a real work-piece and is responsible for organizing all needed manufacturing tasks for the specific real component.

In the following, the different agents constituting the Collaborative Control System architecture are briefly described.

Work-piece Agent: This PC-based type of agent manages planning and processing of one or more work-pieces.

© 2005 by CRC Press LLC

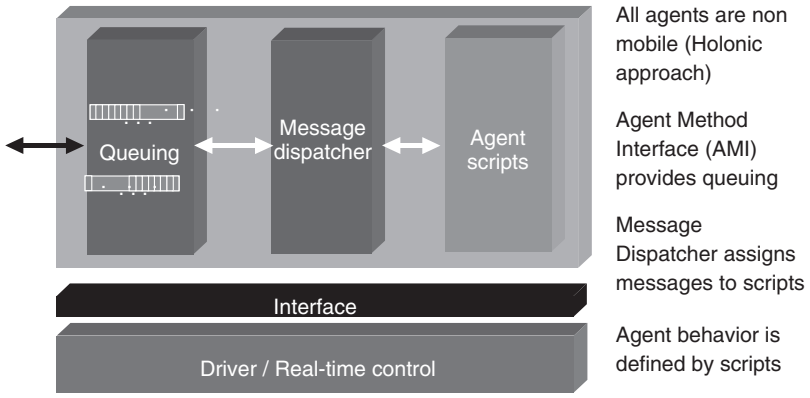

FIGURE 109.6 General architecture of a FactoryBroker agent.

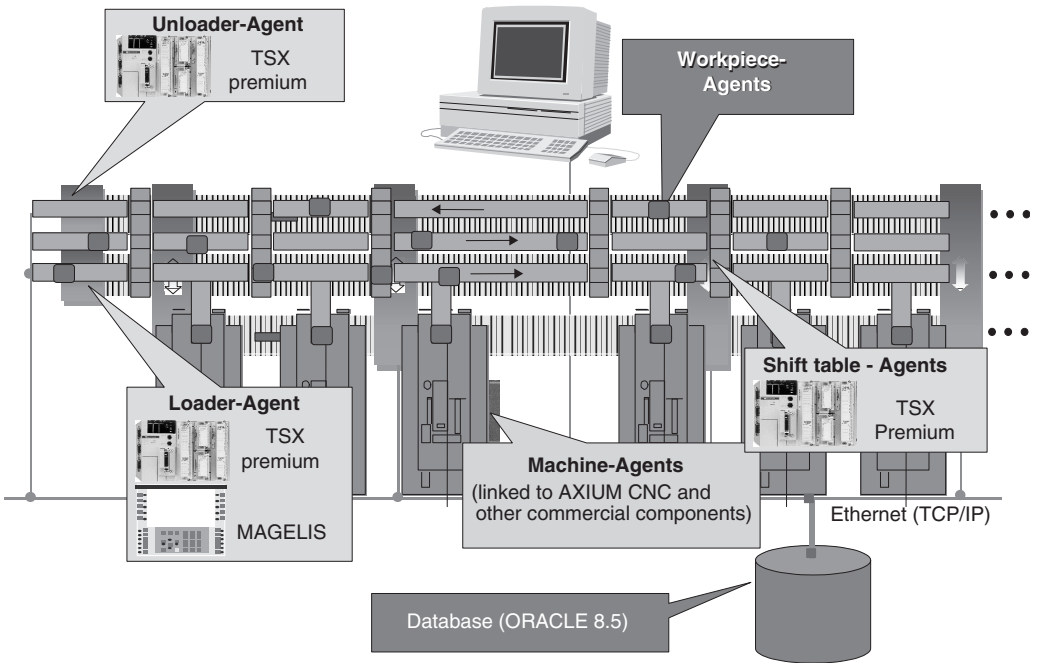

FIGURE 109.7 Architecture of the FactoryBroker Collaborative Manufacturing Control System.

In order to build a redundant system, several workpiece agents are active and share the load of the production system simultaneously. If one agent fails, other work-piece agents take over its work-pieces. At present, running interactions are switched to the new agent responsible. Work-piece agents are implemented as a Windows-NT service and act as a supervisor (identifying the workpiece, checking its required operations, looking for available machines, and initiating the transport).

Machine Agent: A machine agent not only knows the possible tools required for drilling or milling, etc. but also the state and load of its corresponding machine. It acts like a virtual operator, who would be responsible to fill the machine with workpieces and to generate job requests for the machine. Like the workpiece agent, the machine agent is implemented as a Windows-NT service, as depicted in Figure 109.8, and interconnected with the collaborative control platform using, for example, the Internet communication platform.

© 2005 by CRC Press LLC

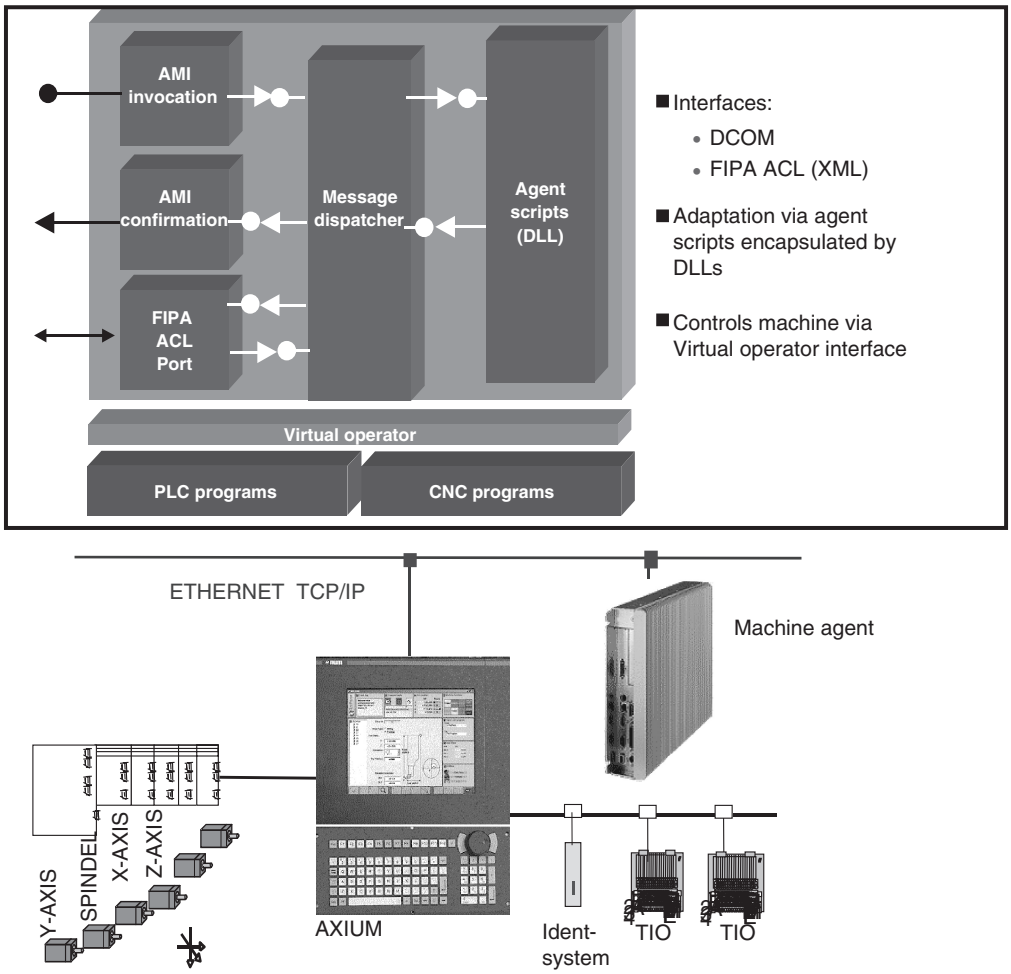

FIGURE 109.8 Structure of a FactoryBroker machine agent.

Transport Agent: There are different types of transport agents but all of them participate in cooperation control/scheduling activity. A *Loader Agent* organizes the loading of new work-pieces into the system. A *Shift Table Agent* is responsible for moving work-pieces between different conveyor belts. This second type knows the destination and decides autonomously which path must be selected to attain transportation to the target machine. Work-pieces that are finished are handled by an *Unloader Agent,* which releases these workpieces to the external environment of the production system.

Note: All types of transportation agents are parameterized corresponding to the topology and design of the flexible material flow system. All these agents are PLC-based and they are implemented as an IEC 61131 DFB inside a PLC application [14].

Communication Interface: The interface of each agent is message-orientated designed as usual. Based on the desired DCOM interface, the messages are mapped to method calls. Therefore, the *FactoryBroker* agent interface is described by the methods.

The subset of interactions were described as a set of methods offered by various Distributed Component Object Model (DCOM)-based classes, which provide a remote Agent Method Interface (AMI) for these interactions for the PC-based agents. The design of PLC-based agent function blocks has been adapted to dedicated network protocols based on TCP/IP.

© 2005 by CRC Press LLC

With respect to the limited set of interactions within the fixed arrangement of the manufacturing system and the restricted degree of freedom of its components, a modification of the behavior can be achieved using a pre-compiled and exchangeable set of script objects. The script objects run as function blocks inside a PLC application as well as Component Object Model (COM) objects inside a DCOM-based framework implemented for PC-based agents such as a work-piece agent [34].

109.4 Negotiation Mechanisms and Interactions between Production Agents for Factory Automation

Holonic Manufacturing Systems proposed that cooperation among "Holons" occurs within logical spaces called *Cooperation Domains*. Following this concept, which maps directly to the FIPA definition of *domain*s, the agents in FactoryBroker communicate and operate within cooperation domains defined by the layout and production specifications of the shopfloor components to be controlled.

An agent has to cover the behavior of the component for which it is responsible and has to interact with other agents to accomplish a specific task.

The interactions between agents within FactoryBroker can also be defined as "conversations" [19], and the overall system behavior is formalized by auction-based interactions between the different agent types [42] (see Figure 109.9).

All steps of processing the manufacturing of a work-piece can be described in a precedence graph (see Figure 109.10). In order to simplify the precedence graph (A), several manufacturing steps are summarized in a resulting manufacturing graph (C) with a partial order formed by these steps. As presented below, in the actual implementation of the system, the workpiece agent drives most of the interactions between the agents of the MAS based on the information given in this manufacturing graph.

The principles of some of the conversation specifications that have been implemented are:

- *Offering/Ordering*: Just after loading a work-piece into the system, the responsible work-piece agent determines the type of work-piece and the manufacturing process to be performed. Based on this, an offering process will be initiated. Machine agents, which are applicable for the necessary manufacturing steps, are requested to send an offer for the work-piece (see Figure 109.9).

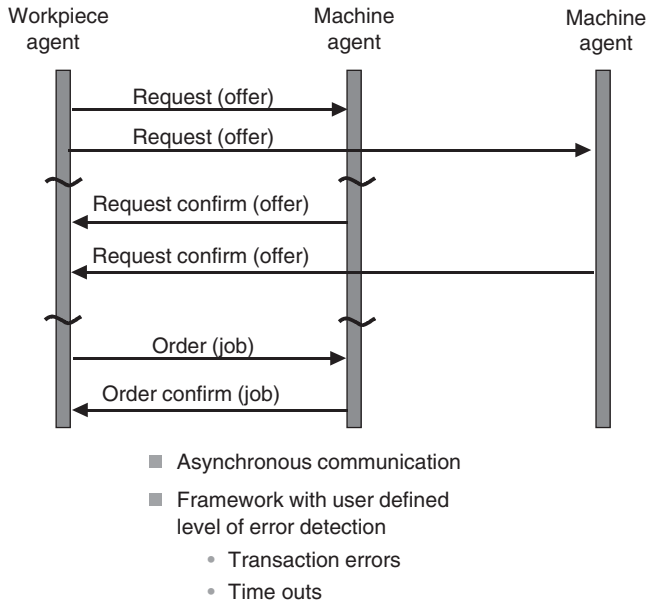

FIGURE 109.9 Interaction mechanisms between agents.

© 2005 by CRC Press LLC

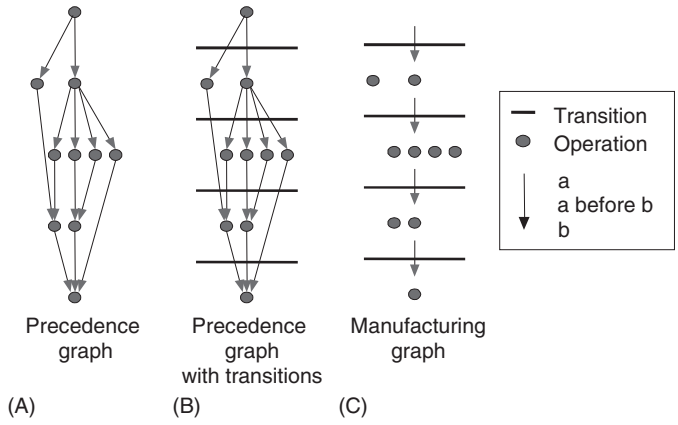

FIGURE 109.10 Manufacturing graph.

The machine agent is responsible for managing in and out buffers for work-pieces, for bidding, and also for controlling the bottleneck capacity of the system. For these purposes, a machine agent applies the algorithm reported by Bussmann and Schild in [6], which was completed with a fairness approach, counting the lifetimes of the work-pieces to be manufactured. All responses are validated and prioritized by the work-piece agent. The best offer will be selected first and the appropriate machine agent is contracted for the job, which must be confirmed. If no confirmation is received, the next offer within the remaining list of best validations is activated. In the case that no responses or confirmations are received, the whole offering process is restarted.

Note: The failure or the partial failure of a machine has an impact on the offering process. Since other machines, however, may provide the required manufacturing steps, the continuous operation of the manufacturing system is guaranteed.

- *Transportation*: In the case that a destination must be defined for a work-piece and it is successfully stated by the offering process, shift table agents are responsible for the selection of the right path within the distributed manufacturing environment. If a shift table fails, a default route is used as an alternate path (e.g., forward direction). The next shift table must redirect the work-piece if necessary. If all machines are occupied or the next destination cannot be precisely defined, the material flow system acts as a dynamic buffer for these work-pieces. In this case, the shift table agents, between the forward and the backward conveyors, rotate the work-piece, until a destination machine is available for the work-piece.
- *Processing*: Usually, a machine agent manages a work-piece as long as it is processed inside the machine. It acts as a virtual operator, which generates and starts a dedicated Numeric Control (NC) program for the manufacture of the workpiece. The progress in the manufacturing process is monitored within a database updated by the work-piece agent each time the machine agent confirms the state of the manufacturing process.

Note: The work-piece is released into the material flow system again after the machine has processed it. In the case that some steps of the manufacturing work still have to be completed, the offering process is restarted. This sequence of negotiations continues as long as necessary until the manufacturing process of the work-piece is finalized.

- *Unloading*: If all manufacturing steps are complete, the work-piece is transported by the shift table agents to the "un-loader agent," which is selected by the work-piece agent. The un-loader agent acts in a manner very similar to the machine agent, except that it does not manufacture the workpiece of course.

© 2005 by CRC Press LLC

Note: The un-loader agent releases the work-piece if, and only if, all data related to this work-piece have been archived in the database by the agent. After completing this step, the work-piece unloads the flexible production system.

109.5 Industrial Applications. Implemented Solutions

Collaborative Automation of an Industrial Production System

Applying the "hardware-in-the-loop" principle, the collaborative control platform is implemented at the industrial level and set into operation. A flexible transfer "line" situated at the DaimlerChrysler cylinder-head manufacturing department, Germany, is currently completely controlled by the developed collaborative (agent-based) controller and operates as the first commercial industrial Collaborative Manufacturing System.

Figure 109.11 shows the shop floor together with its layout. The installation consists of three conveyor belts (two in forward and one in backward motion) and machines that are connected to the material flow system by the lowest conveyor. Each machine has its own set of resources, such as buffers, tools, component trays, etc. Shift tables between the machines connect the different conveyors, providing flexible routing of pallets between the different work places, that is, machines. Each pallet is responsible for carrying a work-piece, that is, a cylinder head. All steps of processing the manufacturing of a work-piece (e.g., drilling 8 (mm)) are dedicated to its specific type (e.g., 4, 6, or 8-cylinder head) and this information is extracted from the manufacturing graph.

Results at the ShopFloor Level

The industrial Collaborative Manufacturing System is operated and fully supervised by the agent-based intelligent control system both during normal shop floor manufacturing as well as performance tests. Throughout the analysis of the architectural and behavioral specifications of the production system under real-time operating conditions, it is possible to evaluate many important "Collaborative" characteristics of the whole system, that is, production equipment with an integrated collaborative (agent-based) control system.

Evaluation of the system's flexibility: As stated earlier in this chapter, one of the main goals for implementing the multiagent-based intelligent controller was to maintain and, when possible, to extend the hardware flexibility with a high degree of control software flexibility. The machine-, routing-, material handling system-, process-, volume-, and expansion-flexibility that is offered by the mechatronics components of the shop floor (see [38]) have all been enhanced by the agent-based software components associated with each of them. Figure 109.12 shows the reaction of the manufacturing system during a working day when different types of workpieces, for example, 2, 3, 4, 5, and 6-cylinder heads are simultaneously manufactured (chaotic manufacturing paradigm).

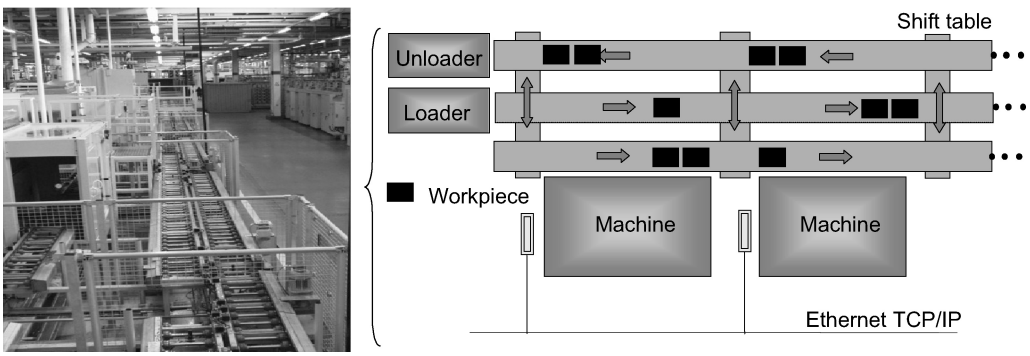

FIGURE 109.11 Industrial shopfloor installation principle.

© 2005 by CRC Press LLC

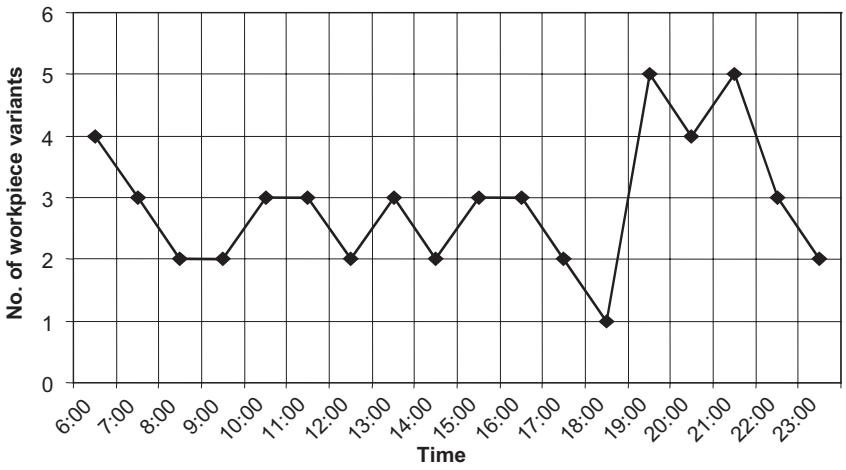

FIGURE 109.12 Flexible behavior in relation to the type of parts manufactured in the system.

Evaluation of the system's agility and reliability: The ability of the intelligent control system to adapt quickly and profitably to continuously changing and unexpected work conditions in the production environment, that is, agility, was tested with respect to the handling of subsystem failures. In particular, a redundant behavior with high system robustness was validated under different working conditions. A self-reconfiguration capability and modular expandability, both from hardware and software points of view, allow the collaborative control system to perform dynamic (re)scheduling. It focuses on the reservation and dynamic allocation of collaborative automation units to manufacturing tasks, aimed at a good overall system performance, both under normal working conditions and in reaction to unexpected situations.

As shown in Figure 109.13, the system is able to maintain its operability and consequently to offer a minimum degree of performance, even when one "collaborative unit," or more, breaks down. This behavior proves a high degree of robustness (see Figure 109.14). In the example, the "proactive" behavior of the system is described as follows: *FactoryBroker* detects an unexpected situation, that is, machine No. 2 fails (e.g., due to a broken tool) at midday. In this case, the workpiece agent, which recognizes the situation, switches its running negotiations from the machine agent of the failed machine to other machine agents (machine No. 3 and later machine No. 1). These agents will take over and share the current jobs subsequently if they can provide the correct handling and machining scope.

Evaluation of system availability: As shown in Figure 109.13, the agent-orientated manufacturing system overcomes the tested failure-situation with a high degree of system availability. The relation of the real availability to the expected availability of a system is defined here as the Availability-factor *A*.

The system attains an *A*-factor 0.89, which represents a substantial improvement in comparison to conventional transfer lines (i.e., *A*-factor 0.66) and a lower production rate remains guaranteed compared to a conventional transfer line. Indeed, both the better behavior in terms of *A*-factor and the increased availability of agent-controlled systems permit a more precise planning of the production output.

Interoperability among Agent-Based Automation Systems: An Approach on how to Implement a Holonic Intraenterprise Platform

Once production objectives, that is, work-plans, have been deployed from the Interenterprise layer to each collaborative partner, each enterprise (now considered as a "Collaborative Unit") has to organize its own resources to fulfill its commitments [40]. The practical experiences of the authors show that two production sections of a holonic enterprise, each controlled by its own MA-based control system (such as the

collaborative manufacturing cell described above, and a flexible transport system composed of AGVs (see [29] and [30])) can be seen as two collaborative sections within the intraenterprise level (see [20] and Figure 109.15).

There is a set of forces governing the collaborative work of such a constellation of production resources, which are mainly related to optimization of resources and rapid (re)configuration of schedules to accommodate new orders in a timely manner. Typical driving forces at this level are both production specifications:

- on-line ordering and negotiation,
- on-line and flexible production (re)configuration, fault-detection, and recovery,
- on-line and dynamic (re)scheduling of orders,

and from an infrastructure perspective:

- registration of agents in the system,
- resources for finding information (including other agents from the other MA-platform), and
- message routing, security management, and error handling.

All of these capabilities can only be implemented if a reliable and safe communication and the corresponding "interoperability" of both MA-platform, is guaranteed, both in their functional and technical aspects.

Integration Approach between MA-Platforms

The main functional specifications of the integration of the two implemented MA-platforms, using the Agent Communication Language (ACL) released by the Foundation for Intelligent Physical Agents (FIPA) as a communication tool [13,44], are depicted in Figure 109.15, and will be briefly summarized here.

© 2005 by CRC Press LLC

The functional communication between the MA-systems is based on the speech–act theory and the technical communication is based on a socket technology.

Each host, the work-piece agent of *FactoryBroker,* as well as the agentified mobile robot system, all implement and set up a socket-server and a socket-client. The workpiece agent receives all the messages from the robot system on its socket-server and sends all the messages to the robot system via the socket-lient. The mobile robot system performs the same function. Once established, the socket connection continues to exist until the computer is shut down or the connection is broken. (The socket communication is done using the port of a communication channel.)

Note: As shown in Figures 109.15(a)–(d), in the socket layer, each FIPA-ACL message is enhanced with a message length descriptor. To specify the communication interface, a Document Type Definition "DTD-file" is used to describe the grammar of the XML-content included in each FIPA ACL message.

109.6 Industrial Trends and Future Requirements

Many manufacturing industry sectors and particularly that of automation technology are developing roadmaps defining the future path for their particular branch. Both national and international organizations, responsible for necessary supportive R&D activities, are observing and supporting this activity. The main objective is to identify technology requirements and make the advances that will help in reducing costs, increase profitability, improve quality, shorten time-to-market, respond to regulatory standards, and to better serve their customers and other stakeholders [23,24].

While a tremendous volume of R&D resources is being expended on developing and implementing new manufacturing technologies, it is clear that:

1. There is much redundant effort being focused in a few key areas.
2. Many manufacturing infrastructure issues that affect the entire industry are receiving insufficient attention.
3. Huge investments in proprietary solutions are either not delivering the promised solutions or are being rendered obsolete by new technologies or by unpredicted changes in the business environment [23].

Taking into account these conclusions and the experience of the authors of this report (see [35]), this section can be summarized as below:

1. There is a set of major challenges for future intelligent automation systems.
2. A set of Key Enabling Technologies (KETs) have to be developed, optimized, and/or adapted to meet these challenges.
3. A set of Technology Research Initiatives (TRIs) is needed to support the development of the KETs.
4. Develop a set of Technology Standardization Initiatives (TSIs) associated with the KETs.

Challenges

Today's manufacturing automation technology requires a growing number of functions, increased flexibility, agility, reliability, and a life-cycle approach encompassing the adaptability to changing operations and conditions in the manufacturing environment. The reason for this development is the varying nature and growing number of industrial processes having, among other things, the following main characteristics:

1. Concurrency in all operations.
2. Rapid reconfiguration of structure in response to changing needs and opportunities, that is, customized functionality.
3. Instantaneous transformation of the information gathered from a vast array of sources into useful knowledge for effective decision making.

© 2005 by CRC Press LLC

4. Integration of human and technical resources to enhance workforce performance and satisfaction (understanding the effects of the agent-based technology on the intelligent manufacturing workforces, working environment, and the surrounding community).

KETs

Automation industry is responding to these challenges with the development of intelligent automation systems, that is, systems with embedded intelligent functions. A new generation of agent-based intelligent automation systems based on multifunctional hardware-platforms for the flexible integration of hardware and software functionality (Collaborative Automation Units) is required. The main characteristic of this kind of system is that it must be focused on the system behavior instead of on the process itself, as in conventional automation technology.

Of course, such intelligent automation systems have not only embedded agent-based technology as one of the main KETs but also other principal information and communication technologies that cover a broad spectrum, such as:

- Web-based Automation.
- Security technologies (secure remote access, peer-to-peer).
- HMI paradigms, Virtual Manufacturing, Transparent/Digital Factory.
- Pervasive Automation.

TRIs

The development of the KETs addressed above is only possible if research effort is put into practice in the areas listed below. This is only possible when a close relation of collaborative R&D, supporting the critical requirements of the automation industry, and research resources is reached.

1. Validation of large, distributed control systems (hundreds of intelligent nodes):
   (a) Self-validation in Collaborative Automation Systems
   (b) Automatic Testing Approaches
2. Distributed planning, dynamic rescheduling, and intelligent supervision:
   (a) Planning and rescheduling capabilities included in an automation island
   (b) Monitoring, Diagnosis, Recovery [decision-making processes]
   (c) Remote monitoring, diagnosis, and maintenance
3. Interoperability between Local Control, Coordination Control Level, and Intraenterprise Level
   (a) Functional, Logic, and Physical System Architecture; Agent-based MES systems
4. Automation Design Environment
   (a) Support the optimization of costs during the life cycle of Automation Solutions
   (b) Integration of Discrete-Event Control Simulation with Process- and Component-Simulation.

TSIs

Proposed improvements in standardization should take into account the new possibilities offered by the KETs above. Standards in intelligent manufacturing automation should consider the functional integration on multipurpose platforms. The seamless exchange and the integration of functions across products require a new type of standard that manages the interchange of information within a configurable network of functions. There is an obvious requirement for a new standardization, supporting the global exchange of automation software functions and the reusability of functional automation software on a variety of platforms [21]. Taking into account these concepts and the new Information–Communication Technologies (ICT), it is obvious that new concepts, such as hardware-independent intracontrol communication, are required.

Finally, it is important to remember that any standardization initiatives should involve the different key players, in particular the equipment vendors, in order to obtain global support and a critical authority for the resulting standardization activities [24].

© 2005 by CRC Press LLC

From the point of view of the authors, intelligent automation and, in particular, agent-based automation systems, should be closely related to any process standardization (plant modularity/flexibility).

We strongly suggest the following areas as candidates for standardization and TSI:

1. Intelligent devices on Ethernet/web (Transparent Ready™):
   (a) Hard real time on Ethernet for automation at the factory floor
   (b) Web pages for intelligent devices (IAONA, IDA)
   (c) Device description for intelligent nodes
2. Agent interfaces, communication, and architectures:
   (a) Foundation for Intelligent Physical Agents (FIPA), including
   (b) Product Design and Manufacturing Group (PDM-WG)
3. Control languages and system models:
   (a) Functional description: flow chart, state graph languages
   (b) Object description: object-oriented frameworks and libraries for application objects+views
   (c) Model description: IEC 61499 (Function Blocks)
4. Enterprise-Control System Integration:
   (a) ISO/IEC 62264-1.

109.7 Conclusions

This chapter briefly summarizes our latest results concerning the industrial application of the emerging "collaborative (agent-based) factory automation technology."

This report indicates that multiagent-technology is an appropriate aid in making the application/implementation of the collaborative manufacturing automation paradigm a reality. Further to discussing the fundamentals of the Multiagent-based "Collaborative" manufacturing control technology, this chapter presents the main specifications of a new collaborative automation and control platform for industrial intelligent manufacturing systems. The developed and implemented collaborative factory automation system, (FactoryBroker), merges the latest research results obtained in the field of Holonic Manufacturing Systems with the latest developments offered by the MAS technology. Besides discussing the suitability of the system for making the intelligent manufacturing system paradigm a reality, this chapter emphasizes the compatibility of the solution with currently implemented industrial production systems. Moreover, this paper presents the results of an application and integration of the mechatronics levels of a collaborative manufacturing automation system at shop floor level with the upper management- and control-layer of an intraenterprise architecture.

As a result of different industrial automation roadmaps, and taking into consideration the experience reported by the authors and other producers of automation systems, a set of challenges and resolutions for future intelligent automation systems is presented. Since these challenges can only be met if KETs are developed, optimized, and/or adapted, some of these KETs are identified and discussed and lead to a summarized set of TRIs that are required to support the development of the addressed KETs.

Finally, a group of TSIs associated with the KETs is proposed, which complete, from the point of view of the authors, *a set of future requirements* on the main subject of this report, that is, Collaborative Factory Automation.

Note: The results presented in this chapter are a summary of our latest reports that can be found in the proceedings of the IECON'01, ETFA'01, ITM'01, IECON'02, and in the IEEE Transaction on Industrial Electronics.

Smart Power Systems Rely on Standards for Information Models and Messaging — IEC 61850

110.1 Introduction
110.2 Primary Application of the Standard IEC 61850
110.3 Information Models
110.4 Information Exchange Models
110.5 IEC 61400-25 communication for wind power plants
110.6 Implementation
110.7 Reusability and device modeling
110.8 Resume

Karlheinz Schwarz
Schwarz Consulting Company (SCC)

110.1 Introduction

Automation and information systems in power systems are widely used. Usually, they are based on an immense number of proprietary specifications or (*de facto*) standards. To reduce this variety and to meet future requirements, the standard IEC 61850 (Communication networks and systems in substations) has been developed by users, vendors, and system integrators.

It is not sufficient to develop systems that only produce, transmit, or distribute power. Fully automated — remotely supervised — systems that require little or no human intervention seem to be ideal. Technologies bundled into the power system, therefore, have to include protection and control equipment, as well as interfaces to supervisory control and data acquisition (SCADA) of control centers. Additional applications that are necessary may include: metering, fault diagnosis, automated dispatch and control, data retrieval, asset management, as well as condition monitoring and diagnosis.

Globally, utility deregulation is expanding and requiring demands to integrate, consolidate, and disseminate real-time information quickly and accurately within all kinds of utility systems — from power plants to customer interfaces. Utilities and vendors spend an everincreasing amount for real-time information exchange; expenses for data integration and maintenance are exploding.

© 2005 by CRC Press LLC

Vendors of power systems have — because of the fast-growing market and market deregulation — very limited resources to implement and apply hundreds of proprietary communication and information systems.

The standard IEC 61850 provides the basis for many application domains. One of the biggest success stories in power systems is the deployment of wind power — now the world's fastest-growing energy source. Utilities and operators of wind turbines are struggling with the fast growing diversity of communication systems for wind turbines. Utilities have initiated the standardization of a communication system in 2001: IEC 61400-25 (Communications for monitoring and control of wind power plants). IEC 61400-25 is based on IEC 61850.

Experts of further application domains like hydro power or distributed energy resources (DER) are specifying information and communication systems based on IEC 61850.

The standards chosen in IEC 61850, for example, Ethernet, TCP/IP, MMS (ISO 9506), and XML make use of advanced IT solutions, the reduced bandwidth costs, and increased processor capabilities in the end devices. IEC 61850 focuses on process data and meta-data. More than 3000 standardized objects with concrete names and type information have been defined. The standard overcomes the huge point lists to be created for each installation in case traditional communication systems are applied.

These definitions can be (re)used by applications for on-line verification of the integration and configuration of databases throughout the utility. The self-description of the device's database significantly reduces the cost of data engineering, management, commissioning, operation, monitoring, diagnostics, and maintenance. It reduces system down times due to configuration errors. An example of an analog measurement data is the value "magnitude." Meta-data are, for example, "SI unit," "offset," "scale," "dead band for reporting," and "description."

The objective of IEC 61850 is to provide for seamless information integration across the utility enterprise using off-the-shelf products implementing these international standards.

The Standard IEC 61850 is developed in international cooperation with broad vendor and utility participation. The primary target is the electrical substation automation (switchyards and transformers in the medium- and high-voltage transport and distribution). Most major utilities (e.g., AEP, EdF, E.ON, ENEL, RWE, etc.) and system suppliers (ABB, Alstom, General Electric, SAT, Siemens, etc.) have contributed to the development of the standard.

110.2 Primary Application of the Standard IEC 61850

Figure 110.1 shows an example of a typical hierarchical automation system (substation). At process level, there are the process interfaces hard-wired in the past and serially linked by the process bus in the future. The protection and control devices are connected by the interbay/station bus. At the station level, there is very often a station computer with human–machine interface (HMI) and a gateway to the control center at the higher network level. The focus of IEC 61850 is the support of substation automation functions by the communication of (numbers in brackets refer to the figure):

- sampled value exchange for current and voltage sensors (1),
- fast exchange of I/O data for protection and control (2),
- control and trip signals (3),
- engineering and configuration (4),
- monitoring and supervision (5),
- control-center communication (6),
- time-synchronization, etc.

The standard IEC 61850 is a multipart standard with 14 parts as depicted in Table 110.1.

The information exchange mechanisms access well-defined information models. These information models and the modeling methods are crucial for IEC 61850. The IEC 61850 uses the approach of modeling the common information found in real devices as shown in Figure 110.2. All common information made available to be exchanged with other devices is defined. The standard applies an advanced name space concept. The name space allows to define private extensions for information that is required by an application but not yet standardized.

Part 7-4	Basic communication structure for substation and feeder equipment — Compatible logical node classes and data classes
Specific mappings to existing protocols	
Part 8-1	Specific communication service mapping (SCSM) — Mappings to MMS (ISO/IEC 9506-1 and ISO/IEC 9506-2) and to ISO/IEC 8802-3
Part 9-1	Specific communication service mapping (SCSM) — Sampled values over serial unidirectional multidrop point to point link
Part 9-2	Specific communication service mapping (SCSM) — Sampled values over ISO/IEC 8802-3
Testing	
Part 10	Conformance testing

IEC 61850 defines the information and information exchange independent of a concrete implementation (i.e., it uses abstract models). The standard also uses the concept of virtualization. Virtualization provides a view of those aspects of a real device that are of interest for the information exchange with other devices. Only those details that are required to provide interoperability of devices are defined in IEC 61850.

© 2005 by CRC Press LLC

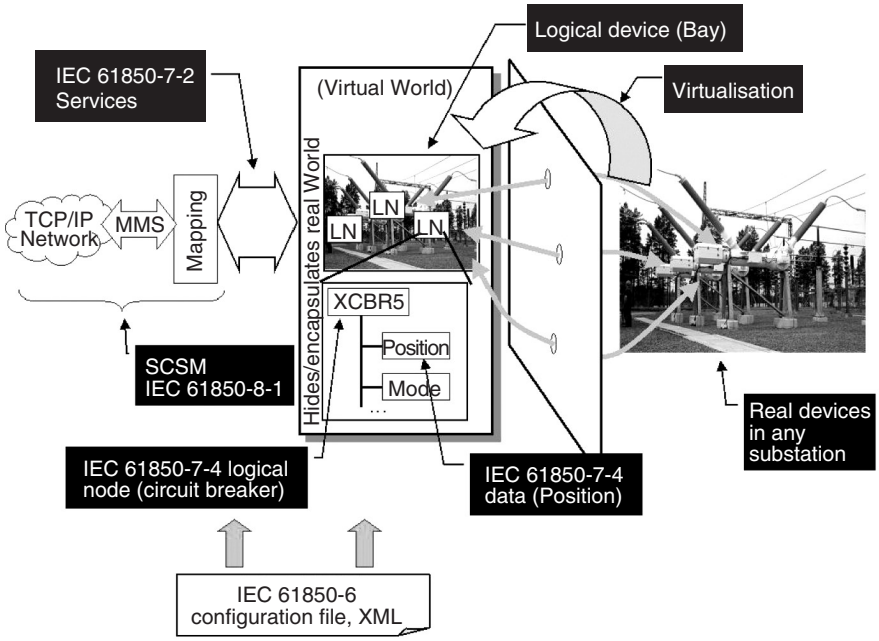

FIGURE 110.2 Conceptual modeling approach.

The approach of the standard is to decompose the application functions into the smallest entities, which are used to exchange information. The granularity is given by a reasonable distributed allocation of these entities to dedicated devices. These entities are called logical nodes (e.g., a virtual representation of a circuit breaker class, with the standardized class name XCBR). Several logical nodes build a logical device (e.g., a representation of a Bay unit). A logical device is always implemented in one Intelligent Electronic Device (IED).

Real devices on the right-hand side of Figure 110.2 are modeled as a virtual model in the middle of the figure. The logical nodes defined in the logical device (e.g., bay) correspond to well-known functions in the real devices. In this example, the logical node XCBR5 represents a specific circuit breaker of the bay to the right.

Based on their functionality, a logical node contains a list of data (e.g., position) with dedicated data attributes. The data have a structure and a well-defined semantic (meaning in the context of substation automation systems). The semantic is partly very common (status or measurement). Other information is substation-specific (directional mode information of a distance protection function). The information represented by the data and their attributes are accessed by various services. The services are implemented by specific and concrete communication means (e.g., using MMS, TCP/IP, and Ethernet among others). The logical nodes and the data contained in the logical nodes are crucial for the description and information exchange of substation automation systems to reach interoperability.

The logical devices, the logical nodes, and the data they contain need to be configured. The main reason for the configuration is to select the appropriate logical nodes and data from the standard and to assign the instance-specific values, for example, concrete references between instances of the logical nodes (their data) and the exchange mechanisms, and initial values for process data.

The four main building blocks (see Figure 110.3) are

Substation automation system information models

IEC 61850-7-4 defines *substation-specific* information models for substation automation functions (e.g., breaker with the status of a breaker position, settings for a protection function, etc.) — *what* is modeled and could be accessed for information exchange. Includes an electronic data sheet embedded in the IED for self-identification and self-description.

© 2005 by CRC Press LLC

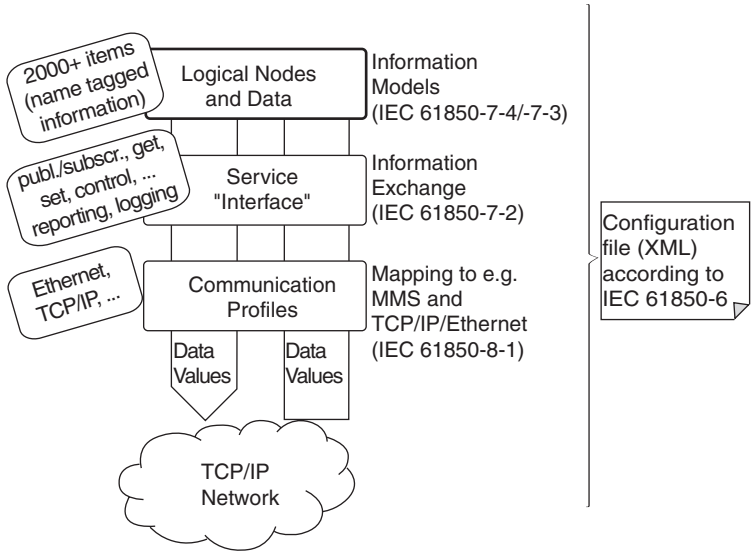

FIGURE 110.3 Levels of the IEC 61850 model.

IEC 61850-7-3 defines a list of *commonly used* information templates (e.g., double-point control, three-phase measurand value, etc.) — *what* is the common basic information.

Information exchange methods

IEC 61850-7-2 provides the services to exchange information for the different kinds of functions (e.g., control, report, log, get and set, etc.) — *how* to exchange information. The information to be accessed also comprises the IED's self-identification and self-description.

Mapping to concrete communication protocols

IEC 61850-8-1 defines the concrete means to communicate the information between IEDs (e.g., the application layer, the encoding, etc.) — *how* to serialize the information in corresponding messages.

Configuration of a substation IED (SCL — substation configuration language)

IEC 61850-6 offers the formal configuration description of a substation IED including the description of the relations with other IEDs and with the power process (single line diagram) — *how* to describe the configuration. This off-line data sheet completely describes the IED. The SCL file (XML document) eliminates the need to manually input this data when configuring an IED. This not only reduces system configuration time but also increases the general integrity and reliability of systems by reducing human error.

These four building blocks are independent of each other to a high degree. The information models can easily be extended by definition of new logical nodes and new data according to specific and flexible rules — as required by another application domains (e.g., wind power plants; see below). In the same way, communication stacks may be exchanged following the state of the art in communication technology.

The information is separated from the presentation and from the information exchange services. The information exchange services are separated from the concrete communication profiles.

110.3 Information Models

Some 100 logical nodes covering the most common applications of substation and feeder equipment are defined. The applications are:

- System information
- Protection functions
- Protection-related functions

© 2005 by CRC Press LLC

- Supervisory control
- Generic references
- Interfacing and archiving
- Automatic control
- Metering and measurement
- Sensors and monitoring
- Switchgear
- Instrument transformer
- Power transformer
- Further power system equipment.

Most logical nodes provide information that can be categorized as depicted in Figure 110.4. The semantic of a logical node is represented by data and data attributes. Logical nodes may provide a few or up to 30 data. Data may contain a few or even more than 20 data attributes. Logical nodes may contain more than 100 individual information (points) organized in a hierarchical structure.

The mean number of specific data provided by logical nodes defined in IEC 61850-7-4 is approximately 20. Each of the data (e.g., position of a circuit breaker) comprises several details (the data attributes). The position (named "Pos") of a circuit breaker is defined in the logical node "XCBR" (see Figure 110.5). The position is defined as data.

The position "Pos" is more than just a simple "point" in the sense of traditional RTU protocols. It is made up of several data attributes. The data attributes are categorized as follows:

- control (status, measured/metered values, or settings),
- substitution, and
- configuration, description, and extension.

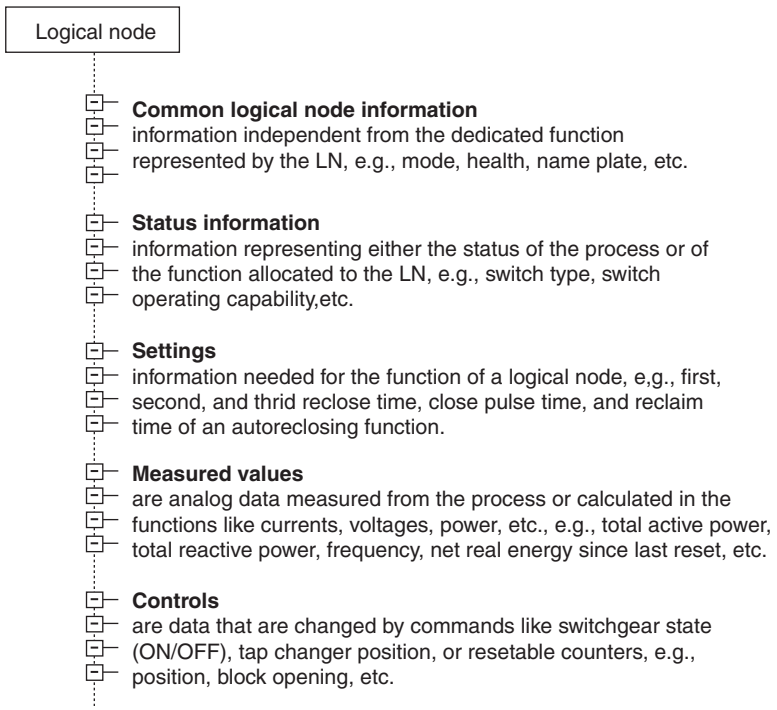

FIGURE 110.4 Logical node information categories.

© 2005 by CRC Press LLC

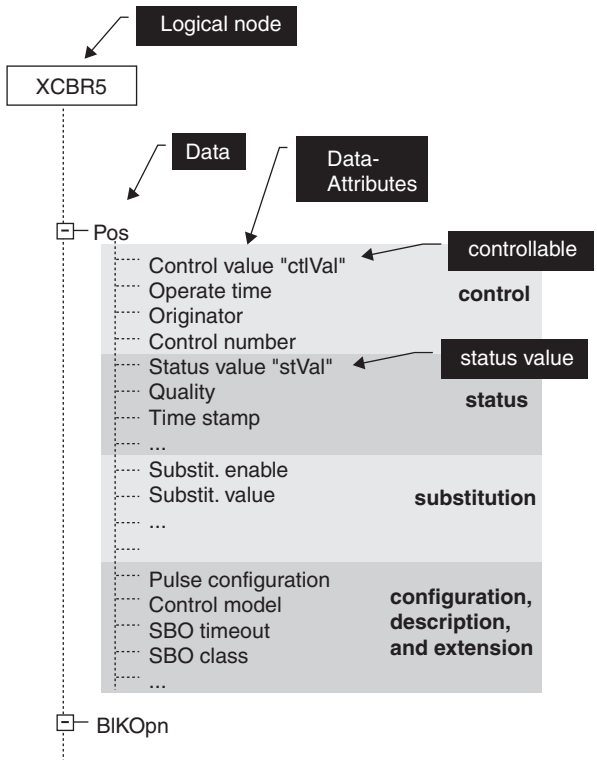

FIGURE 110.5 Position information depicted as a tree (conceptual).

The data example "Pos" has approximately 20 data attributes. The data attribute "Pos.ctlVal" represents the controllable information (can be set to ON or OFF). The data attribute "Pos.stVal" represents the position of the real breaker (could be in intermediate-state, off, on, or bad-state).

The position also has information about when to process the control command (Operate time), the originator that issued the command, and the control number (given by the originator in the request). The quality and time stamp information indicates the current validity of the status value and the time of the last change of the status value.

The current values for "stVal," "q" (quality), and "t" (time stamp) can be read, reported, or logged in a buffer of the IED.

The values for "stVal" and "q" can be remotely substituted. The substituted values take effect immediately after enabling substitution.

Common data classes (templates) are used to define data attributes of data. The crucial common data classes defined in IEC 61850-7-3 are:

Common data classes for status information

- Single point status (SPS)
- Double point status (DPS)
- Integer status (INS)
- Binary counter reading (BCR)

Common data classes for measurand information

- Measured value (MV)
- Complex measured value (CMV)
- Sampled value (SAV)
- Phase to ground-related measured values of a three-phase system (WYE)

© 2005 by CRC Press LLC

- Phase to phase-related measured values of a three-phase system (DEL)
- Harmonic Value (HMV)
- Harmonic value for WYE (HWYE)
- Harmonic value for DEL (HDEL)

Common data classes for controllable status information

- Controllable single point (SPC)
- Controllable double point (DPC)
- Controllable integer status (INC)
- Binary-controlled step position information (BSC)
- Integer-controlled step position information (ISC)

Common data classes for description information

- Device name plate (DPL)
- Logical node name plate (LPL)

The minimum subsets of data attributes of the common data class MV are:

mag: Deadbanded value. Value based on a deadband calculation. The value of mag is updated when the value has changed according to the configuration parameter db (deadband — on-line changeable).

q: Quality of the attribute(s) representing the value of the data.

t: Timestamp of the last change in one of the attribute(s) representing the value of the data or in the q attribute.

These three data attributes can be used for immediate reading, reporting, or logging. Almost all RTU protocols like IEC 60870-5 or DNP3 communicate these three data attributes. The complete set of data attributes of the common data class MV is listed in Table 110.2.

Changes in the data attributes "mag," "range," or "q" can be used to issue a spontaneous report to registered clients indicating the change. Or the change event can be used to log the change in a log of the IED.

The logical nodes, data, and data attributes are defined mainly to specify the information required to perform an application, and for the exchange of information between IEDs. The information exchange is defined by means of services.

TABLE 110.2 Common Data Class MV

Attribute Category	Data Attribute	Explanation
Measured attributes	instMag	Instantaneous value
	mag	Deadbanded value (according to db in per cent)
	range	Normal|high|low|high-high|low-low|...
	q	Quality information
	t	Timestamp
Substitution	subEna	Enable the subMag instead of the process value
	subMag	Value to be used for mag
	subQ	Value to be used for q
	subID	Substitution ID — who substituted the value?
Configuration, description and extension	units	Engineering units (SI units)
	db	Deadband value (in per cent)
	zeroDb	mag is Zero as long as value is less than zeroDb
	sVC	Scale and offset for INTEGER representation of mag
	rangeC	Values for hhLim, hLim, lLim, llLim, min, max
	smpRate	Sampling rate used to determine the analogue value
	d	Textual description
	dU	Textual description (based on UNICODE)
	cdcNs	Common data class name space
	cdcName	Common data class name
	dataNs	Data name space

110.4 Information Exchange Models

An excerpt of the information exchange services is displayed in Figure 110.6. The circles with the numbers refer to the bulleted list below.

The operate service manipulates the control-specific data attributes of a circuit breaker position (open or close the breaker). The report services spontaneously inform another device that the position of the circuit breaker has been changed. The substitute service forces a specific data attribute to be set to a value independent of the process.

The categories of services (defined in IEC 61850-7-2) are as follows:

- control devices (operate service or by multicast trip signals) (1),
- fast and reliable peer-to-peer exchange of status information (tripping or blocking of functions or devices) (2),
- reporting of any set of data (data attributes), SoE — cyclic and event triggered (3),
- logging and retrieving of any set of data (data attributes) — cyclic and event triggered (4),
- substitution (5),
- handling and setting of parameter setting groups,
- transmission of sampled values from sensors,
- time synchronization,
- file transfer,
- on-line configuration (6), and
- retrieving the self-description of a device (7).

The information exchange models are as listed in Table 110.3.

The information exchange supports various methods to access process data (see Table 110.4).

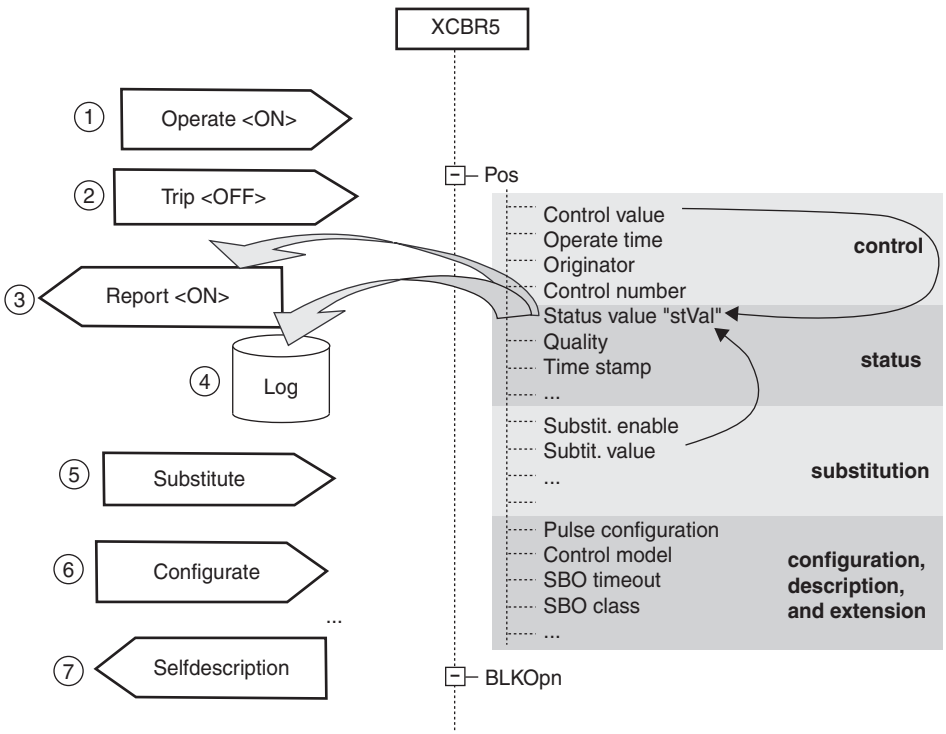

FIGURE 110.6 Service excerpt.

© 2005 by CRC Press LLC

TABLE 110.3 Information Exchange Models

Information Exchange Model	Description	Services
Server	Represents the external visible behaviour of a device. All other ACSI models are part of the server.	ServerDirectory
Application association	Provision of how two or more devices can be connected. Provides different views to a device: restricted access to the server's information and functions.	Associate Abort Release
Logical device	Represents a group of functions; each function is defined as a logical node.	LogicalDeviceDirectory GetAllDataValues
Logical node	Represents a specific function of the substation system, for example, overvoltage protection.	LogicalNodeDirectory
Data	Provides a means to specify typed information, for example, position of a switch with quality information, and timestamp.	GetDataValues SetDataValues GetDataDefinition GetDataDirectory
Data set	Allow to group various data together.	GetDataSetValue SetDataSetValue CreateDataSet DeleteDataSet GetDataSetDirectory
Substitution	The client can request the server to replace a process value by a value set by the client, for example, in the case of an invalid measurement value.	SetDataValues
Setting group control	Defines how to switch from one set of setting values to another one and how to edit setting groups.	SelectActiveSG SelectEditSG SetSGValues ConfirmEditSGValues GetSGValues GetSGCBValues
Reporting and logging `	Describes the conditions for generating reports and logs based on parameters set by the client. Reports may be triggered by changes of process data values (e.g., state change or deadband) or by quality changes. Logs can be queried for later retrieval. Reports may be sent immediately or deferred (buffered). Reports provide change-of-state and sequence-of-events information exchange.	*Buffered RCB* Report GetBRCBValues SetBRCBValues *Unbuffered RCB*: Report GetURCBValues SetURCBValues *Log CB* GetLCBValues SetLCBValues *Log* QueryLogByTime QueryLogAfter GetLogStatusValues
Generic substation events (GSE)	Provides fast and reliable system-wide distribution of data; peer-to-peer exchange of IED binary status information. GOOSE means Generic Object Oriented Substation Event and supports the exchange of a wide range of possible common data organised by a DATA-SET GSSE means Generic Substation State Event and provides the capability to convey state change information (bit pairs).	*GOOSE CB* SendGOOSEMessage GetGoReference GetGOOSEElementNumber GetGoCBValues SetGoCBValues *GSSE CB* SendGSSEMessage GetGsReference GetGSSEElementNumber

© 2005 by CRC Press LLC

TABLE 110.3 (*Continued*)

Information Exchange Model	Description	Services
		GetGsCBValues SetGsCBValues
Transmission of sampled values	Fast and cyclic transfer of samples, for example, of instrument transformers.	*Multicast SVC* SendMSVMessage GetMSVCBValues SetMSVCBValues *Unicast SVC* SendUSVMessage GetUSVCBValues SetUSVCBValues
Control	Describes the services to control, for example, devices or parameter setting groups.	Select SelectWithValue Cancel Operate CommandTermination TimeActivatedOperate
Time and time synchronization	Provides the time base for the device and system.	Services in SCSM
File transfer	Defines the exchange of huge data blocks such as programs.	GetFile SetFile DeleteFile GetFileAttributeValues

TABLE 110.4 Retrieval Methods

Retrieval Method	Time-Critical Information Exchange	Can Loose Changes (of Sequence)	Multiple Clients to Receive Information
Polling (GetDataValues)	NO	YES	YES
Unbuffered Reporting	YES	YES	NO
Buffered Reporting	YES	NO	NO
Log (used for SOE logging)	NO	NO	YES

The polling is the most common method. The use is restricted to applications that do not rely on sequence-of-events (SoE). Data values may be lost because the value may have been overwritten by the application between two GetDataValue requests.

The buffered and unbuffered reporting starts with the configuration of the report control blocks. The basic buffered reporting mechanism is shown in Figure 110.7. The reporting starts with setting the enable buffer attribute to TRUE; setting to FALSE stops the reporting.

The specific characteristic of the buffered report control block is that it continues buffering the event data as they occur according to the enabled trigger options in case of, for example, a communication loss. The reporting process continues as soon as the communication is available again. The buffered report control block guarantees the SoEs up to some practical limits (e.g., buffer size and maximum interruption time).

Figure 110.8 shows an example of a log and three log control blocks. The first step is to configure and enable log control blocks. After enabling, the association with that server may be closed. The log entries are stored in the log as they arrive for inclusion into the log. The logs are stored in time sequence order. This allows retrieval of a SoEs list.

© 2005 by CRC Press LLC

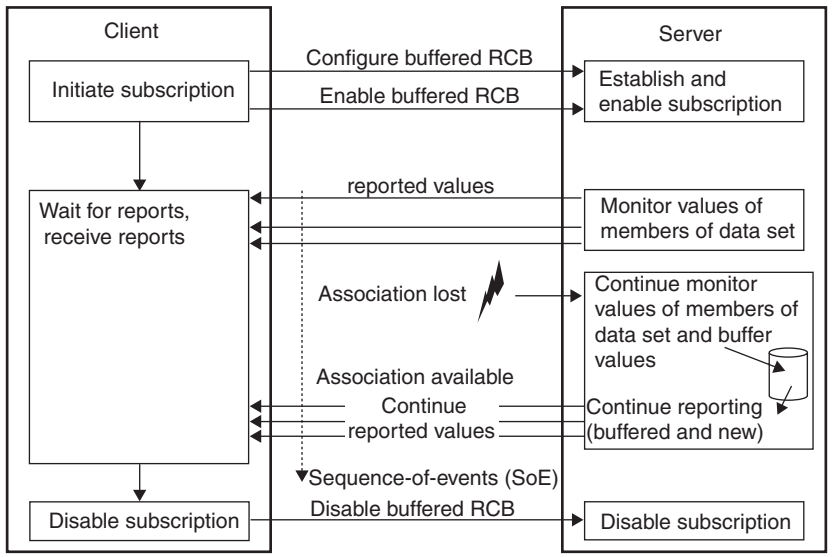

FIGURE 110.7 Buffered reporting (conceptual).

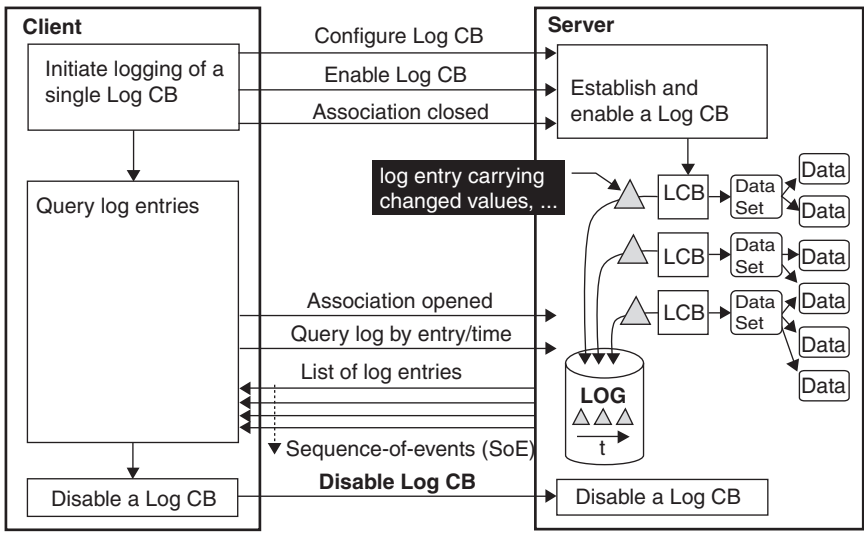

FIGURE 110.8 Log control block (conceptual).

The different log control blocks allow storage of information from different data sets into a log instance. Each log control block is independent of the other control blocks.

Two models are dedicated to the transmission of information with high priority:

GOOSE (Generic Object Oriented System Event) is used to model the transmission of high-priority information like trip commands or interlocking information. The model is based on cyclic and high-priority transmission of status information. Information like a trip command is transmitted spontaneously and then cyclically at increasing intervals.

SV (Sampled Value) is used to model the exchange of the sampled measured values from current and voltage transducers to any IED that needs the samples. The model is based on an unconfirmed transmission of

© 2005 by CRC Press LLC

a set of sampled values. A counter is added to time correlate samples from different sources and to detect the loss of a set of samples.

GOOSE and SV service models are defined in IEC 61850-7-2. The mapping of the SMV model to a concrete communication system is specified in IEC 61850-9-1.

IEC 61850-9-1 defines a unidirectional serial communication interface connecting current/voltage transducers with digital output to electrical metering and protection devices. The goal of the standard is to support interoperability between such devices from different manufacturers. With devices supporting this standard, the customer has the possibility to select a current/voltage transducer of one manufacturer and connect it to a protection device or a meter of another manufacturer. Being convinced that this is of real benefit for the customer, ABB and SIEMENS decided to support this standard. In order to demonstrate the feasibility, the real-time exchange of sampled measured values between ABB and SIEMENS devices was shown at the UCA user group and utility initiative meeting in Dana Point, CA (U.S.A.) in January 2002.

Both ABB and SIEMENS each developed a device called Merging Unit converting their own proprietary signals from the current/voltage transducers (CT/VT) to messages according to IEC 61850-9-1 transmitted over Ethernet [1]. Each message contains sampled values of currents and voltages for the three phases and neutral.

On the data sink side, ABB and SIEMENS each developed a distance protection relay, supporting the IEC 61850-9-1 messages as input signals. In addition, SIEMENS developed a meter with the same interface.

An overview of the five devices is given in Figure 110.9.

Each merging unit transmits synchronized samples with a transmission rate of 1000 messages/sec. Two sample rates — 1000 and 4000 samples/sec — are supported. In the case of 4000 samples/sec, four sets of samples are transmitted in one message.

110.5 IEC 61400-25 communication for wind power plants

The IEC Technical Committee 88 has set up a new project to develop a communication standard for distributed generation (primary scope per TC 88: wind power plants) in 2001:

IEC 61400 Part 25: Communications for monitoring and control of wind power plants

This standard defines like IEC 61850 several levels:

- wind power plant-specific information,
- information description methods (reference to IEC 61850),
- substation configuration method (reference to IEC 61850),
- information exchange for monitoring and control systems for wind power plants (reference to IEC 61850), and
- communications profiles (reference to IEC 61850 and definition of additional mappings).

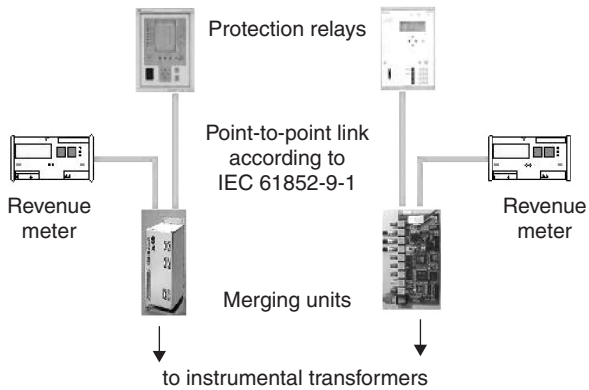

FIGURE 110.9 Devices with IEC 61850-9-1 interfaces.

© 2005 by CRC Press LLC

The information defined in this standard comprises mainly wind power plant-specific information like status, counters, measurands, and control information of various parts of a wind power plant, for example, turbine, generator, gear, rotor, and grid.

The standard IEC 61400-25 mainly defines additional information models and common data classes. The following wind power plant-specific logical nodes (Table 110.5) comprise a total of some 150 data.

The data are more comprehensive than those defined in IEC 61850. An analog value, for example, comprises the Instantaneous value, Deadbanded value, Average value, Root-mean-square value (effective), as well as the characteristics and historical information listed in Table 110.6.

An analog value is very comprehensive (not complex!). Most data attributes defined in these templates are optional. That means if they are needed then the standardized names can be used.

Many status and measurement information can optionally be stored in various logs for later retrieval. Advanced turbine controller may comprise several thousand information points to be reported and logged, respectively. IEC 61400-25 defines many common logs, for example, turbine commands, turbine status, high urgent alarms, low urgent alarms, counting information, and event timing information.

Figure 110.10 shows the current situation. Among other challenges, equipment having different proprietary protocols cannot be integrated without the installation of Remote Terminal Units (RTUs) to perform the translation work (Gateway), which is both expensive and labor-intensive. Usually raw data are exchanged on a cyclic basis.

The move to international standards provides the basis for the migration of common SCADA processing functions, for example, logging of historical and statistical information in the turbine controller. Self-identification and self-description may also be stored in the IED's database.

Today's advanced controllers already provide most of the historical and statistical information. In this regard, the standard IEC 61400-25 follows the market — not vice versa.

The object-oriented information description methods allow precise and complete specification of the information.

The information exchange provides:

- real-time data access and retrieval,
- controlling devices,
- event/alarm reporting and logging,
- self-description of devices,
- data typing and discovery of data types, and
- file transfer.

IEC 61400-25 has been developed in order to provide a uniform communications basis for the monitoring and control of wind power plants. It defines wind power plant-specific information, the mecha-

TABLE 110.5 Wind Power Plant-Specific Logical Nodes

Logical Node	Description

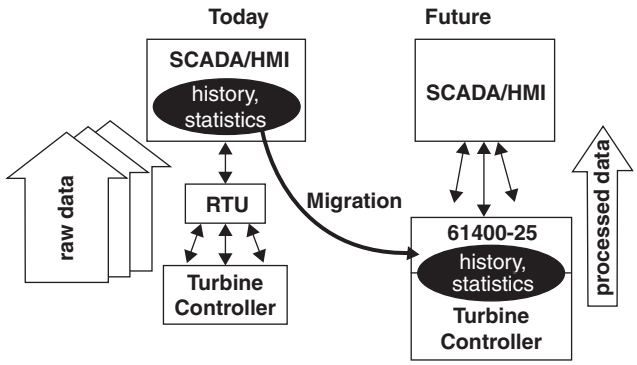

FIGURE 110.10 Migration of processing to IEDs.

nisms for information exchange and the mapping to communication protocols. In this regard, the standard defines all details required to connect wind power plant components in a multivendor environment and to exchange the information made available by a component. This is done by definitions given in this chapter or by reference to other commonly used standards.

The wind power plant-specific information models the crucial and common process data and metadata of a wind power plant. Process information is hierarchically structured and covers, for example, common process information found in the rotor, generator, converter, grid connection, and the like. The

© 2005 by CRC Press LLC

data may be simple (value, timestamp, and quality) or more comprehensive (adding more meta-data, e.g., engineering unit, scale, description, short hand reference, statistical, and historical information of the process value). All information of a wind power plant defined in this standard is name tagged — it defines a comprehensive name space. A concise meaning of each signal is given. The standardized wind power plant information can be easily extended by means of a name space extension rule.

All process and meta-data can be exchanged by corresponding services like get, set, publish–subscribe (report), logging, and control. Access to the meta-data (including configuration information with regard to the wind power plant information model and services and communication stacks) provides the so-called self-description of a device. The self-description could also be contained in an XML-based configuration file. The references include commonly applied standards like XML, ISO 9506 (MMS), SOAP, OPC XML-DA, IEC 60870-5-104, DNP3, and TCP/IP (see Figure 110.11).

This standard allows SCADA systems to communicate with wind turbine controllers from multiple vendors. The standardized self-description (contained either in an XML file or retrieved on-line from a device) can be used to configure SCADA applications. Standardization of SCADA applications is excluded in IEC 61400-25 but standardized common wind turbine information provides means for reuse of applications and operator screens for wind turbines from different vendors. From a utility perspective, unified definitions of common data minimize conversion and recalculation of data values for evaluation and comparison of all their wind power plants.

The standard can be applied to any wind power plant operation concept, that is, both in individual and integrated operations. The application area of IEC 61400-25 covers all components required for the operation of wind power plants, that is, not only the wind turbine but also the meteorological system (reference wind mast), the electrical system, and the wind power plant management system. The wind power plant-specific information in IEC 61400-25 excludes information associated with feeders and substations. Substation and feeder communication is covered by IEC 61850.

110.6 Implementation

An easy software architecture applicable for getting started is shown in Figure 110.12.

The DLL approach is an easy way of integration of the server into an existing software environment. The server "serves" one or more clients for real-time information exchange implemented in the IEC 61850 server.

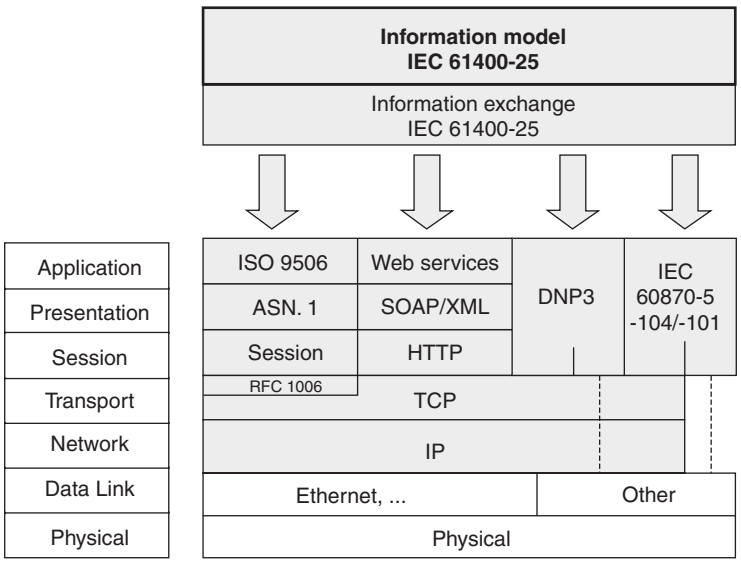

FIGURE 110.11 Communication profiles.

© 2005 by CRC Press LLC

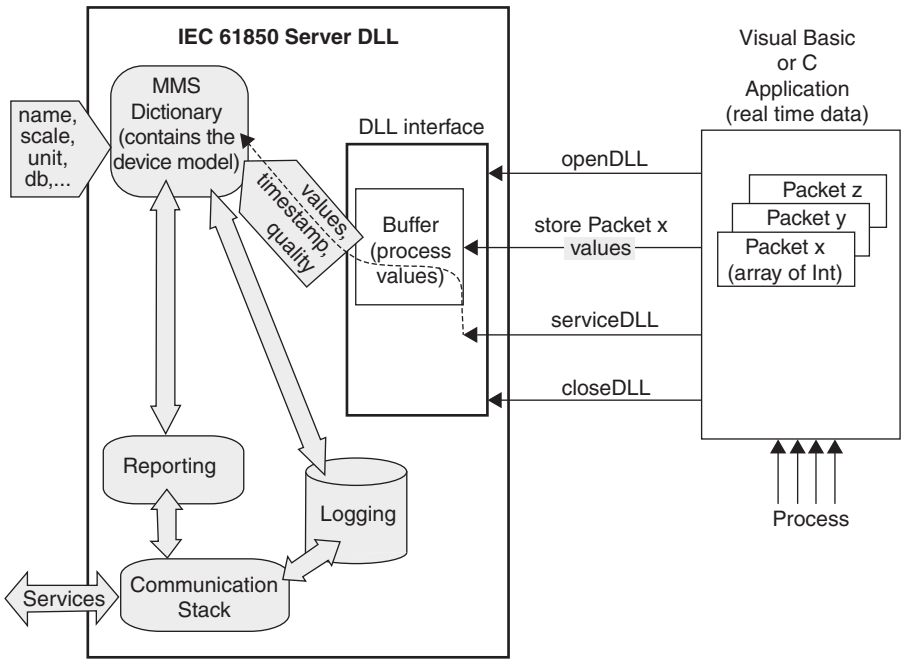

FIGURE 110.12 IEC 61850 DLL software.

The server provides an additional software for the HTTP access (exchanging HTML and XML coded pages) providing values in a non-real-time manner.

The interface between the Visual Basic application and the server DLL is defined by four local calls: openDLL, storePacket x, serviceDLL, and coseDLL. The application controls the DLL. The first action is to open the DLL (openDLL). The process data values are stored in the server applying the "storePacketx" calls. When all data values are store, the application calls the "serviceDLL" call. This call starts the processing of the server DLL.

The information model is stored in the DLL. All services like reporting (including the monitoring process if the data value has changed more than specified by the configuration attribute "db" since the last report) and logging are autonomously processed by the DLL.

This DLL approach is the easiest way to get started with IEC 61400-25 and IEC 61850. The interface between the communication software and the application may require an approach other than a DLL. The DLL runs only when it is called by the application. As a consequence of this DLL-typical behavior, the server DLL processes incoming and outgoing messages as often as the application calls the server DLL.

110.7 Reusability and device modeling

Describing device functionality by specifying the data (syntax and semantic) and the dynamic behavior (state machines) of devices (as seem from remote) is one of the fundamental challenges in the standardization. Many standardization groups have started defining different views of domain-specific device types. The views are, for example:

- Engineering (in the context of a plant),
- Commissioning,
- Configuration,
- Operation,
- Asset management,

© 2005 by CRC Press LLC

- Maintenance, and
- Decommissioning.

Hardware and software, as well as communication networks, are subject to frequent innovation. Therefore, it is worthwhile to standardize independent (abstract) interfaces for communication networks and the access to the application objects.

The abstract objects (objects define the semantic of the device functions) will continuously be used (with minor changes only). The object definitions will be enhanced in the future to meet additional requirements, that is, reusing the definitions specified in the past (see Figure 110.13).

The most important objective of the device description is to define reusable parts to be used for specifying the data models and behavior of various types of industrial devices. Reusability has two aspects. First, reuse of a given functionality in many devices throughout an application domain (we may call this: horizontal reuse). Second, reuse of a given function in the definition of an enhanced or specialized function (we may call this vertical reuse). The reusability is a crucial factor in reducing the costs of the overall system design, engineering, operation, and maintenance. Support of reusability is the key issue in the standardization!

The reusable parts describe, for example, how a substation can be configured using part 6 (SCL). A diagram as shown in Figure 110.14 maps to an XML file representing the use of the classes defined in part IEC 61850-7-4.

The application of the SCL allows to describe the complete configuration of a single device or a substation. An excerpt is shown in Figure 110.15.

The real benefit of device modeling is the reuse of (common) definitions made in the past. This is our daily practice! We are using common terms at work (key board, laser printer, office, etc.) or at home (kitchen, chair, wheel chair, bath room, etc.). Just misunderstandings are the result if terms are not understood uniquely on both sides (sender and receiver). It is not only a matter to define something completely — it is more important to understand it uniquely. All technical specifications in the area of distributed systems have to follow distinct rules for defining, exchanging, and unique interpreting exchanged information.

Interpretation is quite easy if we can reuse common terms learned in the past. In our daily life, we reuse (instantiate) the term "laser printer" (more precisely, we reuse the class definition that is associated with term "laser printer") for a laser printer next to you "laser printer in room 23" or we may reuse the term for a special type of a laser printer: A4 laser printer ("A4 laser printer in room 23").

Distributed systems should operate in the way they have been told to do. If they do not? This may have many reasons. A major issue is that independently developed devices may follow the specification of their

FIGURE 110.15 Application of SCL (excerpt).

implementers but the implementers may have different interpretations of the specification that describes the cooperation of the devices!

Devices will not operate in the way they should do, if the human beings (the implementers) do not understand each other!

Device models are collections of terms with associated semantics and a description of the dynamical behavior.

Usually, models are abstract in the sense that they do describe only those aspects that are visible to the remote user of a device. It is sufficient to know the external visible data and behavior of the device (the WHAT). The concrete realization of the device, its internal interfaces, and programming language or operating system (the HOW) are not of interest for the view from outside.

IEC 61400-25 reuses IEC 61850 instead of developing this new standard from scratch.

110.8 Resume

Deregulation will place greater demands for information on utilities than they have experienced before. IEC 61850, IEC 61400-25, and IEEE's UCA "UCA" is a Trademark of EPRI, Palo Alto, CA, USA provide a timely, cost-effective, and standardized solution to allow advanced IED functions and distributed systems to form the foundation for "next-generation" electric utility systems.

The benefactors of the results of open device data integration span the entire industry and include all of the stakeholders in this industry. With the standard IEC 61850, intelligent protection relays and other real-time devices are becoming more common. Utilities could take advantage of these new developments, and make the power systems safer than before — taking into account that all critical information (status and measurements) is available (at any time and anywhere) when making control decisions.

The customers are in a position to save large sums of money and time. The vendors who provide solutions that meet or exceed expectations will become very successful. This is an exciting time in the industry with an inexorable move toward practical software components.

The most important issues are the models of the real device data and the rules (service interface) how to access these data. On the other hand, it is obvious that an appropriate transport mechanism (communication profiles), for example, the TCP/IP or a point-to-point link, must be used to exchange the messages between devices.

© 2005 by CRC Press LLC

By providing a common communications protocol stack, IEC 61850 and IEC 61400-25 support the "plug-and-play" equipment from different vendors. The specification of the uniquely tagged semantic of the most important device model data leads to a tremendous cost reduction during engineering, commissioning, operation, asset management, and maintenance. The solution provides plant- and enterprisewide seamless integration.

IEC 61850 is based mainly on UCA. The UCA 2.0 specification will be harmonized with the final IEC 61850 standard.

An evaluation CD ROM is available, which includes original software of several vendors and documentation helping to get started applying the IEC 61850, IEC 61400-25, UCA, and MMS approach (also including the IEEE TR 1550). For details, see:

www.Nettedautomation.com/solutions/uca/evalkit/index.html

A comprehensive free Demo Software and Tutorial for IEC 61850/IEC 61400-25/UCA™/MMS (with Web/XML support) executable on PCs (Win 95, 98, NT, 2000, XP) could be downloaded from the following URL:

The JEVIS Service Platform — Distributed Energy Data Acquisition and Management

111.1 Introduction
111.2 JEVis Architecture
111.3 Distributed Data Acquisition, Storage, and Access
111.4 Global Energy Management
111.5 Outlook

Peter Palensky
Vienna University of Technology

111.1 Introduction

The deregulation and liberalization of large parts of the European energy market had a number of essential implications. Besides the wanted and expected consequences like increased competition — and therefore decreased prices — the energy customers became more and more aware of energy as being a part of their daily financial balance. Having the opportunity to choose between different suppliers that offer in deed different "products" resulted in the need to know what and how much energy is consumed where and by whom.

The types of customer that is currently taking advantage of the liberalized energy market are typically small and medium enterprises (SMEs), multi-site customers (e.g., supermarket chains), and medium industrial customers. Large customers and large industrial sites like metal or glass industry are — as a part of their customer retention efforts — looked after by the respective electric utilities' key account managers anyway, while the medium customers do not enjoy such attention.

These customers might change the supplying utility company but have no basis for this decision. It is generally not possible to estimate if tariff A is more suitable for some customer than tariff B unless you know the exact consumption behavior.

This demand for information was the starting point of the JEVis project (Java Envidatec Visualization). The Institute of Computer Technology (ICT) at the Vienna University of Technology (Austria) and Envidatec GmbH, a service provider in the domain of energy in Hamburg (Germany) created a concept of a new and modern data acquisition system that is capable of processing millions of new records per day and that offers high availability and scalability called the JEVis system (see also www.my-jevis.com).

© 2005 by CRC Press LLC

Customers that join (i.e., that are connected to) this JEVis system can browse through and analyze the consumption of every process within their production site or shopping mall. This transparency enables them to optimize their business and to choose the optimal energy tariff. Some of the customers are subsequently equipped with an automatic load scheduling system, which helps to avoid expensive consumption peaks and can directly determine their savings via the JEVis system.

Modern energy bills for SMEs are based on the so-called load chart, a consumption chart with 96 samples per day (15-min consumption values). A typical tariff in Mid-Europe is that not only the consumed energy (counted by an energy counter, in kWh) but also the three largest 15-min consumption values (the consumption "peaks") are taken into account. Additionally, the power peaks constitute quite a large portion of the bill; thus, avoiding or decreasing these peaks can significantly reduce the energy bill. The JEVis system stores the energy consumption charts and offers the recorded data via a web-portal.

The next step after having a detailed load chart of the consumption is to find out what processes or what parts of the customer installation are responsible for a particular power peak or the load shape in general. As already mentioned, sometimes it is even possible by simply looking at the chart while knowing the customer's processes. Usually, it is, however, not that easy. Large buildings and industrial sites with a large number of electrical consumers sometimes cannot be overlooked in terms of power consumption. It is thus necessary to apply additional sensors, besides the existing energy meter, to increase the granularity of the information.

The JEVis system is, for instance, used for "benchmarking" (e.g., comparing) multiple branches of one business to identify the most efficient and the least efficient ones. This massively depends on how much information you "get out" of the building or the process and into your calculation and optimization algorithms. The sources of this information are a large number of sensors and actuators that are queried by a database that is capable of storing these large amounts of data. The main challenges in the JEVis project are the highly distributed nature of the customer installations. Long-range communication is entirely based on the Internet or other IP-based communication infrastructure like virtual private networks (VPNs). Topics like reliability and security are vital for the JEVis system, as well as how IP can be used for flat peer-to-peer networking as it is needed for "global" automation applications.

111.2 JEVis Architecture

The customer-side part of the JEVis system interconnects all necessary sensors and actuators at the customer's site via a local control network (also known as field area network or "fieldbus" [1]) that can be accessed via the Internet. See later in this chapter for a more detailed description of the respective communication infrastructure.

Having this infrastructure, the JEVis system can not only record and analyze energy consumption data but virtually any kind of measurement data. The usage of machinery, temperatures, the number of persons entering a supermarket, the status of the air conditioning equipment, and many other things are fed into the JEVis database for further processing. The customer can then not only see the load chart but also its correlation to other measurement charts and thus identify those parts of his facilities that are responsible for power peaks. The combination of process data and consumption data enables the customer to evaluate the performance of different branches of his enterprise and to optimize his overall business. The JEVis system offers an all-in-one solution to acquire, process, and use these data.

The IGUANA project (1999–2001, [2]) aimed toward generating the customer-side infrastructure for sensor networks and data acquisition. IGUANA is the direct predecessor to the JEVis project and resulted in a flexible Internet/fieldbus gateway that meanwhile runs on various different hardware platforms. The JEVis system uses the IGUANA gateway software on an embedded rail-mounted industrial PC called "VIDA." The key properties of this VIDA are

- Intel-architecture industrial PC
- Linux operating system with web-server, SSL (secure socket layer), SSH (secure shell), etc.

© 2005 by CRC Press LLC

- Robust transaction-based nonvolatile flash memory, no moving parts
- Digital input channels for energy meters (electricity, gas, water, etc.)
- Digital outputs channels for relays
- LonWorks control network interface for additional sensors and actuators
- Ethernet or analog, ISDN (integrated services digital network) or GSM (global system for mobile communication) modem for IP-connectivity.

The VIDA hardware is designed for robustness and usage in a rough and EMC-critical (electromagnetic compatibility) environment. Therefore, all inputs and outputs (I/Os) are galvanically insulated. It has no moving or maintainable parts and can be installed in closed switchboards. When powered up, the IGUANA gateway software scans the attached LonWorks network for sensors and actuators. After the discovery procedure, each node that was found is registered in an on-board database and can thereafter be used and operated by the VIDA software.

Being originally intended to serve as a remote configuration node for the Envidatec Load Management System, it turned out that the customers were much more interested in an "auxiliary" feature of the VIDA: data logging. Meanwhile, providing historical measurement values and generating alarms depending on the system state and some rules is the majority of VIDA's usage.

The VIDA was initially used as an autonomous system, playing the role of an "agent" in terms of network management (= a server that simply responds to queries and simultaneously an alarm notificator that can initiate messages as well), using its on-board http-server and other server- and alarm-features. Now, the features and services of the VIDA are massively "grafted" and extended by including it in the JEVis system.

An alarm message is not only an E-Mail that is sent out by the VIDA anymore, it is part of a whole alarm management concept: the JEVis system takes alarm messages from VIDAs and creates FAX messages, GSM SMS (short message service), telephone calls, and other ways to reach the intended recipient of the alarm message. If the receiving of the alarm is not confirmed within a defined time, further alarm messages are sent to other responsible persons until the problem is solved. Managing all this is too much for embedded nodes like the VIDA, but is no big deal for sophisticated platforms like the JEVis system.

These extended services were the driving factors for JEVis. The result is a flexible platform that can collect, calculate, distribute, and manage data that are typically acquired via some measurement system. The increased granularity of knowledge about a building or an industrial process makes it more easy to identify problems and to optimize the processes. Devices and facilities that were previously controlled and run independently can now be analyzed and viewed by using a global and correlating view. The shared energy supply always "links" the individual processes of a plant when it comes to energy consumption, although they are not controlled collectively. JEVis now enables the customer to obtain an overview and to identify and overcome logistical and organizational problems.

A typical situation that can be found at customer sites is sketched in Figure 111.1 A number of energy-consuming customer processes (manufacturing lanes, compressed air production, etc.) are controlled individually but supplied collectively. Since the behavior of the individual processes is not coordinated, unnecessary and unwanted consumption peaks may very likely occur.

The customer-side part of the JEVis system interconnects the individual devices and their controlling processes with a control network and schedules them with an energy management algorithm. Such energy management systems (EMS) coordinate processes in a more or less sophisticated way. Sometimes, like in the case of the Envidatec EMS, even a short-time prognosis of the individual consumers is used to optimize the consumption shape.

Interprocess coordination is, however, just one side of the medal. Even within the processes consumption, coordination is usually missing. Equipping the consuming appliances with the respective JEVis sensors that measure consumption and operation enables the customers to find out what parts of his system are responsible for consumption peaks. The detailed knowledge about the processes is then the basis for the configuration of the energy management.

Some of the JEVis customers are not consumers of electrical energy but rather producers. A typical example is a wind power station, which is usually not allowed to feed energy into the grid whenever

© 2005 by CRC Press LLC

possible. The respective policy of energy supply and production determines how much a particular wind power station might produce, depending on the time, the situation on the grid, and so forth. The optimization process here is no consumption optimization and load shaping but production and injection optimization. The algorithms are similar and the hardware equipment is almost identical. A control network measures the power production, the wind, etc. and feeds energy into the grid or not. Having logs about the production is essential, since produced energy is a valuable thing, in addition to the consumed energy.

The JEVis service provider side consists basically of a database that stores and processes the collected measurement data. The results are subsequently offered as Internet-content via web-interfaces to the customer. Hence, the JEVis system consists of three parts (Figure 111.2).

- The customer-side installation: the customer processes, equipped with an Internet-gateway (the VIDA, for instance) and probably some control network connected to this VIDA for additional sensors and actuators.
- The JEVis server, an Internet-able database.
- The customer as a client to the JEVis server, using a standard web-browser.

The VIDA gateway is, as already mentioned, an embedded rail-mounted personal computer, which is in charge of offering a remote control channel to a local control network, of evaluating alarm conditions, and of measuring and logging data like water consumption, temperatures, and so forth.

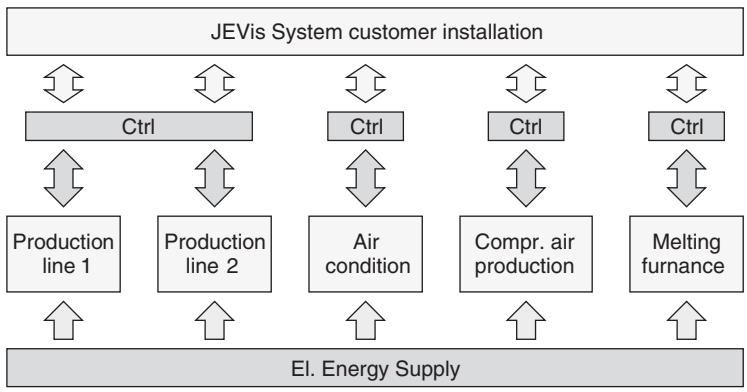

FIGURE 111.1 Separate processes linked via the JEVis system.

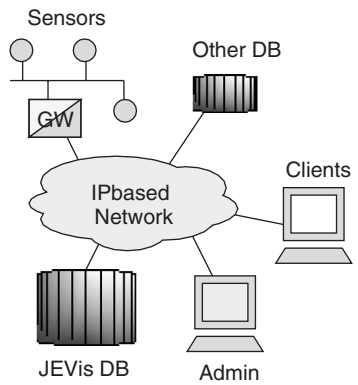

FIGURE 111.2 The JEVis database with its sinks and sources of data.

© 2005 by CRC Press LLC

The main innovation of the VIDA is its network capabilities. Equipped with a flexible Linux-based set of software and some modem(s), it is able to

- pick up incoming calls and establish IP connectivity,
- to dial into a number of ISPs on-demand,
- to be permanently connected to an IP network like digital subscriber line (DSL), local area network (LAN), etc., and
- to be "woken up" by a telephone signal (e.g., a "ring") and to call back for IP connectivity.

These flexible networking options were the key to success. The VIDA can be installed virtually everywhere, in corporate networks, "in the field," etc. The customer's sites are subsequently equipped with VIDAs and the respective sensors. If only typical consumption data like electrical energy or heat consumption are needed, there is no need for a local control network, if temperatures, air pressure, and other values are needed as well, external sensor nodes must be attached. The protocols of the VIDA were carefully selected to safely pass firewalls and proxies while offering strong data security. Since conventional proxies often only allow http (hypertext transfer protocol) traffic, the gateway protocols must be embedded in http. The security-relevant layers must therefore be either embedded in http as well or be based on widely accepted standard protocols like secure socket layer (SSL). The JEVis system does both: it has internal authentication and wraps the traffic in SSL, when public networks like the Internet are used for connectivity. Key distribution for the cryptographic parts of the security layers is based on electronic chip cards, which is beyond the scope of this chapter. See [3] for a discussion on security and fieldbus/Internet connectivity.

One of the main challenges of the system was availability and reliability. The domain of energy supply is dominated by the high quality of energy supply in the last decades. Electrical energy was always available and had a constant quality. This is what the customers in this domain expect from anything that has to do with energy. When it comes to electronics, communication systems, servers, and the Internet, we find a totally different level of quality. These systems are, due to their complexity, much more instable and endangered by hardware and software problems than the proved components of energy supply. Therefore, all software parts of the JEVis system are monitored by watchdog-like programs for proper functionality and valid states. Two communicating software components (a client and a server), for instance, mutually monitor each other for timeouts, stability, correct behavior, valid status, and other things. Only these measures made it possible to offer the required availability. Figure 111.3 depicts two replicated instances of the JEVis system that exchange data for replication purposes and additionally monitor the system behavior of the peer besides two processes inside a system that have a client/server relation.

The monitoring occurs in a variety of ways. Typically, customer queries are issued (emulated) and the result is analyzed. This guarantees that at least the customer requests are processed correctly. Additionally, there are system-internal channels for supervision, which provide a deeper insight into the current state of the observed system. Key aspects like memory usage, system load, and other operating system-level attributes can be transported via these channels as well as state information of the individual processes of the systems. Figure 111.3 shows two processes on one and the same or even (or say "even better") on individual machines of the JEVis network. The processes are usually part of a client/server relation. Operational data are transmitted via these relations as well as monitoring data. In this way, one process A can be a watchdog for another process B. Since all parts of the JEVis system use or can use secured interprocess communication channels, the individual processes might be located on geographically

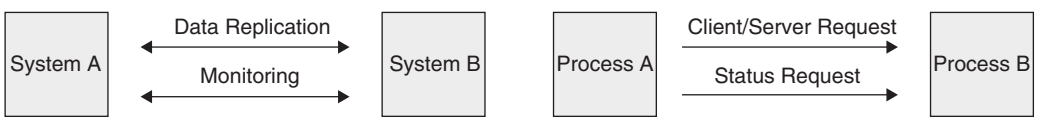

FIGURE 111.3 Systems and processes monitor each other.

© 2005 by CRC Press LLC

distributed servers. This fundamental design decision makes it possible to install the system in a distributed and fault-tolerant way. One important rule of mutual supervision is that the final decision chain of "who resets who" (in the case of a detected faulty state) must be strictly hierarchical in order to prevent loops and meshes in the decision process. The propagation of rollback or reset actions must be absolutely deterministic. The internal client/server relations for the status requests and reset commands of all components must therefore follow a strict hierarchy.

111.3 Distributed Data Acquisition, Storage, and Access

Data are acquired via a number of different channels since the gateways can establish outgoing connections as well as incoming ones as already mentioned. If, for instance, one ISP is not reachable for a gateway, it tries to contact other ones and probably even via another channel (a GSM modem as a backup solution for the ordinary ISDN connection).

Let us take the incoming modem connection ("pick up" by the gateway) as an example. A connectivity component of the JEVis database calls the gateways via modems and transfers data via the subsequently established IP point-to-point connection. The JEVis network in Figure 111.4 has two replicated instances of its database and all its components (JEVis System 1 and JEVis System 2).

It serves two customer sites (customer A and customer B); one of the services might be to read out the data loggers of the gateways once a day. Let us suppose that the customer's sites are in different countries (customer A and JEVis System 1 in the same country as well as customer B and JEVis System 2) and the connectivity costs money, depending on the distance (public telephone network). The JEVis system therefore chooses the instance with the lowest on-line costs for each particular data retrieval job so that customer A will be queried by JEVis system 1 while customer B is read out by JEVis system 2.

The databases in the JEVis system instances synchronize with and replicate each other — some parts permanently, some parts at defined times or system states. The problems arise when parts of the JEVis instances are considered to fail. If one session that retrieves some thousands of data samples breaks because of hardware reasons or something similar, another data retrieval component has to finish the job. Thus, it might happen that JEVis system 2 continues a job that was initially started by JEVis system 1. System 2 therefore checks the status of the retrieval queue of system 1 and vice versa. If a job hangs or fails, the partner system tries to continue it. A transaction-oriented retrieval, storage, and replication policy ensures that the databases remain consistent.

The database has a number of storages and registries that are beyond the scope of this chapter, but two important data storages shall be explained as examples. The first one is the "samples storage." Databases for SCADA (supervisory control and data acquisition) like the JEVis system have to store "engineering values," that is, retrieved measurement values that are slightly more than plain numbers (See the ISO 16484 standard for an impression of the variety of datapoints that can be found in a modern building). A "sample" is an "extended" physical engineering value with a timestamp. The "extended" means that a single sample might

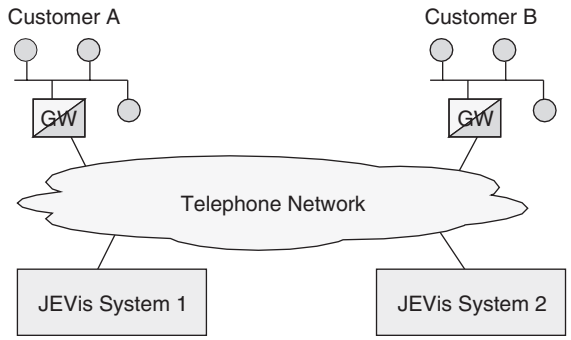

FIGURE 111.4 Geographically distributed customers and JEVis systems.

© 2005 by CRC Press LLC

be a measurement value, a setpoint, a digital photo image, the status of a machine, a statistical, or organizational value typed in by some user and so on. Such samples typically consist of a set of attributes like

- relative accuracy of the value (in percent),
- absolute accuracy of the value (in the respective unit),
- physical unit in SI units,
- absolute accuracy of the timestamp (in sec),
- an absolute validity (from timestamp A to timestamp B),
- a relative validity: the interval in seconds around the timestamp (e.g., [0, 900[or]−450, 450]),
- the value itself, etc.

All JEVis services use these samples. Statistics are calculated, alarm conditions are evaluated, prognoses are estimated, etc., and all of this is stored in the samples storage. All entries in the samples storage provide additional information about the retrieval procedure so that it is possible to determine how a sample got into the sample storage. Samples are never deleted; they can only be updated by a newer sample with a more recent timestamp.

Data samples can be assigned to data rows like measurement rows (samples from one data source) or other rows like consumption samples from holidays or the temperatures of the 15th of March of the last 10 years.

Another important registry in the JEVis database is the "organizational hierarchy registry." Customers might see their sites and branches in different views. One example is that a supermarket chain sorts its branches by

- geographical location or
- financial clusters,

since a troubleshooting team for the freezers needs the first "view" of the sites, while the accounting department would use the latter one. Although both views finally contain the same sites, the views are different. Users that authenticate themselves to the JEVis portal can choose their preferred views and work with them.

The database replicates its tables and data structures depending on their contents and their role in the system. Configuration data like "data retrieval schedules," for instance, are replicated synchronously and immediately. Data storages are replicated on demand and asynchronously since they are unique in the system anyway. If two samples represent a value from the same data source, logged at the same time, a deterministic collision and conflict resolution algorithm cleans the samples storage.

Data are put into and read out of the database via components that tightly attach themselves to the database via standard interfaces like ODBC or JDBC (open database connectivity, Java database connectivity). These components typically reside on the same system and machine as the database itself. These components either have a client- or a server-interface to the rest of the system or to the outside. Data input components (DIs) and data output components (DOs) furthermore might be of an interactive nature or of a batch nature. The first one usually interfaces to humans, which results in the requirement of low latency and quick responses.

Figure 111.5 shows typical data input components and data output components. The HTTP Server DO, for instance, would be an interactive DO because it is typically queried by human users using a web browser. The SMTP Client DO is noninteractive since the simple mail transfer protocol (SMTP) does not define any qualities of service regarding interactivity.

Server components are always queried by some client while client components might contact other servers. The server DIs and DOs are therefore the front-ends of the system, while the clients are back-ends that retrieve data or send data somewhere.

The simple object access protocol (SOAP) client DI in Figure 111.5 is a classical DI. It queries JEVis gateways for measurement data and other information from the customer site via SOAP. This client DI is used by the database and abstracts or encapsulates all gateway-relevant technology like special protocols, authentication mechanisms, datatype abstraction, and so forth. The HTTP Server DO is, as already

© 2005 by CRC Press LLC

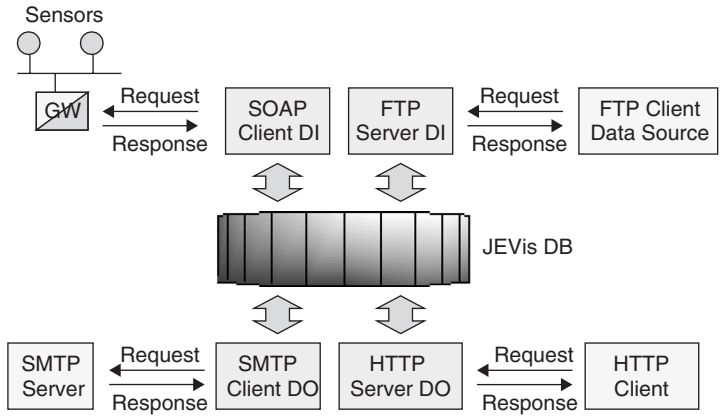

FIGURE 111.5 Paths of data into and out of the database.

mentioned, an interactive DO. Usability, response time, user interfaces (typically graphical user interfaces, GUIs), and other aspects are the main concerns for developing these components, since they are the direct "face" to the customer that wants to be satisfied. Interactive DIs and DOs are therefore typically web-enabled forms and GUIs, based on Java servlet/applet technology.

The distributed nature of the system requires some considerations to protect data and other aspects of security. The data replication channels, for instance, should be protected from unauthorized access or manipulation. Therefore, JEVis implements the following methods:

- secure data transport between all communication entities and components of the system,
- secure data storage,
- powerful and flexible access right methods,
- usage of smart card security, and
- secure customer front-ends.

See [3] for further details on data security for control networks and smart card technology.

111.4 Global Energy Management

Considering influence on the consumption behavior is generally called energy management or more precisely demand side management (DSM). DSM usually consists of three parts, namely

- retrofitting (changing insulation, devices, etc.),
- logistical optimization, and
- load scheduling.

In our context, energy management means load scheduling, the active influence on the operation of equipment. The customer-side part of the JEVis system contains an energy management subsystem that actively schedules electrical consumers. The rules for this scheduling are based on the specific energy tariff. After having analyzed the customer processes with the JEVis system, and after having identified the reasons for power peaks and other unwanted behavior of the system, it is easy to configure and tune the energy management system in order to avoid this behavior.

Global energy management (GEM) goes one step further. The deregulated energy market in Europe moves toward a direction where customers are allowed to group their geographically distributed sites ("multi site customers") onto one energy bill. The overall consumption load is then used as a basis for the energy bill. The energy meters might record the individual load charts, which are then summed up, but the individual local energy management systems usually do not cooperate globally.

© 2005 by CRC Press LLC

The problem of "global" energy management is basically the same as local energy management: a number of resource-consuming entities are to be organized and scheduled in order to impose some overall behavior. The difference to local energy management lies in the communication channels. The problems that a GEM application faces in the world of the Internet are perfectly transferable to other "global" automation problems. The weak quality of services, the limited ways of establishing network connectivity, and the restricted transport of information in the Internet are problems that any distributed automation application faces so that global energy management can be seen as an example.

Local EM interconnects the energy consumers or say the controllers of the energy consumers via some kind of local network — a control network or a LAN. The availability of these network resources is generally very high and not connected to any "on-line costs." The local EM peers can count on the fact that the connectivity is a permanent one, and every member of the EM system can reach any other member whenever needed.

GEM faces a different network infrastructure. Long-distance connectivity is costly; the nodes might be connected to the Internet via GSM channels, telephone lines, or other ways of "going on-line." The Internet is virtually the only affordable network that offers long-range peer-to-peer connectivity at reasonable prices, but it still costs. Therefore, the members of the GEM system will not stay on-line 24 h a day but only at certain times or on demand. Not only the frequency of data exchange but also the amount of exchanged data is relevant since it directly influences communication costs.

As a consequence, the JEVis GEM system estimates the future behavior of its members and uses this prognosis to calculate the schedule in an as-off-line-as-possible way. The algorithms of this optimization process will not be discussed here but another important aspect of the system: the need for flexible communication. The GEM system consists of a number of nodes that represent an energy-consuming or-producing entity like

- a wind power station,
- a private home with a fuel cell system,
- a bakery,
- an industrial site, or
- a supermarket with a number of freezers.

Some of these nodes might "store virtual energy" like the freezers or the bakery; others can produce energy like the fuel cell and the wind power stations, and the majority simply consumes energy. Thus, the system consists of a geographically distributed number of energy consumers, storages, and producers with restricting rules of consumption, storage, and production. A wind power station, for instance, cannot be influenced in order to produce more energy and a bakery may not be switched off anytime but only under certain circumstances. Thus, the optimization process tries to take advantage of the degrees of freedom that the system offers in order to find an acceptable schedule for all members. Finding the right schedule that satisfies the "global goal" (some overall load chart, some special consumption peak avoidance in a region, etc.) strongly depends on the amount of information that the algorithm has about the situation. The degrees of freedom of every member sum up to a very complex optimization problem, which results in large amounts of data to be exchanged. Independent of the type of algorithm (negotiation-based, search for solution, etc.), the members actually need "flat" peer-to-peer connectivity in order to exchange data like tables, statistics, states, commands, etc.

The Internet usually offers peer-to-peer IP networking once the nodes are on-line. Unfortunately, depending on the Internet service provider, some of the dial-up nodes are hidden behind an IP proxy so that they cannot offer any services (open and "listening" IP) to the outside network. In this case, methods used by Internet Relay Chat (IRC) must be applied, where a publicly available server routes the requests of the GEM members that appear as IP clients. Figure 111.6, for instance, shows a wind power station and a gateway GW1 that want to communicate. Since the wind power station is behind a proxy, they use the JEVis relay to communicate instead of using native IP peer-to-peer communication. The same would occur if a GW goes on-line via standard GPRS (general-purpose radio switching, a packet-oriented GSM service), since a GPRS node gets an "internal" IP address behind a masquerading firewall

© 2005 by CRC Press LLC

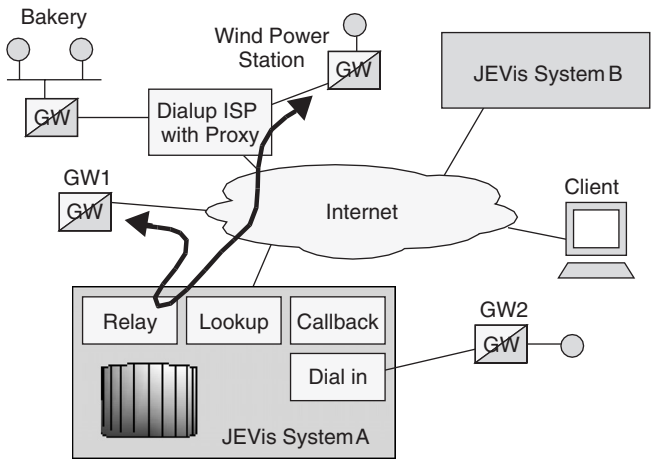

FIGURE 111.6 Connectivity services of the JEVis system.

and is not accessible from outside. Such firewalls, proxies, and other phenomena on the Internet restrict the communication massively and therefore the system must use technologies that are widely accepted and therefore supported and not inhibited by the Internet service providers. Additionally, the nodes might be organized in clusters and groups where not every node knows who and where its peers are. As a consequence, there must be some lookup tables where nodes can register in order to be found by other nodes.

The JEVis system therefore does not only host a database but also a number of other useful services that make a global automation application like global energy management possible:

- managing new dial-up connections (call back) on behalf of other nodes,
- dial-in service,
- lookup service for nodes to find peers, and
- communication relay for nodes with restricted transport (behind proxies, firewalls, etc.).

Another problem is the quality of services (QoS) like latency, availability, real-time aspects, and so forth. The IP protocol usually does not offer any guarantees. If the algorithm relies on the assumption that an offer (as a part of a negotiation procedure) is transmitted for sure within 5 sec, the algorithm is a bad choice for an Internet-based solution. Additionally, the Internet protocol itself is not the only unreliable part of the system. The lower-layer transports like dial-up telephone lines or GSM networks have a nondeterministic availability. It is not guaranteed that the node gets a free telephone line when it is needed. Therefore, the algorithm must be designed in such a way that it copes with unavailable information and unreliable and nondeterministic communication. The nodes must have as much "intelligence" as necessary to work fine even when communication is not possible for hours or days. This "local intelligence" results in a very robust and fault-tolerant system, which is one of the typical goals of distributed systems. The drawback of such a distributed architecture is that distributed network management is much more complicated. Therefore, the central JEVis system must be the location for network management-related things like node-configuration, diagnosis, and the like.

The distributed and robust nature of the GEM network would be destroyed if the JEVis system would not be redundant and distributed as well. If only one central server offers the communication relay and the other services, this server represents a single point of failure. The replicated and distributed nature of the JEVis system is therefore a good contribution to the fault tolerance of the GEM system.

© 2005 by CRC Press LLC

111.5 Outlook

The JEVis system is, although very mature and massively in use, still subject to intensive research and development. The current research and development activities are system availability, alternative database systems, and, as already described, the infrastructure for GEM, which is probably the biggest challenge.

The availability of the overall system is still more limited than necessary due to insufficiencies of the Internet technology itself. By using dynamic host resolving, automatic query relays, and other dynamic methods, we hope to further increase the fault tolerance and availability of the system.

The JEVis database is currently based on an Oracle 9i® system, and proved stability and high performance. The philosophy of the JEVis services, however, would actually suggest an object-oriented design and not a relational database. Object-oriented databases (OODBs) are expected to be more flexible when it comes to different types of data that have to be stored. As an example, the configuration of all equipment used in the JEVis system (IP gateways, sensors, fieldbus nodes, etc.) is stored in and maintained by the JEVis database. A new type of device can result in a change of the data structures because it demands new, specialized data fields to be stored. An OODB has more flexibility in that aspect and can abstract devices and encapsulate data structures.

Another interesting branch of database technology is active databases (ADBMS) [4]. Active databases and especially active real-time databases are preferably used for job shop scheduling, work flow management, and production processes. Reactive behavior, triggered actions, and the action scheduling features of ADBMS are actually ideal for the JEVis services — the JEVis system also reacts to various changes in its environment. However, Oracle triggers are currently sufficient for the reactivity of the JEVis system.

Extensions like new services for customers, new devices, and components like alternative gateways and protocols are further fields of development.

ABB Corporate Research

112.1 Introduction

Today, companies involved in power distribution and transmission require network control systems not only with advanced graphical user interface, like Windows look & feel, panning, zooming, etc., but also with advanced integration and migration opportunities. The integration opportunities cover the Supervisory Control and Data Acquisition (SCADA) application itself and other systems including commercial applications like, for example, Enterprise Asset Management and technical systems like Geographical Information System. All of them can be integrated with a reasonable effort using the Industrial IT Aspect Integrator Platform (AIP) [2,5]. Additionally, one will always have an option of migrating to other SCADA systems by simply replacing the SCADA servers without losing system integration work and developed Human–Machine Interface (HMI). This means that the complete system will not have to be discarded, as was the case earlier.

In today's scenario, SCADA users often carry out most of the data engineering and picture building work themselves using an efficient engineering concept for both data engineering and picture building. For example, it should be possible to copy and paste the engineering data of one station (e.g., complete electrical or gas substation), like in Windows scenario, with the possibility of later editing it to create a new station. This requirement can be simply reused from ABB's Industrial IT AIP by saving time on engineering and concentrating mainly on system configuration, customization, and optimization.

112.2 System Architecture

Industrial control applications for power distribution and transformation usually perform different functions such as HMI, data logging, advanced control, input/output operations, enterprise connectivity, etc. [1,3,4]. Personal computer (PC) systems running Windows-based operating systems, like Windows 2000

© 2005 by CRC Press LLC

and Windows XP, are increasingly being used in industrial applications due to their open PC architecture, Windows look & feel, availability of common Office Tools, a wide variety of off-the-shelf software and hardware products, which provide a range of data acquisition, analysis, presentation, management tools, and relatively easy connection to various computer systems within a network. The practical question here is how to use all these applications effectively, namely, perform data exchange, navigation, substitution of components, and system maintenance in a fast and easy way [6, 7]. Another important aspect in power distribution and transformation applications is the possibility of migration from one SCADA system to another or the integration of more than one SCADA system behind one graphical user interface. The industrial IT concept presents a unique opportunity here, namely, the iterative migration of components on the Industrial IT basis. In Figure 112.1, we show one of the solutions, namely, the exemplary architecture of the network control system based on the migration of SCADA system to Industrial IT AIP.

In the system architecture (see Figure 112.1), process data are transferred between SCADA server and AIP server using process data cache with standard OPC (OLE for Process Control) interface inherited from the AIP that has its own OPC server and OPC client with advanced caching features. This provides a high system performance due to the fact that process data cache has a short access time for retrieving cached data. An intelligent supervisory manager, associated with the process data cache on the client machine, controls storage of the process data in the cache and selectively transfers process data from the server computer system to data cache of client node using data subscription mechanism.

The system components of a given SCADA system based on AIP can be defined for each particular implementation separately, depending on the given requirements. In Figure 112.1, various box types show that components from different systems have been easily integrated into the AIP. The conceptual scheme of network management system for power transformation and distribution applications includes

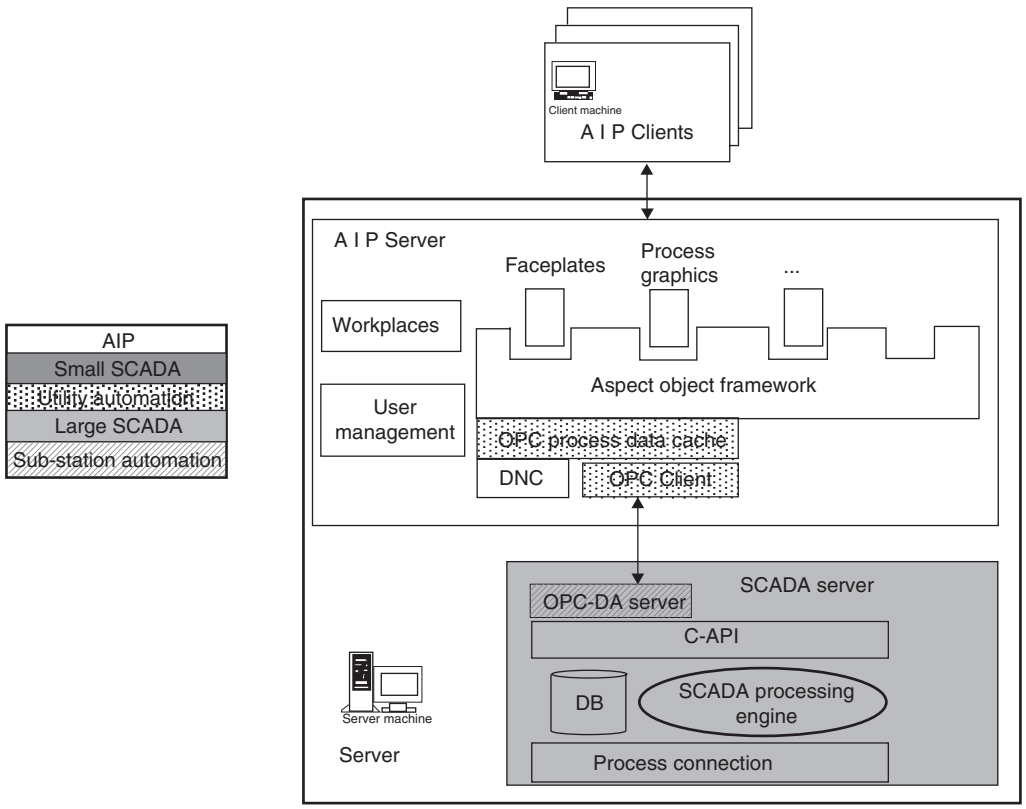

FIGURE 112.1 Exemplary architecture of network control system based on Industrial IT platform.

© 2005 by CRC Press LLC

the following main exchangeable components and systems integrated on the Industrial IT basis (other components, like Alarm & Event Lists, Trend Displays, etc. are reused from the AIP):

- Process Graphics (WS 500, DataViews, GraphWorX, etc.);
- SCADA server;
- Client OPC Process Data Cache;
- OPC–DA server (Data Access) of SCADA server; and
- DNC (Dynamic Network Coloring application).

SCADA server application includes real-time database (responsible for the handling of a subset of the process variables related to data acquisition, alarm handling, and archiving), process connection module that interfaces controllers of I/O devices, processing module, and OPC server. The process connection module is used to poll the controllers of I/O devices at a user-defined polling rate. The polling rate may be different for different parameters. Time stamping of the process parameters is typically performed in the controllers and this time stamp is taken over by the OPC server that receives process data at the end to make them available for subscription to various OPC clients located on client machines.

In the given AIP-based implementation of the OPC, the OPC server exposes an OPC–DA interface that has functions to read and write variable values. These functions are marshaled across the network using stable CSLib (ABB's proprietary protocol) so that clients are able to call them. After an OPC item on the server has been subscribed to from the client, any data value change in the server application automatically updates the associated value in the client application. The CSLib-based implementation of the OPC has an advantage that DCOM (raising a number of stability problems) is not used for implementing OPC–DA.

The AIP-based process data cache contains a set of classes that implement all mandatory OPC DA interfaces, as shown in Figure 112.2. OPC Items contain process data in the form of the attributes that are listed in Table 112.1.

Supervisory manager of AIP-based process data cache offers features that allow customizing how items are cached and how long they are cached. It is possible to instruct supervisory manager to give certain items priority over other items when the supervisory manager performs removal of seldom used or unimportant items to free some memory.

The AIP-based system architecture provides a high flexibility to define customized SCADA solutions and data flows, in particular, on the common OPC basis with advanced integration and iterative migration opportunities. The components coming from different control systems can be quite easily integrated using Industrial IT Aspect Integrator Platform using standard OPC and COM interfaces inherited from the AIP.

112.3 Real Case

Generally, it is not very difficult to integrate modern, component-based applications supporting well-known integration standards like CORBA, COM, etc. [3, 6] and running on the same platforms at which the integration framework is targeted. However, integrating monolithic applications with poor or not clearly defined application programming interfaces is not only difficult but sometimes is even highly questionable due to the very high cost of integration work. Unfortunately, the latter kinds of legacy applications are often used in power distribution and transmission systems. In this case, some easy and flexible integration approaches are required.

The implementation of the integration concept based on ABB's Industrial IT AIP for power distribution and transformation companies was done for public municipalities in Germany by ABB Utility Automation. The conceptual scheme of the Industrial IT-based system for network management on the Industrial IT basis is shown in Figure 112.3. Some of the public municipalities in Germany requested new workstations with advanced Windows look & feel graphical user interface, advanced navigation

© 2005 by CRC Press LLC

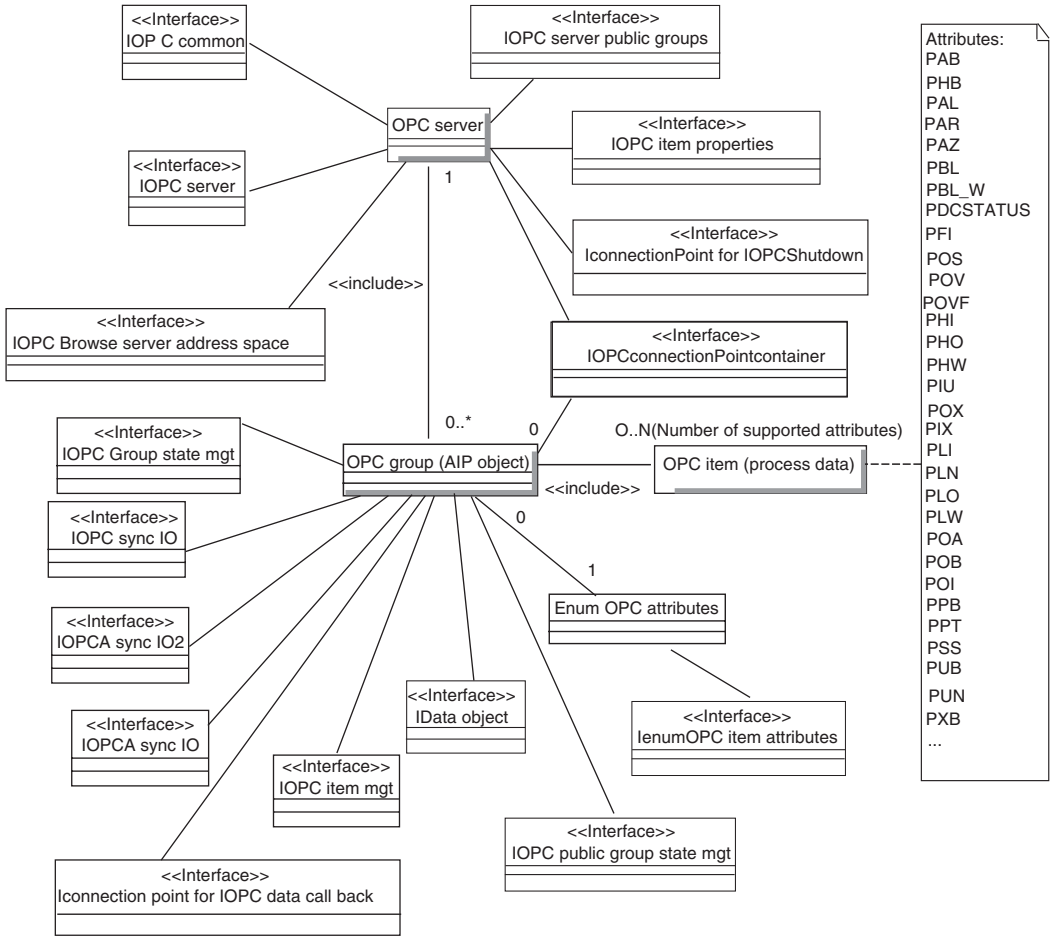

FIGURE 112.2 Class diagram for OPC implementation in AIP.

possibilities within system components (Trends, Alarm & Event Lists, Faceplates, Workplaces, and Geographical Information System), but with the use of its previous SCADA server and unchanged process connections. User management in the Industrial IT-based control system was implemented based on Windows accounts. This means that every authenticated user has a certain role within the control system and certain permissions and rights to available objects, aspects, and aspect systems in the AIP. Standard technologies, like ActiveX, COM, DCOM, and OPC [3], have been used to implement ABB's concept of Aspects and Objects.

To minimize development costs in integration projects, it is a good approach to concentrate on reuse and, thus, on Industrial IT with AIP.

112.4 Implementation Approaches

One of the typical examples of AIP use for network management applications is the new way of implementing Interlocking and Sequential Control functionality. The goal has been to design Interlocking and Sequential Control components in such a way that they will easily work with different SCADA servers. The purpose of the Interlocking component is to prevent prohibited commands, set point values, and manual entries of inappropriate data. Normally, for a two-state device, the operator may define interlock

© 2005 by CRC Press LLC

TABLE 112.1 Selected Attributes of SCADA Process Object Presented as OPC Items in AIP

Attribute	Description	Possible Values	Data Type
AB	Alarm Blocking	0 = no blocking 1 = blocking	Long
AL	Alarm	0 = no alarm 1 = alarm is prevailing	Long
AR	Alarm Receipt	0 = alarm is not acknowledged 1 = alarm is acknowledged	Long
AZ	Alarm Zone	0 = normal state 1 = low alarm 2 = high alarm 3 = low warning 4 = high warning	Long
BL	Blocked	0 = no blocking 1 = blocking	Long
HB	History Blocking	0 = no blocking 1 = blocking	Long
IU	In Use	0 = not in use 1 = in use	Long
IX	Index	Integer	Long
LI	Lower Input	Float	Float
LN	Logical Name	Max 255 characters	BSTR
LO	Lower Output	Float	Float
LW	Lower Warning	Float	Float
OA	Object Address	Integer	Long
OB	Object Bit address	Integer	Long
OI	Object Identifier	Max 255 characters	BSTR
OV	Object Value	Integer or float (depending on Object Type)	Long or Float
…	…	…	…

conditions that must be valid to allow switching of a device. Control requests that do not meet these conditions will be rejected but can be bypassed in emergency and test situations. The Interlocking component allows the user to define an interlock condition, or a sequence of conditions, to be checked each time a control command is given or a new status of an indication is manually entered.

The Sequential Control (automatic switching order) function provides for the control of a number of devices by means of predefined sequences of control commands, which can also include safety checks, delays, etc. Sequential Control can be used for:

1. connection/disconnection of lines to bus-bars with a sequence of control commands for isolators and breakers in a bay,
2. reconfiguration of bus-bars,
3. multiple On/Off commands to breakers for load shedding and load restoration,
4. regulation of objects, and
5. supplying the operators with work instructions, etc.

© 2005 by CRC Press LLC

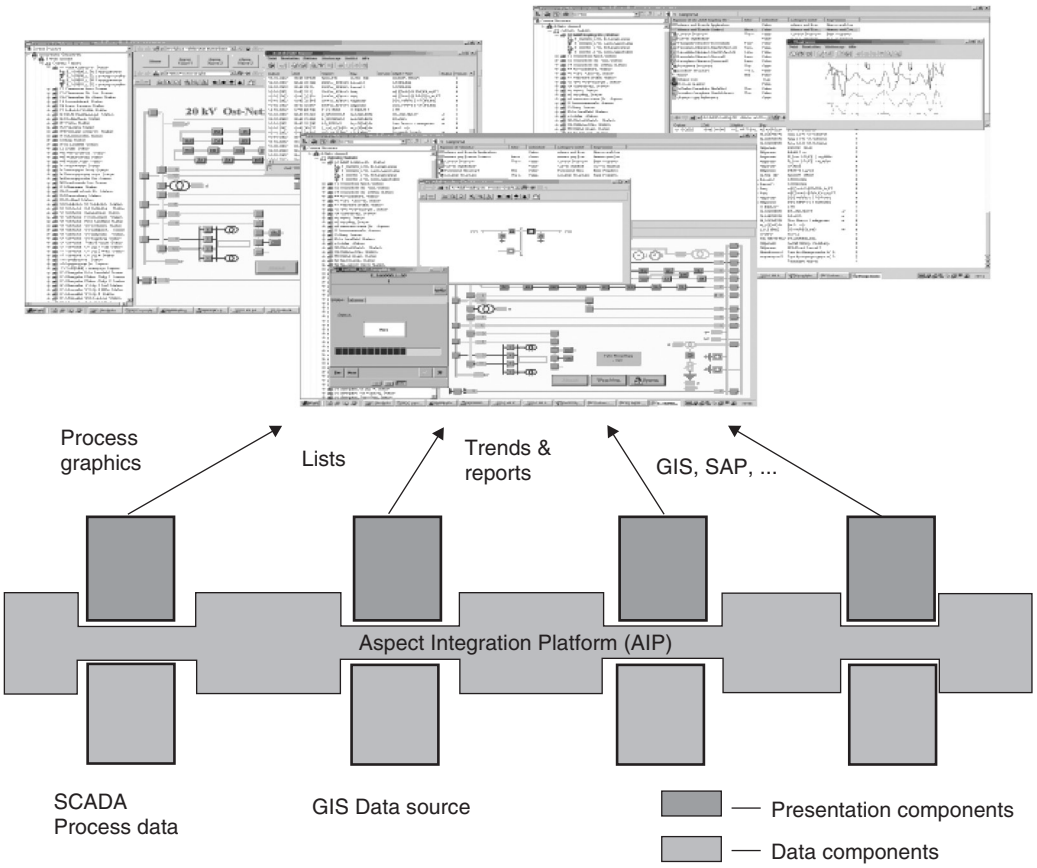

FIGURE 112.3 Industrial IT-based network management for power distribution and transformation applications.

Possible technical solutions for Interlocking and Sequential Control are:

- SCADA server-based solution (old approach) and
- AIP-based solution (new approach).

The AIP-based solution suggests that Interlocking and Sequential Control components are implemented as Aspect Systems in the AIP and, thus, can be easily reused. The schematic presentation of the given solution is shown in Figure 112.4(a). In this case, one can easily use Interlocking and Sequential Control aspects in Faceplates and distribute them between different objects using Aspect Object Model of AIP.

As an alternative to AIP-based solution, the native Interlocking and Sequential Control functionality of the given SCADA server can be used in the given network control application. In this case, the common API (Application Programming Interface) of the given SCADA can be used to access the Interlocking functions from external applications like AIP or others. The schematic presentation of the SCADA server-based solution is shown in Figure 112.4(b). The comparison analysis of AIP-based and SCADA server-based solutions for Interlocking and Sequential Control is presented in Table 112.2.

The main benefit of the SCADA server-based solution is that high robustness can be provided due to the fact that the Interlocking and Sequential Control modules run on the SCADA server (closer to the process in comparison to the AIP-based solution). The main drawback of this solution is that it can be used only with the given SCADA server. Additionally, some SCADA servers have a limited Interlocking and Sequential Control functionality, which is not easy to configure or reuse in other SCADA applications.

The main benefit of AIP-based Interlocking and Sequential Control solution is that it can be used with almost any SCADA server. Additionally, the implementation of the Interlocking and Sequential Control

© 2005 by CRC Press LLC

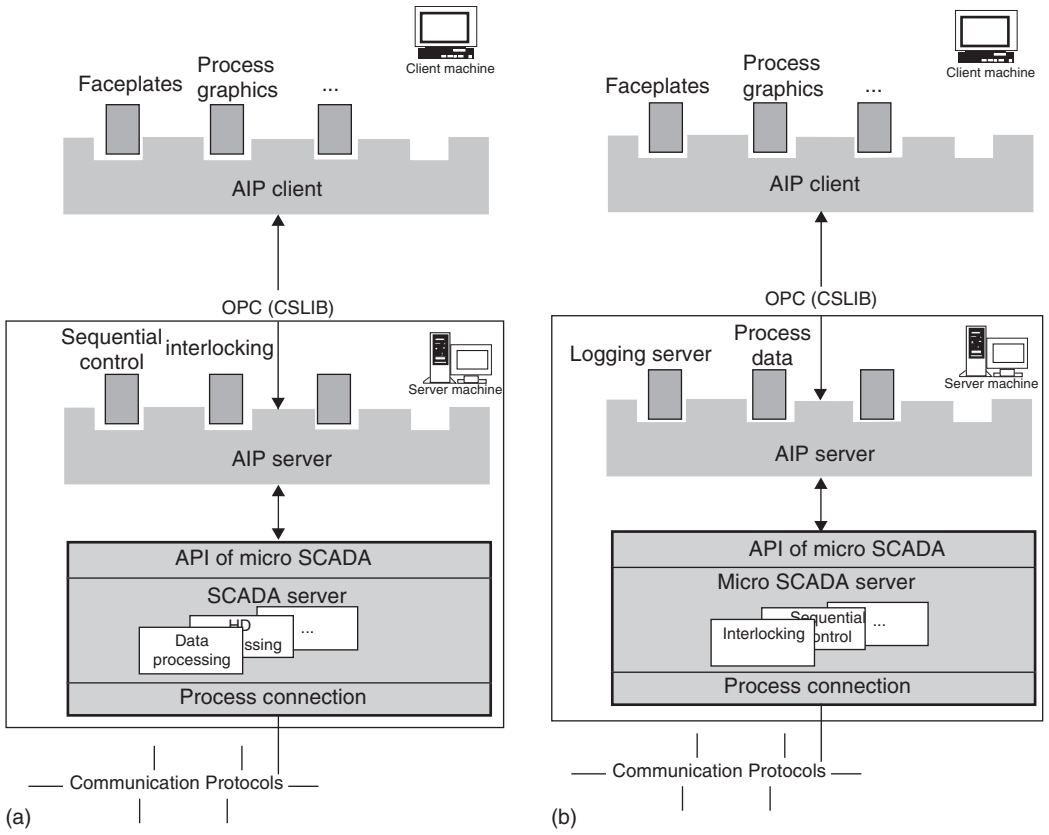

FIGURE 112.4 Interlocking and Sequential Control: (a) AIP-based solution and (b) SCADA server-based solution.

TABLE 112.2 Comparison Analysis of Possible Solutions for Interlocking and Sequential Control

Criterion/Solution	AIP-Based Solution	SCADA Server-Based Solution
Robustness and Stability	Middle	High
Reusability	High	Low
Easy to implement and maintain	Yes	No
Flexibility (easy to extend)	Yes	No

functionality based on the AIP is relatively easy due to the availability of many reuse opportunities of components that provide similar functionality. As an example, the use of the standard AIP's Property Translation Aspect allows implementing Interlocking using Logical Expressions and without any additional programming. Figure 112.5 presents schematically using AIP's Plant Explorer how the Logical Expression can be defined for a given valve in the gas network.

Typically, multifunctional AIP's Property Translation Aspect can be used to create text strings presenting the result of an evaluation or calculation of one or several AIP's object properties. The result is available as an OPC String Property. All Aspect Systems in the AIP can access this information as an ordinary OPC Item. The data collection can be done from any public aspect object property. This means that object properties in controllers and SCADA systems are accessible as data sources. Object properties are usually made available through OPC servers connected with Generic OPC Solution of AIP. The usage of the Property Translation Aspect is quite easy. One has to add this aspect to the object that has to contain

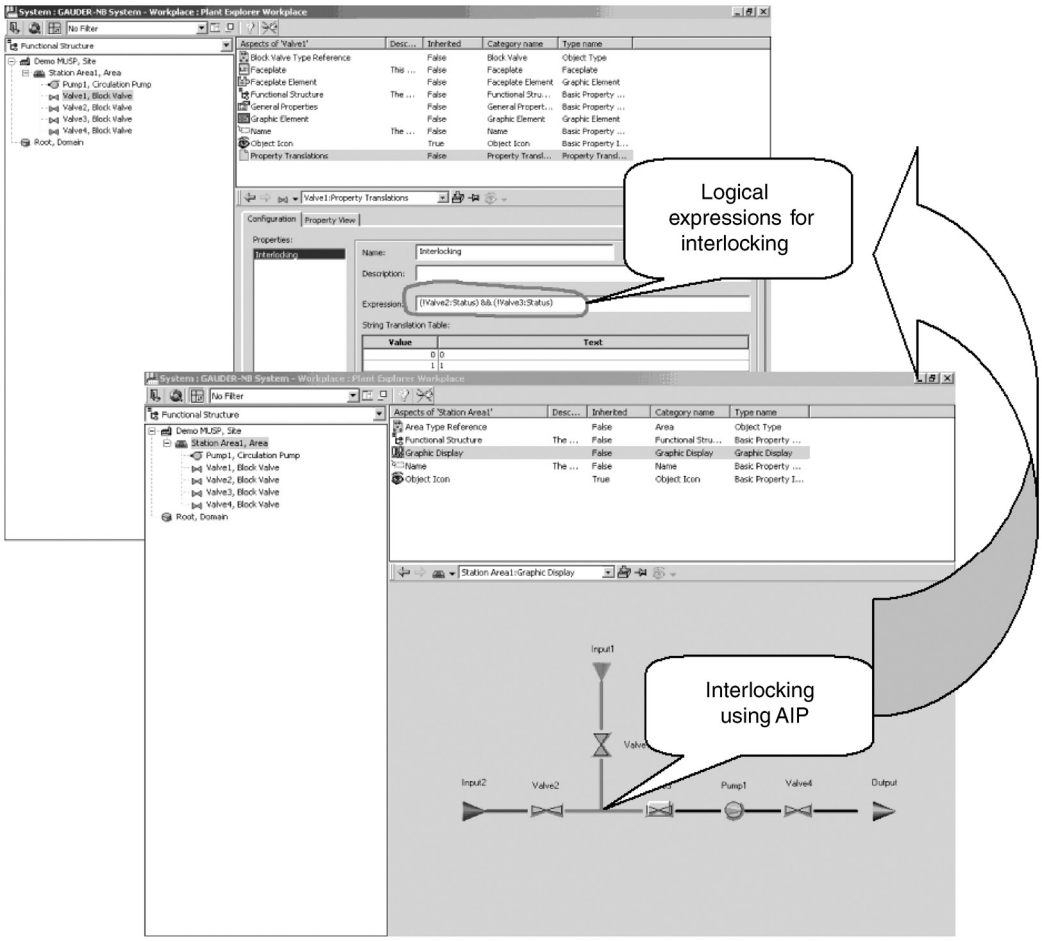

FIGURE 112.5 Interlocking using AIP's Property Translation Aspect.

an Interlocking rule and configure this aspect by setting Interlocking rule Name, Description, Values, and the logical expression that define the Interlocking rule.

112.5 Benefits

The use of ABB's Industrial IT AIP provided the following key benefits to the power distribution and transmission applications:

- component-based network control system architecture;
- companywide migration opportunities with a low investment;
- reduced effort for data engineering (40–50%);
- reuse (configuration is required) of Industrial IT AIP components like User Management, Faceplates, Workplaces, Navigation, Data Structuring, etc.;
- easy integration and reuse of common commercial and technical systems, like Enterprise Asset Management, Geographical Information System, and others on Industrial IT basis; and
- windows look & feel based on standard Industrial IT graphical user interface.

In this case, the integration and reuse based on Industrial IT allow locating appropriate and related information timely with minimum modifications in various existing legacy systems.

© 2005 by CRC Press LLC

112.6 Summary

We have shown the use of ABB's Industrial IT AIP in power distribution and transmission applications, for instance, in SCADA systems. Some of the key customer benefits provided by Industrial IT include component-based network control system architecture and companywide migration opportunities with a low investment. Additionally, many reuse options became available for SCADA users. It is especially important for companies that wish to minimize their development costs in integration projects. ABB's Industrial IT Aspect Integrator Platform provided not only a run-time and design environment but also a number of standard ABB's and non-ABB's reusable components on the Industrial IT basis as well as a concept of how to easily build a common GUI of network control systems using Industrial IT.
